### **Materials and Methods**

**Definition and Calculation of codon pair bias.** We developed an algorithm to quantify codon pair bias. For each of the 3721 possible codon pairs (excluding Stop codon pairs) we calculated a “Codon Pair Score”, or “CPS”. We define the CPS as the natural log of the ratio of the observed over the expected number of occurrences of each codon pair over all human coding regions (Fig. S1, Table S1). Although the calculation of the observed occurrences of a particular codon pair is straightforward (the actual count within the gene set), the expected number of occurrences of a codon pair requires additional calculation. We calculate this expected number so as to be independent both of amino acid frequency and of codon bias similarly to Gutman and Hatfield (S1). That is, the expected frequency is calculated based on the relative proportion of the number of times an amino acid is encoded by a specific codon (Fig. S1). A positive CPS value signifies that the given codon pair is statistically over-represented, and a negative CPS indicates the pair is statistically under-represented in the human genome. The calculated CPS scores for all 3721 possible codon pairs can be found in Table S1.

Using these calculated CPSs, the *Codon Pair Bias* (CPB) for an entire open reading frame can then be calculated as the arithmetic mean of the individual codon pair scores. The CPB has been calculated for a core set of 14795 consistently annotated human genes (CCDS data set issued by NBCI, release date March 2nd 2005) using the equations shown in Fig. S1 and plotted (Fig. 1B, main text). Each point in the graph

corresponds to the CPB of a single human gene. A negative CPB signifies a prevalent use of underrepresented codon pairs, while a positive CPB indicates predominant use of overrepresented codon pairs. The peak of the distribution has a positive codon pair bias of 0.07, which is the mean score for all annotated human genes.

**Development and Implementation of computer-based algorithm to produce codon pair deoptimized sequences.** Using these formulas we next developed a computer based algorithm to manipulate the CPB of any coding region while maintaining the original amino acid sequence. The algorithm has the critical ability to maintain the codon usage of a gene (i.e. preserve the frequency of use of each existing codon) but “shuffle” the existing codons so that the CPB can be increased or decreased. The algorithm uses simulated annealing, a mathematical process suitable for full-length optimization (S2). Other parameters are also under the control of this algorithm; for instance, the free energy of the folding of the RNA. This free energy is maintained within a narrow range, to prevent large changes in secondary structure as a consequence of codon re-arrangement. The optimization process specifically excludes the creation of any regions with large secondary structures, such as hairpins or stem loops, which could otherwise arise in the customized RNA. Using this computer software the user simply needs to input the cDNA sequence of a given gene and the CPB of the gene can be customized as the experimenter sees fit. In the experiments here, the starting CPB of wild-type poliovirus (i.e., PV(M)-wt) is -0.02, while PV-Min has a CPB of -0.48, and PV-Max has a CPB of 0.25.

Additional customization included inclusion of restriction sites that were designed into both synthetic sequences at given intervals, to allow for sub-cloning of the P1 region.

**DNA Synthesis, Plasmids, Sub cloning of Synthetic Capsids and Bacteria.** Poliovirus cDNA fragments with altered codon pair bias, corresponding to nucleotides 495 to 3636 of the viral genome, were synthesized *de novo* (Blue Heron Corp, Bothell, WA). All subsequent poliovirus cDNA clones/sub clones were constructed based on plasmid pT7PVM, which contains a full length infectious cDNA clone of poliovirus type 1 Mahoney [PV(M)] downstream of a T7 RNA polymerase promoter (S3). Specifically, the synthetic PV-Min, PV-Max cassettes were released from Blue Heron's carrier vector via *PflM* I digestion and used to replace the respective *PflM* I fragment in the pT7PVM vector. The PV-MinXY and PV-MinZ constructs were obtained by digestion with *Nhe* I and *Bgl* II simultaneously, then swapping this fragment with a pT7PVM vector digested similarly. PV-MinX and PV-MinYZ were constructed via *Bsm* I digestion and exchanging the fragment/vector with the similarly digested pT7PVM. PV-MinY was constructed by digesting the PV-MinXY construct with *Bsm* I and swapping this fragment with the *Bsm* I fragment for a digested pT7PVM. Plasmid transformation and amplification were all performed in *Escherichia coli* DH5 $\alpha$ .

**In vitro Transcription and RNA transfection.** 1.5  $\mu$ g of plasmid DNA was linearized with *EcoR* I and then transcribed by T7 RNA polymerase driven by a T7 promoter upstream of the cDNA for 2 hours at 37°C (S3). 1  $\mu$ g of transcript RNA was transfected into 1 x 10<sup>6</sup> HeLa R19 cells using a modified DEAE-Dextran method (S3). These cells

were then incubated at room-temperature (RT) for 30 minutes after which the transfection supernatant was replaced with Dulbecco's modified Eagle medium (DMEM) containing 2% bovine calf serum (BCS). The cells were then incubated at 37° C and observed (up to 4 days) for the onset of cytopathic effect (CPE).

**Cells, virus, virus amplification, plaque assay, and one-step growth curves.** HeLa R19 cells were maintained as a monolayer in DMEM containing 10% BCS. Viruses were amplified on  $1.0 \times 10^8$  HeLa R19 cell monolayers infected at a multiplicity of infection (MOI) of 1. Infected cells were incubated at 37°C in DMEM with 2% BCS for three days or until CPE was observed. After three freeze/thaw cycles cell debris was removed from the lysates via low speed centrifugation and the supernatant containing virus was used for further experiments.

