Abstract—Recent works have shown that prompting large language models with audio encodings can unlock speech recognition capabilities. However, existing techniques do not scale efficiently, especially while handling long form streaming audio inputs — not only do they extrapolate poorly beyond the audio length seen during training, but they are also computationally inefficient due to the quadratic cost of attention.

In this work, we introduce SpeechLLM-XL, a linear scaling decoder-only model for streaming speech recognition. We process audios in configurable chunks using limited attention window for reduced computation, and the text tokens for each audio chunk are generated auto-regressively until an EOS is predicted. During training, the transcript is segmented into chunks, using a CTC forced alignment estimated from encoder output. SpeechLLM-XL with 1.28 seconds chunk size achieves 2.7%/6.7% WER on LibriSpeech test clean/other, and it shows no quality degradation on long form utterances 10x longer than the training utterances.

Index Terms—Large language models, Speech recognition, Linear scaling.

I. INTRODUCTION

Recent studies have shown that a decoder-only large language model (LLM) pretrained on a large amount of text corpus can be adapted to understand multi-modal input (e.g. image and audio) by simply prompting the LLM with embeddings of the corresponding modality [1]–[5]. Specifically for automatic speech recognition (ASR), it has been established that a LLM can be finetuned to generate transcription when prompted with speech input [6]–[8]. In short, an audio encoder converts the input audio into a sequence of encodings, then the LLM auto-regressively predict all transcript tokens conditioned on the audio sequence. This class of methods have achieved state-of-the-art (SoTA) accuracy on ASR benchmarks, and will be denoted as *SpeechLLMs* in the following discussion.

Despite their success, a practical limitation of SpeechLLMs is that they are unsuitable for processing long form utterances. First, SpeechLLMs have limited length extrapolation abilities, i.e., their performance significantly degrades when the audio length goes beyond the maximum audio length during training. This is because SpeechLLMs are trained to predict an EOS to terminate decoding after all transcript tokens are generated, and they tend to terminate early when an utterance’s transcript is longer than all the utterances the models have seen during training. We will discuss this in detail in section IV-D. Second, even if we increase the length of training utterances to improve the accuracy on long form audios, a computational challenge is that per-token inference cost scales linearly with the audio length due to decoder LLM attention, and the overall inference

cost scales quadratically with length. Finally, deploying an ASR model to production system typically has a low latency requirement. Since SpeechLLMs are non-streaming models that generate all transcript at once after an entire utterance has been received, the user perceived latency on long utterances would be much higher than short utterances. This problem is further worsen by the quadratic-scaling inference cost.

In this work, we tackle these challenges on long form ASR with *SpeechLLM-XL (extra long)*, which is a streaming model that scales linearly with audio length. Our model consists of an audio encoder and a LLM decoder, and its key mechanism is audio chunking. The input audio is segmented into static-length chunks, which implies each chunk could have a variable number of transcript tokens. After, the input audio is processed chunk-by-chunk. In particular, the encoding of the k^{th} audio chunk is used to prompt the LLM decoder, which auto-regressively generate transcript tokens until an EOS is predicted; later, when the LLM is prompted with $(k+1)^{\text{th}}$ audio chunk, the previous audio chunks and decoded tokens are used as the LLM context. We introduce two hyper-parameters to trade off accuracy verses latency and computation, 1) audio chunk size controls the model latency, 2) LLM context size controls the computational cost of the attention operations. We will discuss those tradeoffs in detail in sections IV-A and IV-B.

SpeechLLM-XL is trained on paired audio/text data, and we use the audio/text alignment to segment the text transcript. When the reference alignment is not available, we add an auxiliary CTC loss to the audio encoder and use a CTC forced aligner [9] to align the encoder output and transcript. We will analyze the quality of CTC forced alignment in section IV-C.

We conduct a throughout empirical study using LibriSpeech dataset, which shows SpeechLLM-XL successfully addresses all three aforementioned challenges on long form utterances. First, to demonstrate its length extrapolation ability, we use a SpeechLLM-XL model trained on regular LibriSpeech training data to decode a concatenated version of test-clean/other utterances. As discuss in section IV-D, no quality degradation is observed on the concatenated long form utterances. Second, to demonstrate its efficiency, we show in section IV-B that the attention window of the LLM decoder in SpeechLLM-XL can be aggressively reduced without hurting model accuracy. Thus using a small static LLM context would reduce the overall inference cost from quadratic to linear in audio length, and enables efficient inference for long form utterances. Finally, to demonstrate its streaming capability, we show in section IV-A that a SpeechLLM-XL model with a small chunk size of 1.28

