# J-shaped relationship between Chinese visceral adiposity index and hyperuricemia: a cross-sectional study

Yuntong Liu<sup>1,2</sup>, Lan Luo<sup>2\*</sup> and Zhengnan Gao<sup>2\*</sup>

## Abstract

**Background** Recent years have seen the emergence of numerous novel indicators for visceral obesity. This study investigates the potential correlation between the Chinese visceral adiposity index (CVAI) and hyperuricemia (HUA).

**Methods** This research, derived from a 2011 cross-sectional analysis in Dalian, China, employed restricted cubic spline (RCS) plots to identify inflection points. Subsequently, one-way and multifactorial logistic regression models were utilized, with HUA as the outcome variable. Additionally, subgroup analyses and interaction tests were conducted. Eventually, receiver operating characteristic (ROC) curves were calculated to assess the effectiveness of CVAI and other body composition indices in predicting HUA.

**Results** The study included 10,061 individuals, with a HUA prevalence of 14.25%. Significant relationships with HUA were observed for CVAI. RCS analysis revealed a J-shaped relationship between CVAI and HUA. Compared to those in the low CVAI category, HUA was notably associated with individuals in the high CVAI category in multifactorial logistic regression (OR = 2.661, 95% CI: 2.323, 3.047). Subgroup analyses demonstrated stronger relationships in women, participants without hypertension, and participants without diabetes. Additional modeling via ROC curves suggested that the CVAI may offer effective predictive value for HUA.

**Conclusion** This study confirmed that an elevated CVAI elevates the risk of HUA in middle-aged and elderly populations in the Dalian community. The findings advance obesity prevention strategies that mitigate HUA risk and support healthcare initiatives for China's aging population.

**Keywords** Chinese visceral adiposity index, Hyperuricemia, Cross-sectional study, Obesity

## Introduction

Uric acid is the final substance produced through the metabolism of purines within the body's metabolic processes. When a large amount of purine-rich foods are

consumed, or when the body's capacity to excrete uric acid is diminished, this will lead to an accumulation of uric acid. This condition, characterized by increased uric acid levels in the bloodstream, is referred to as hyperuricemia (HUA) [1]. HUA may precipitate a range of complications including gout, metabolic syndrome, renal disease, and cardiovascular and cerebrovascular diseases [2–6]. Recent lifestyle changes, particularly in diet, have contributed to a rising prevalence of HUA [7–9]. For instance, the prevalence among Chinese adults increased from 11.1% in 2015–16 to 14.0% in 2018–19, with higher rates observed in men than in women [10]. With China's aging population projected to grow, an annual increase

in the incidence of HUA is expected among middle-aged and elderly populations. As a result, it is becoming more critical to emphasize the prevention and management of HUA within this aging demographic for the purposes of health maintenance and treatment.

Past research has shown a connection between HUA and obesity [11]. A recent study highlighted a steady rise in both abdominal and overall obesity among adults in their middle years, with more than half of the adult population in China being overweight or obese [12, 13]. While body mass index (BMI) is frequently employed as a metric to assess obesity, it has significant limitations. Specifically, BMI cannot differentiate between muscle mass and fat mass, nor can it accurately represent fat distribution. For instance, individuals who have substantial muscle mass and a low body fat percentage might be incorrectly categorized as overweight by BMI, whereas those with high fat mass and low muscle mass might appear normal or underweight [14, 15]. Given that Asians tend to have higher visceral fat levels than Westerners do at equivalent BMI levels, waist circumference (WC), the waist-to-hip ratio (WHpR), and the waist-to-height ratio (WHtR) have been consistently utilized to evaluate central obesity, while it also has limitations in accurately differentiating subcutaneous from visceral fat. Increased visceral adipose tissue can lead to dysfunctional obesity. Therefore, assessing visceral obesity is crucial for evaluating the risk of HUA among Chinese individuals [16, 17]. However, the routine use of CT and MRI for assessing visceral fat may not be practical for widespread clinical application. The relevant literature indicates that the lipid accumulation product (LAP) and a body shape index (ABSI) can be used as indicators to assess visceral obesity. In recent years, Xia et al. developed the Chinese visceral adiposity index (CVAI) as a tool to measure visceral obesity in Asian populations [18]. Previous studies have linked CVAI with several health conditions, including cardiovascular disease, diabetes, pancreatitis, and stroke [19–23]. Currently, just a single study has documented the relationship between CVAI and HUA. In a cohort study from a Chinese region, Liu et al. discovered that the CVAI had superior predictive power for HUA compared to other indicators, particularly in the female population [24]. However, there has been no comprehensive examination of this relationship. Therefore, in this cross-sectional analysis, we examined the relationship between CVAI and HUA in middle-aged and elderly populations, utilizing data collected in the Dalian area during 2011. It also evaluates the predictive ability of CVAI relative to other body composition indices (BMI, WHpR, WHtR, LAP, ABSI) for HUA. This study sought to provide a comprehensive understanding of how CVAI and HUA are related in this specific population subset.