Fig. 1: Overview of the proposed model. (A) SpeechLLM-XL consists of an audio encoder, a LLM decoder, and a text embedding layer. The audio sequence is processed in static-length chunks, and the resulting audio encodings (denoted as alphabet) are interleaved with text embedding (denoted as numbers) according to audio-text alignment, and the entire sequence is fed into the LLM. The model is trained for next-token-prediction to generate text tokens for each chunk, plus an EOS token \$ indicating the end-of-chunk. (B) We use a limited attention window in the LLM decoder to reduce computation. In this plot, the audio/text encodings in each chunk only attend to previous one chunk besides the current chunk (i.e. token 4 would attend to $\{a, b, c, d, 1, e, f, g, h, 2, 3, 4\}$). (C) During training, the audio-text alignment is computed using a CTC forced aligner to align audio encodings and text tokens.

seconds gives comparable accuracy with the non-streaming SpeechLLM. We also compare our model with other streaming baselines with similar latency in section V, and SpeechLLM-XL compares favorably against the existing methods.

II. BACKGROUND ON SPEECHLLM

Given an input utterance $\mathbf{X} = (\mathbf{x}_1, \dots, \mathbf{x}_T)$ where $\mathbf{x}_t \in \mathbb{R}^d$ denotes Log-Mel audio features, the goal is to predict the transcription $\mathbf{y} = (y_1, \dots, y_U)$ where $y_u \in \mathcal{V}$ denotes a text token. SpeechLLM estimates the conditional distribution of the transcription \mathbf{y} given the audio \mathbf{X} :

$$P(\mathbf{y}|\mathbf{X}) \approx P_\theta(\mathbf{y}|\mathbf{X}) = \prod_{u=1}^U P_\theta(y_u|y_{1:u-1}, \mathbf{X}) \cdot P_\theta(\$|\mathbf{y}, \mathbf{X})$$

where \$ denotes the EOS token and P_θ is parametrized with a neural network. For simplicity, we set $y_{U+1} = \$$ to extend the transcript $\tilde{\mathbf{y}} = (y_1, \dots, y_U, \$)$ and rewrite:

$$P_\theta(\mathbf{y}|\mathbf{X}) = P_\theta(\tilde{\mathbf{y}}|\mathbf{X}) = \prod_{u=1}^{U+1} P_\theta(y_u|y_{1:u-1}, \mathbf{X})$$

During training, given a collection of paired audio/text data $\{(\mathbf{X}^{(n)}, \mathbf{y}^{(n)})\}_{n=1}^N$, the neural network is trained to maximize the conditional probability of the entire training set:

$$\begin{aligned} \theta &= \arg \max_{\theta} \prod_{n=1}^N P_\theta(\tilde{\mathbf{y}}^{(n)}|\mathbf{X}^{(n)}) \\ &= \arg \min_{\theta} -\frac{1}{N} \sum_{n=1}^N \sum_{u=1}^{U+1} \log P_\theta(y_u^{(n)}|y_{1:u-1}^{(n)}, \mathbf{X}^{(n)}) \end{aligned}$$

which is to minimize the averaged cross-entropy loss across all tokens including EOS. During inference, given an input \mathbf{X} , the extended transcript $\tilde{\mathbf{y}}$ is generated auto-regressively using beam search, and EOS is removed for the final transcript \mathbf{y} .

III. SPEECHLLM-XL

Given an audio/text pair \mathbf{X}, \mathbf{y} , we segment \mathbf{X} into chunks $(\mathbf{X}_1 \dots \mathbf{X}_k \dots \mathbf{X}_K)$ with chunk size c . Assuming the audio/text alignment is known, we further segment \mathbf{y} and define:

$$\tilde{\mathbf{y}} = (\tilde{y}_1, \dots, \tilde{y}_k, \dots, \tilde{y}_K) = (\mathbf{y}_1, \$, \dots, \mathbf{y}_k, \$, \dots, \mathbf{y}_K, \$)$$

where \mathbf{y}_k denotes the text in the k^{th} chunk. Then, we write the conditional probability of the entire sequence as:

$$P_\theta(\tilde{\mathbf{y}}|\mathbf{X}) = \prod_{k=1}^K P_\theta(\tilde{y}_k|\mathbf{X}_k, \{\tilde{y}_{1:k-1}, \mathbf{X}_{1:k-1}\})$$

Note the probability of predicting \tilde{y}_k given the current chunk \mathbf{X}_k depends on audio and transcripts of the previous chunks $\{\tilde{y}_{1:k-1}, \mathbf{X}_{1:k-1}\}$. To explicitly model this dependency, when computing LLM decoder self-attention on tokens representing the current chunk k , we attend to the cached attention values of the previous b chunks; the total size of the LLM attention window is $b \times c$. The entire architecture of our model is illustrated in fig. 1A. In order to reduce the attention computation on long form utterances, we typically choose a small value b to limit the LLM context. For example, the model in fig. 1B use LLM context $b = 1$, which only covers the previous chunk, plus the current chunk. We will study the impact of chunk size and LLM context size on accuracy in sections IV-A and IV-B.

So far, we have assumed the availability of ground truth alignment between audio and text. When the alignment is not available, we use CTC forced alignment between audio encodings and text tokens to determine the token end time, as shown in fig. 1C. Empirically, we found the CTC forced alignment is a good approximation and SpeechLLM-XL trained with CTC forced alignment gives similar accuracy as the reference alignment. We will discuss the CTC forced alignment quality and its impact on overall model accuracy section IV-C.

During inference, our beam search decoding algorithm is similar to the alignment-synchronous search for neural transducers [10], meaning in each decoding step, all hypotheses in the beam have the same number of tokens including the EOS.

IV. EXPERIMENTS

We benchmark our model performance and conduct ablation studies on the LibriSpeech dataset [11], which consists of 960h training data sourced from English audio-books. Audio features are 80 mel-spaced log filter-bank channels with a sliding window of 25ms at 10ms frame shift. A time reduction layer stacks features with a stride of 4, and the resulting 320-dimensional vectors form the input to the encoder.

Since the focus of this paper is on the SpeechLLM-XL architecture and its hyper-parameters, we keep the encoder,

decoder and output vocabulary size constant across all experiments. The audio encoder is a 20-layer streaming Emformer with 240ms of lookahead, 8 self-attention heads, embedding dimension 512, FFN dimension 2048, followed by a linear projection with dimension 768, totaling 107M parameters. The decoder is a 12-layer LLM downsized from Llama2, with 12 self-attention heads, embedding dimension 768, FFN dimension 2048, totaling 92M parameters. The output vocabulary is 4096 unigram SentencePieces estimated from the training transcripts, plus the CTC blank symbol. The segment size of the Emformer encoder is the same as the audio segment size of SpeechLLM-XL. The encoder is pretrained with CTC loss on LibriSpeech training data, and the decoder is pretrained on the transcript text corpus. After, the encoder and decoder is combined and SpeechLLM-XL is trained on LibriSpeech training data with cross-entropy loss, plus a CTC auxiliary loss with weight 0.5. We use a CTC forced aligner to estimate the audio/text alignment unless described otherwise. We conduct a series of ablation studies on SpeechLLM-XL and denote the resulting models as ① – ⑩. All models are trained with an Adam optimizer with a tri-stage learning rate schedule and a peak learning rate of 1×10^{-4} . For each run, we select the best checkpoint based on the dev-clean WER, and we report the final WER on both dev-clean/other and test-clean/other.

A. Chunk Size

We vary audio chunk size to explore the trade-off between latency and accuracy. We fix the LLM context to 5.12s and consider a range of audio chunk size options from 2.56s to 0.32s, and we also include a non-streaming SpeechLLM¹ as a baseline for comparison. The results are summarized in table I.

First, compared with the non-streaming SpeechLLM, the streaming model ① with 2.56s chunk size gives better WER on dev/test-clean. Looking into the WER breakdown on the dev-clean dataset, we find that SpeechLLM performs much worse on long utterances and the majorities of the mistakes are deletion errors. In particular, on the 50 longest utterances in dev-clean, SpeechLLM gives a total WER of 16.4 and deletion rate of 13.9, while ① gives a total WER of 2.2 and deletion rate of 0.1. This confirms our hypothesis that SpeechLLM-XL is suitable for long utterances. We will further compare the length extrapolation abilities of SpeechLLM-XL against SpeechLLM in section IV-D.

Second, as we decrease the chunk size, WER increase on all evaluation datasets. This is expected since reducing chunk size reduces the model latency. We find a chunk size of 1.28s gives a good trade-off between latency and accuracy, and we will use this chunk size for the remaining of the paper.