## Methods

### Study design

The REACTION (Risk Evaluation of Cancers in Chinese Diabetic Individuals: A Longitudinal Study) was a comprehensive nationwide investigation that focused on a broad population of individuals aged 40 years or older residing in the community. It included 25 centers throughout mainland China, encompassing a total of 259,657 participants [25–27]. Data from the Dalian Center, which were collected between August and December 2011, were analyzed in the present study. Individuals with incomplete data, those on medications affecting serum uric acid (SUA) levels, those with a history of gout, and anyone under 40 years of age were excluded. Ultimately, 10,061 subjects meeting these criteria were enrolled, and the screening process is illustrated in Fig. 1. This study received ethical approval from the Institutional Review Board of Ruijin Hospital at the Medical College of Shanghai Jiao Tong University (RUIJIN-2011–14), and all participants provided written informed consent.

### Strategies for research

The participants involved in this survey included medical and nursing staff from the Department of Endocrinology at Dalian Central Hospital, all trained by Shanghai Ruijin Hospital prior to conducting this epidemiological survey. A questionnaire was utilized to gather personal information and data on demographic characteristics (age, sex, height, weight, WC), lifestyle habits (smoking and drinking alcohol), and past chronic diseases. Detailed information on chronic diseases, smoking, and alcohol consumption can be found in Table S1. Trained inspectors collected fasting venous blood samples to measure blood lipids, SUA, and fasting plasma glucose (FPG). The RGZ-120 device was used to measure patients' weight and height, with patients being required to remove their clothes and shoes for accuracy; height was measured to the nearest tenth of a centimeter. Blood pressure readings were obtained under controlled conditions while the participants were seated. The researchers also ensured accuracy by recording the average of three blood pressure readings.

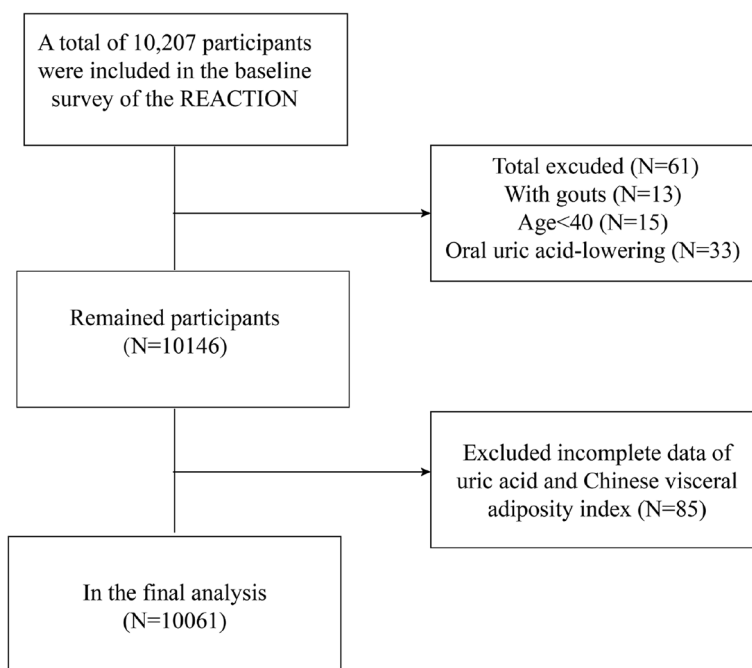

### Variable definition

HUA: SUA levels  $\geq 420$   $\mu\text{mol/L}$  in men or  $\geq 360$   $\mu\text{mol/L}$  in women [28].

Figure 2 displays the methods used to calculate CVAI and several body composition indices.

### Statistical analysis

Categorical variables were summarized by frequency and constitutive ratio (n%). Chi-square tests were utilized for

**Fig. 1** Screening flowchart

Men:  $CVAI = -267.93 + 0.68 \times \text{age} + 0.03 \times \text{BMI} + 4.00 \times \text{WC (cm)} + 22 \times \text{lgTG} - 16.32 \times \text{HDL-C}$   
 Woman:  $CVAI = -187.32 + 1.71 \times \text{age} + 4.23 \times \text{BMI} + 1.12 \times \text{WC (cm)} + 39.76 \times \text{lgTG} - 11.66 \times \text{HDL-C}$   
 $BMI = \text{Weight (kg)} / \text{Height (m)}^2$   
 $WHPR = \text{WC (cm)} / \text{Hip circumference (cm)}$   
 $WHtR = \text{WC (cm)} / \text{Height (cm)}$   
 Men:  $LAP = [\text{WC (cm)} - 65] \times \text{TG (mmol/L)}$   
 Women:  $LAP = [\text{WC (cm)} - 58] \times \text{TG (mmol/L)}$   
 $ABSI = \text{WC (cm)} / \text{BMI}^{2/3} \times \text{Height (m)}^{1/2}$

**Fig. 2** Several body composition indices calculation formulas

comparisons between the two groups. Normality tests were conducted on all continuous numerical variables using the Kolmogorov–Smirnov test to assess normality. For variables not adhering to a normal distribution, the median (represented as Q25, Q75) was calculated. These median values were then log-transformed prior to conducting t-tests. Missing data were handled through multiple interpolations. A 3-knot restricted cubic spline (RCS) plot was utilized to explore the nonlinear relationship between CVAI and HUA. The aim was to establish the cutoff point using the RCS curve, followed by conducting a multivariable logistic regression analysis anchored on this threshold. This analysis led to the construction of three models: Model 1 was not adjusted; Model 2 included adjustments for age and sex; and Model 3 was further adjusted for a history of hypertension, coronary heart disease (CHD), diabetes, and alcohol consumption. Subsequently, subgroup analyses were performed to assess whether potential covariates (age, sex, BMI, history of hypertension, and diabetes) altered

the connection between CVAI and HUA, with  $P < 0.05$  indicating significant interactions. Furthermore, the receiver operating characteristic (ROC) curves were used to establish a basic model incorporating age, sex, hypertension, diabetes, CHD, alcohol consumption, creatinine, alanine aminotransferase (ALT), aspartate aminotransferase (AST), and FPG. Six traditional and novel body composition indices were sequentially added to the model. The incremental predictive ability of these indices for HUA was observed and compared based on the area under the curve (AUC). All statistical tests were conducted with R software (version 4.3.2). When analyzing statistical significance, it is important to consider two-sided  $P$ -values of less than 0.05.