B. LLM Context

Next, we study how the LLM context impact model quality. We fix the audio chunk size to 1.28s and consider a range of

¹Following [6], the SpeechLLM baseline uses a non-streaming Conformer encoder consists of a convolutional frontend with stride 4 followed by 24 Conformer layer, totaling 110M parameters. It uses the same 92M parameters LLM decoder as SpeechLLM-XL.

TABLE I: The effect of SpeechLLM-XL audio chunk size on model quality, where both the audio chunk size and LLM context size are measured in seconds. As the audio chunk size is reduced, the model latency is reduced at the cost of higher WER. The non-streaming SpeechLLM is included as a baseline.

Model	LLM context	Chunk size	dev		test	
			clean	other	clean	other
SpeechLLM	–	∞	2.9	5.4	3.4	5.5
①	5.12s	2.56s	2.4	6.8	2.5	6.5
②		1.28s	2.5	6.9	2.7	6.7
③		0.64s	2.7	7.3	2.9	7.4
④		0.32s	3.0	7.9	3.1	7.8

TABLE II: The effect of LLM left context size on WER. There is little degradation in accuracy as we reduce the LLM context from ∞ to 1.28s, until we completely removed all the previous chunks from the LLM context.

Model	LLM context	Chunk size	dev		test	
			clean	other	clean	other
⑤	∞	1.28s	2.6	6.8	2.7	6.7
②	5.12s		2.5	6.9	2.7	6.7
⑥	2.56s		2.5	6.9	2.7	6.8
⑦	1.28s		2.5	6.8	2.7	6.8
⑧	0		2.7	7.4	3.0	7.2

LLM left context from ∞ (full context) to 0 (no context). The results are summarized in table II. First, we did not observe a considerable quality degradation as we reduce decoder context from ∞ to 1.28s. This indicates SpeechLLM-XL works well with a small LLM context, thus the inference cost can be reduced from quadratic to linear in audio length without impacting accuracy. However, when we fully remove all previous audio chunks from LLM context, we observe a notable quality degradation from ⑦ to ⑧. This indicates a small LLM context is still necessary and naively segment the audio and decode each chunk separately does not work as well.

C. CTC Forced Alignment

So far, we have used CTC forced alignment during training without examining alignment quality. To this end, we compare the CTC forced alignment from the audio encoder verses the reference alignment from a chenone hybrid acoustic model [12]. We measure the CTC forced alignment quality by the averaged *alignment delay* and *alignment delta* measured on LibriSpeech dev-clean/other. The alignment delay is defined as the token end time difference averaged across all tokens $\frac{1}{U} \sum_{u=1}^U t(y_u) - \hat{t}(y_u)$, where $t(y_u)$ and $\hat{t}(y_u)$ is the token end time for y_u from CTC alignment and hybrid alignment, respectively. The alignment delta is defined as the token end time absolute difference $\frac{1}{U} \sum_{u=1}^U |t(y_u) - \hat{t}(y_u)|$. To understand the impact of alignment quality on ASR accuracy, we also replicated ② using the reference hybrid alignment for text segmentation. The results are summarized in table III.

The token end time from CTC forced alignment is on-averaged 52ms ahead of the reference hybrid alignment, as indicated by the negative alignment delay. Overall, the CTC

TABLE III: The quality of CTC forced alignment compared against the reference hybrid alignment. The CTC alignment is on-averaged 52ms ahead of the hybrid alignment, as indicated by the negative alignment delay. The SpeechLLM-XL model trained with reference hybrid alignment slightly out-performs CTC forced alignment.

Model	Align.	Align. delay	Align. delta	dev		test	
				clean	other	clean	other
②	CTC	-52ms	63ms	2.5	6.9	2.7	6.7
⑨	hybrid	-	-	2.4	6.7	2.7	6.5

TABLE IV: The length extrapolation ability of SpeechLLM and SpeechLLM-XL, both of which are trained on regular LibriSpeech utterances. SpeechLLM significantly degrade when tested on concatenated utterances that are 2x of the training length. SpeechLLM-XL extrapolates to 10x of the training length with no quality degradation.

Model	test (1x)		test (2x)		test (10x)	
	clean	other	clean	other	clean	other
SpeechLLM	3.4	5.5	15.8	15.1	80.6	80.0
②	2.7	6.7	2.7	6.6	2.7	6.5

alignment and the hybrid alignment is very close, with an alignment delta of 63ms. In terms of downstream ASR model quality, the SpeechLLM-XL model trained with CTC alignment slightly under-performs the model trained with hybrid alignment, likely due to the negative emission delay.