**Results**

**Baseline characteristics**

The baseline characteristics of the HUA group were analyzed in comparison to those of the control group. Table 1 shows that of the subjects, 8,627 (85.75%) were classified

**Table 1** Basic characteristics of participants

Variable	Overall (N=10061)	HUA (N=1434)	Control (N=8627)	P-value
Age (years)	56.95 (52.15, 62.61)	58.83 (53.89, 65.49)	56.67 (51.79, 62.06)	<0.001

For continuous variables, the median (Q25, Q75) was calculated. These median values were subsequently log-transformed before conducting t-tests. For categorical variables, percentages were used and the P value was calculated using the chi-square test

**Abbreviation:** CHD coronary heart disease, SBP systolic blood pressure, DBP diastolic blood pressure, BMI body mass index, CVAI Chinese visceral adiposity index, WHpR waist-to-hip ratio, WHtR waist-to-height ratio, LAP lipid accumulation product, ABSI a body shape index, SUA serum uric acid, HDL high-density lipoprotein, LDL low-density lipoprotein, TG triglycerides, ALT alanine aminotransferase, AST aspartate aminotransferase, FPG fast plasma glucose, HUA hyperuricemia

into the control group, whereas 1,434 (14.25%) were classified into the HUA group. The prevalence of HUA was 14.25%. All variables showed notable differences between the HUA and control groups, except for smoking. The HUA group presented higher values for age; SBP, DBP, CVAI, BMI, WC, WHpR, WHtR, LAP, SUA, creatinine, LDL, TG, ALT, AST, FPG, and insulin levels. Conversely, the ABSI and HDL levels were lower. Additionally, the HUA group presented a greater male ratio; a more frequent occurrence of hypertension, diabetes, CHD, and regular alcohol consumption; and lower education levels than did the control group.

#### Dose–response relationship between the CVAI and HUA

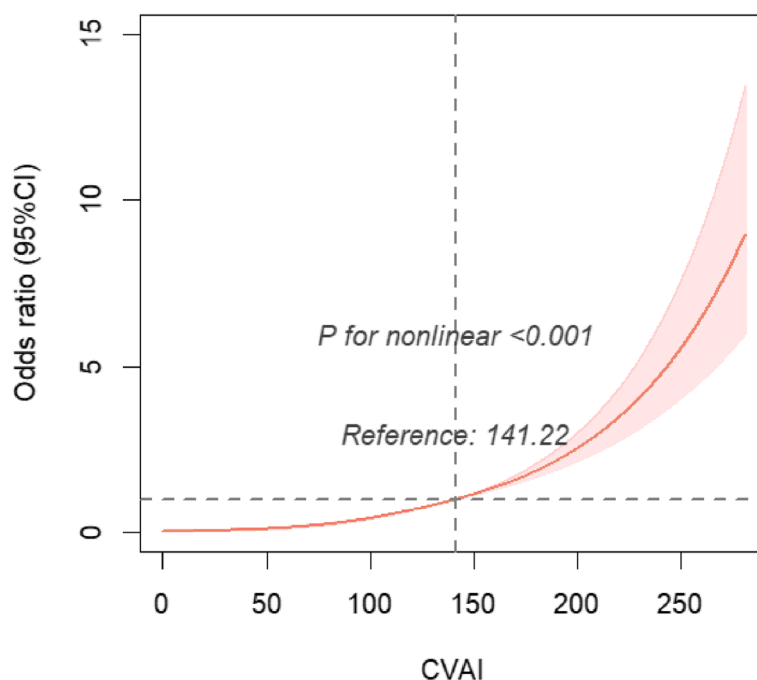

In addition, a 3-knot RCS was employed to model the relationship between CVAI and elevated HUA, as depicted in Fig. 3. The CVAI was plotted as the horizontal coordinate and the odds ratio (OR) was plotted as the vertical coordinate. The results, after adjusting for potential covariates, indicated that higher levels of CVAI corresponded with an increasing risk of HUA, displaying an approximately J-shaped curve (nonlinear  $P < 0.001$ ). The corresponding inflection point value was 141.22.

#### Relationship between CVAI and HUA

The relationship between CVAI and HUA is detailed in Table 2. After accounting for potential confounders in Model 3, the findings indicated a notable positive relationship with an OR of 1.018 (95% CI: 1.016, 1.020). The RCS was applied to examine the nonlinear relationship between CVAI and HUA. An inflection point value of 141.22 was derived, which was then used as a cutoff point to classify the CVAI as a dichotomous variable for multifactor logistic regression. In Model 1, the OR for the upper category in comparison with the lower category was 3.1 (95% CI: 2.761, 3.481). In Model 2, the OR for the higher category increased to 2.891 (95% CI: 2.532, 3.302). Even after further adjustments in Model 2 for additional covariates, the OR was 2.661 (95% CI: 2.323, 3.047), indicating that the relationship between higher CVAI and HUA remained statistically significant. The trend analysis confirmed a consistent positive correlation between the two categories ( $P$  for trend  $< 0.001$ ). The study indicates a significant link between CVAI and HUA.

#### Subgroup analyses

Subgroup analyses and interaction tests were further carried out, stratifying the subgroups by age, sex, BMI, hypertension, diabetes, and CHD. As presented in Fig. 4, these analyses revealed that these

**Fig. 3** The dose–response relationship between CVAI and HUA. We employed a 3-knot RCS to fit the dose–response relationship between CVAI and HUA. We adjusted the model fully for age, sex, history of hypertension, CHD, diabetes, and alcohol consumption. The red solid line represents the curve fitting between variables, and the shaded area indicates the 95% CI of the fit. Abbreviation: RCS, restricted cubic spline; CVAI, Chinese visceral adiposity index; CHD, coronary heart disease; CI, confidence interval