D. Length Extrapolation

One major advantage of SpeechLLM-XL over the baseline SpeechLLM is its length extrapolation ability. To demonstrate this advantage, we conduct a length extrapolation experiment by repeating (and concatenating) each test-clean/other utterances multiple times. We test the concatenated utterances on the SpeechLLM baseline and SpeechLLM-XL ②, and we summarize the results in table IV. Unsurprisingly, SpeechLLM fails to extrapolate beyond the audio length the original model was trained on. The WER more than tripled on concatenated test-clean/other utterances 2x longer than the utterances seen during training. In contrast, SpeechLLM-XL extrapolates perfectly beyond the training length, even yielding a slightly lower WER on 2x/10x concatenated test-other utterances.

The length extrapolation ability is important for production deployment because 1) it allows the ASR model to be more robust to edge case input, 2) it allows training on segmented short utterances for better batching and training efficiency, while still maintaining model quality on long form utterances.

V. ADDITIONAL BASELINES AND RELATED WORKS

We compare SpeechLLM-XL with some additional baselines². The results are summarized³ in table V.

First, we consider some classic baselines. LAS with SpecAugment [14] is widely used non-streaming baseline without

²Pushing for SoTA WER on LibriSpeech often requires self-supervised pre-training, pseudo labeling, or LM shallow fusion, and is not the purpose of this work, therefore we do not consider baselines with those modeling tricks.

³The LAS model is estimated to be over 270M parameters [13]. Chunked AED did not specify model size. ReaLLM considers on two model size 82M and 7B, we present the numbers on their 82M model, which has a lower WER. CTC-prompt-LM is perhaps the smallest, with a total of 52M parameters.

TABLE V: SpeechLLM-XL is competitive when compared to other streaming ASR models with similar latency and training recipe.

Model	Look ahead	Chunk size	dev		test	
			clean	other	clean	other
LAS	-	-	-	-	2.8	6.8
CTC	0.24s	1.28s	3.4	8.7	3.6	8.8
Transducer	0.24s	1.28s	2.9	7.6	3.0	7.7
SpeechLLM-XL	0.24s	1.28s	2.5	6.9	2.7	6.7
Chunked AED	0.30s	1.20s	-	6.7	-	6.7
ReaLLM	0.96s	1.92s	2.7	7.6	3.0	7.4
CTC-prompt-LM	0.64s	0.64s	-	-	3.2	7.9

additional training tricks, where the encoder is a BiLSTM and decoder is a RNN. SpeechLLM-XL out-performs this model despite being streaming and smaller-in-size. For the streaming baselines, we trained a CTC model and a Transducer model. The CTC model is an Emformer with the same look ahead and chunk size as the SpeechLLM-XL encoder, but with 28 layers and hidden dimension 768, totaling 246M parameters; the Transducer model further adds a predictor-joiner network on top, totalling 256M parameters. SpeechLLM-XL performs notably better than both the CTC and the Transducer models.

Second, many cross-attention based encoder-decoder (AED) models were proposed for streaming ASR [15]–[21]. Chunked AED [21] is the most recent and also most relevant to our work, and it explores a similar chunking idea for long form ASR. SpeechLLM-XL gives a similar WER when compared against Chunked AED under a similar decoder chunk size and encoder look ahead. The main difference is that SpeechLLM-XL uses self-attention based decoder-only model architecture, which makes it easier to integrate with a pretrained LLM.

Finally, although there has been a lot of works on using decoder-only LLMs for speech-processing [6]–[8], [22]–[27] and efficient streaming LLMs [28]–[34], leveraging decoder-only models for streaming ASR is an under-explored area. One recent work is ReaLLM [13], where each encoder output frame is used to prompt the LLM to generate its transcript (possibly empty), followed by a blank symbol. ReaLLM scales quadratically with audio length, and it adds one additional blank prediction per frame during inference. To reduce the attention computation and the number of blank predictions, the authors use a large encoder stride of 24 in their experiments. SpeechLLM-XL performs notably better than ReaLLM, despite using a smaller encoder look ahead and decoder chunk size. Another relevant work is [35], which uses blank-filtered CTC encoder frames from each chunk to prompt the LM (therefore denoted as *CTC-prompt-LM*). In contrast to our work, they find CTC forced alignment works poorly on their model, and they instead use random prefix prompt for model training. Most importantly, rather than having the decoder to output an EOS to move to next chunk, they use a joint CTC and decoder score fusion beam search to determine the end of chunk. As such, the max decoding length for each chunk is upper-bounded by the CTC predictions. SpeechLLM-XL out-performs CTC-prompt-LM by a considerable margin.