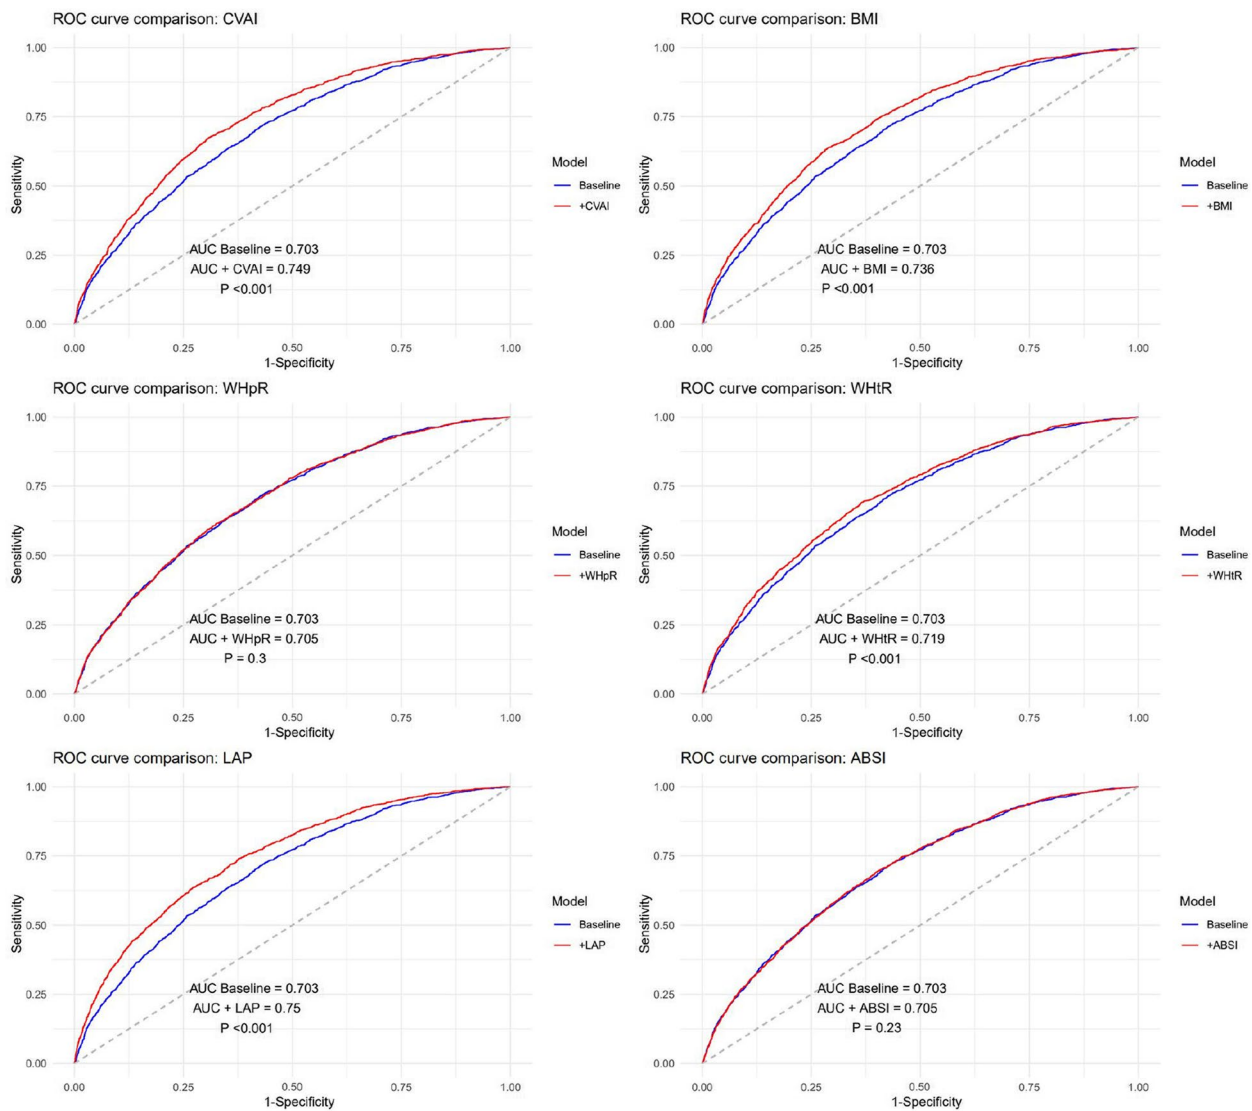

**Fig. 4** Subgroup analyses of the relationship between CVAI and HUA. Age, sex, hypertension, diabetes, CHD, alcohol consumption were adjusted. Abbreviation: OR, odds ratio; CHD, coronary heart disease; BMI, body mass index

factors influenced the relationship between the CVAI and HUA. The link between CVAI and HUA appeared stronger within specific subgroups: women, individuals without hypertension, and individuals without diabetes (*P* for interaction < 0.05). Additionally, age, BMI,

and CHD appeared to have no substantial impact (*P* for interaction > 0.05). The test for interaction between subgroups indicated that the relationship between CVAI and HUA varies significantly across different subgroups.

**Fig. 5** The AUC curves of CVAI and several body composition indices to identify HUA. The AUC curves of CVAI and several body composition indices to identify HUA. In the ROC curves, the blue line represents the baseline model, whereas the red line signifies the enhanced model that sequentially incorporates various obesity indices. ### ROC curves

A baseline model was developed incorporating age, sex, hypertension, diabetes, CHD, alcohol consumption, creatinine, ALT, AST, and FPG. The sequential addition of six traditional and novel body composition indices, as detailed in Fig. 5 and Table 3, altered the model's AUC. Initially, the AUC was 0.703 (95% CI: 0.689, 0.717). It increased to 0.749 (95% CI: 0.735, 0.762) with the inclusion of the CVAI, to 0.736 (95% CI: 0.723, 0.750) with the BMI, to 0.705 (95% CI: 0.691, 0.719) with the WHpR, to 0.719 (95% CI: 0.705, 0.732) with the WHtR, to 0.750 (95% CI: 0.736, 0.763) with the LAP, and to 0.705 (95% CI: 0.691, 0.719) with the

ABSI. The CVAI, BMI, WHtR, and LAP significantly improved the model's predictive accuracy ( $P < 0.05$ ), particularly the LAP, which provided the highest incremental predictive value, followed by the CVAI, BMI, and WHtR. Conversely, the WHpR and ABSI did not significantly enhance the model's accuracy ( $P > 0.05$ ). These results indicate that CVAI is a potentially effective marker for predicting HUA.

### Discussion

The objective of this study was to investigate the relationship between the CVAI and HUA among middle-aged and elderly community-dwelling populations in

**Table 3** AUC for different body composition indices in identifying HUA

Variable	AUC (95%CI)	P-Value (compared to basic model)	Sensitivity	Specificity	Youden index
Basic model	0.703 (0.689, 0.717)		0.699	0.597	0.296
+CVAI	0.749 (0.735, 0.762)	<0.001	0.704	0.668	0.372
+BMI	0.736 (0.723, 0.750)	<0.001	0.623	0.732	0.355

Dalian, China. This cross-sectional analysis of 10,061 participants revealed a J-shaped correlation between elevated CVAI levels and HUA. Subgroup analyses further demonstrated that this correlation was particularly pronounced in women, individuals without hypertension, and individuals without diabetes. Additionally, the application of ROC curves indicated that the CVAI might serve as an effective predictor of HUA. Importantly, this study marks the initial discovery of a J-shaped correlation between CVAI and HUA among the Chinese population.

Han et al. reported an upward correlation involving BMI, WC, and SUA levels [29]. Research involving 14,624 adults in the United States demonstrated a dose-dependent relationship between BMI and HUA, attributing a population-attributable risk of 44% to this association [11]. Xiao et al. noted that low muscle mass significantly linked to a heightened risk of HUA, a finding consistent across different age and sex subgroups [30]. Further studies in the Xinjiang and Korean regions respectively found heightened risks of HUA in individuals with overweight, obesity, or abdominal obesity compared with their normal-weight counterparts [31], and in those with concurrently elevated serum TG levels and WC [32]. Moreover, other emerging indicators have been explored for their relationship with obesity and HUA. A three-year follow-up study indicated that neck circumference, unlike WC, stood as a standalone predictor of subsequent HUA in women [33]. Another study highlighted that the WHtR proved superior to BMI and WC in forecasting HUA [34]. A US cross-sectional study also reported a nonlinear relationship between the triglyceride glucose index and HUA [35].

The mechanisms underlying these findings can be elucidated as follows: Firstly, CVAI measures the accumulation of visceral fat, which increases free fatty acids. These acids flow into the liver, inducing de novo synthesis of purines and consequently elevating SUA levels [36, 37]. Secondly, the CVAI consists of HDL, reflecting lipid metabolism. Dysregulation in this system can

impair renal blood flow. Additionally, increased adipose tissue may compress the kidneys, further diminishing renal blood flow and reducing uric acid excretion, thus elevating uric acid [38, 39]. Thirdly, visceral adipose deposition may disrupt lipid metabolism, influencing the body's inflammatory response and insulin resistance. This disturbance can adversely affect renal function, leading to increased SUA levels [40–42]. Lastly, enhanced accumulation of belly fat stimulates the release of inflammatory cytokines such as interleukin-6. These cytokines trigger inflammatory reactions and oxidative stress, which impair vascular endothelial function and contribute to metabolic abnormalities, further elevating uric acid levels [43, 44].

Subgroup analyses indicated a more pronounced correlation between CVAI and HUA in women and those without hypertension or diabetes. For the sex subgroups, intrinsic differences in adipose distribution and adipocyte characteristics between men and women may explain these findings. Firstly, men typically have more visceral adipose tissue (fat in the abdominopelvic cavity) compared to women, who generally have more subcutaneous adipose tissue (fat beneath the dermis) [45, 46]. Although women possess lower amounts of visceral fat, this may result in heightened sensitivity of CVAI to HUA. Additionally, studies have shown that the intraperitoneal adipocyte ratio is lower in women than in men and that fat cell size influences insulin resistance and the expression of proinflammatory adipokines. These differences might lead to a more pronounced relationship between visceral fat mass and SUA levels in women. Lastly, women differ from men in terms of metabolic rates and the metabolism of fats and carbohydrates. These differences may enhance the efficacy of the CVAI as a predictive marker for HUA risk in women. Regarding the subgroups without hypertension and diabetes, these conditions are associated with metabolic disorders that can mask or influence the relationship between visceral fat mass and SUA. In populations

without hypertension and diabetes, changes in CVAI and SUA levels may better reflect the physiological interaction between visceral fat and SUA levels.

### Advantages and drawbacks

The study presents several advantages when compared to previous research conducted in this specific field. Firstly, the study began by analyzing a large group of middle-aged and elderly populations from Dalian, China, to explore the connection between CVAI and HUA, which is applicable to the Chinese population. The homogeneity of the sample reduces sample bias and enhances representativeness. Secondly, the study conducted rigorous screening of the included population, excluding individuals with previous gout and those taking medications that affect SUA levels, thereby improving the dependability of the findings. Thirdly, the absence of some covariates could lead to inaccurate analysis results, thereby potentially affecting the conclusions. To minimize the impact of missing data, we employed multiple imputation techniques. However, this study has several limitations: Firstly, as Dalian is a coastal city in northern China, its residents consume more purine-rich foods such as seafood. The study was unable to exclude the potential interference of diet, exercise, and other lifestyle factors from the findings. Secondly, the sample was derived from the same region and consisted solely of community residents aged 40 and above; therefore, the study lacks generalizability and is not applicable to children, young adults, or populations in other countries and regions. Lastly, this cross-sectional study precludes establishing a causative link between CVAI and HUA.

### Conclusion

This study revealed a J-shaped relationship between CVAI and HUA. The CVAI could serve as a potential marker for detecting HUA and preventing disease progression in middle-aged and elderly populations. This study's findings offer crucial tools for HUA's early detection, especially in women, without hypertension, and without diabetes. This study provides significant value for the early detection and targeted prevention of HUA. Such insights facilitate personalized treatment and monitoring, enhancing the precision management of this condition.

### Abbreviations

HUA	Hyperuricemia
SUA	Serum uric acid
BMI	Body mass index
WHpR	Waist-to-hip ratio
WHtR	Waist-to-height ratio
CVAI	Chinese visceral adiposity index
WC	Waist circumference
SBP	Systolic blood pressure

ABSI	A body shape index
DBP	Diastolic blood pressure
LAP	Lipid accumulation product
CHD	Coronary heart disease
ALT	Alanine aminotransferase
AST	Aspartate aminotransferase
FPG	Fast plasma glucose
ROC	Receiver operating characteristic
AUC	Area under the curve
CI	Confidence interval
OR	Odds ratio

### Acknowledgements

The authors thank all participants in the study. The authors thank the Guang Ning Team at Ruijin hospital, Shanghai Jiaotong University School of Medicine, for helping establish the data set in the communities.

### Authors' contributions

Study design: ZN-G and YT-L. Data collection and analysis: L-L. Drafting and revising the manuscript: YT-L and L-L. All authors have read and agreed to the final manuscript.

### Funding

The study was supported by grants from the National Key R&D Program of China (2018YFC1311800) and the Dalian Science and Technology Bureau (project 2022RG11).

### Availability of data and materials

The data analyzed in this article are not disclosed to the public but are available from the corresponding author on reasonable request.

### Data availability

No datasets were generated or analysed during the current study.

### Declarations

#### Ethics approval and consent to participate

The protocol was approved by the Ethical Review Committee of Ruijin Hospital (RUJIN-2011-14), and all participants provided written informed consent.

#### Consent for publication

Not applicable.

#### Competing interests

The authors declare no competing interests.