One-Step growth curves were obtained by infecting a monolayer of HeLa R19 cells with 2 MOI of a given virus. Excess inoculum was removed after 30 min after which the cells were washed 2x with PBS and incubated at 37°C for 0, 2, 4, 7, 10, 24, and 48 hours. Virus produced at these time points was quantified after 72 hours by plaque assays on HeLa cell monolayers.

**Heat stability and passaging.** The thermal stability of the synthetic viruses, PV-MinXY and PV-Min Z, was tested and compared to the wt virus PV(M). This was done by heating  $1 \times 10^8$  particles suspended in PBS at 50°C for 5, 15, 30 and, 60 minutes followed by plaque assays to measure the decrease of infectious virus at the different time points (Fig. S2). In order to test the genetic stability of the synthetic portions of the P1 region of

PV-MinXY and PV-MinZ, viruses were serial passaged and their genomes were sequenced. Briefly, monolayers of  $1 \times 10^6$  HeLa R19 cells were infected with 0.5 MOI of PV-MinXY and PV-MinZ and incubated until CPE was clearly visible. Throughout passages, the time interval until CPE developed, remained constant. Finally, the titers and nucleotide sequences of viruses that emerged after passage 5, 9, 15, 17 and 19 were determined (data not shown).

**Virus Purification and determination of viral particles via OD<sub>260</sub> absorbance.** A monolayer of HeLa R19 cells on a 15 cm dish ( $1 \times 10^8$  cells) was infected with wt virus PV1(M), PV-Max, PV-MinXY or PV-Min Z at an MOI of 1 and incubated until CPE was observed. After three freeze/thaw cycles the cell lysates were subjected to two centrifugations at 3,000 x g for 15 minutes and then to one centrifugation at 10,000 x g for 15 minutes. 10 µg/ml of RNase A was added to the supernatants of the second centrifugation to destroy free RNA. After an incubation at room temperature for 1 hour the supernatants were gently mixed with sodium dodecyl sulfate (SDS) and EDTA at final concentrations of 0.5 % and 2 mM, respectively, followed by incubation at room temperature for 30 minutes (S4). Only properly formed, intact virus particles survive this treatment (S5). These supernatants were placed above a 6ml sucrose cushion [30% sucrose in Hank's Buffered Salt Solution (HBSS)] and virus particles were sedimented by ultracentrifugation for 3.5 hours at 28,000 rpm using an SW28 swing-bucket rotor (S4).

After centrifugation, the supernatant above the sucrose cushion was removed and the tube was rinsed two times with HBBS without disturbing the sucrose cushion. The sucrose was then gently removed and the virus pellet at the bottom was re-suspended in

PBS containing 0.1% SDS (4). Viral titers were determined via plaque assay see (above). Virus particle concentration was determined via the average of three measurements of the optical density at 260nm of the solution via the NanoDrop spectrophotometer (NanoDrop Technologies) using the formula  $9.4 \times 10^{12}$  particles/ml = 1 OD<sub>260</sub> unit (S4, 6)

**Dicistronic reporter construction, and in vivo translation.** The dicistronic reporter replicons were all constructed based upon pdiLuc-PV (S4). PV-Max and PV-Min capsid regions were amplified via PCR using the oligonucleotides P1max-2A-RI (+)/P1max-2A-RI (-) or P1min-2A-RI (+)/P1min-2A-RI (-) respectively. The PCR fragment was gel purified and then inserted into an intermediate vector pCR-®-XL-TOPO® (Invitrogen Corp.). This intermediate vector was then amplified in One Shot® TOP10 chemically competent cells (Invitrogen Corp.). After preparation of the plasmid using Qiagen miniprep columns (Qiagen, Hilden Germany), the intermediate vectors containing PV-Min were digested with EcoRI and these fragments were ligated into the pdiLuc-PV vector that was equally digested with *EcoR* I (S4). These plasmids were also amplified in One Shot® TOP10 chemically competent cells. To construct pdiLuc-PV-MinXY and pdiLuc-PV-MinZ, pdiLuc-PV and pdiLuc-PV-Min each were digested with NheI and the resulting restriction fragments were exchanged between the respective vectors. These were then transformed into One Shot® TOP10 chemically competent cells and amplified. From all four of these clones RNA was in vitro transcribed as described above.

To analyze the in vivo translation efficiency of the synthetic region encoding the poliovirus capsids the RNAs of the dicistronic reporter constructs each were transfected into  $2 \times 10^5$  HeLa R19 cells on 12-well dishes using Lipofectamine 2000 (Invitrogen

Corp.). In order to quantify the translation of only the input RNA transfactions were carried out in the presence of 2 mM guanidine hydrochloride (GnHCL), a potent and specific inhibitor of poliovirus RNA replication. Six hours after transfection cells were lysed in passive lysis buffer (Promega, Madison, WI) and these lysates were analyzed by a dual firefly (F-Luc) *Renilla* (R-Luc) luciferase assay (Promega).

**Oligonucleotides.** The following oligonucleotides were utilized to perform PCR:

P1max-2A-RI(+), 5'

CAAGAATTCTGACCACATACGGAGCTCAAGTATCTCACAAAAAGTTGG-3';

P1max-2A-RI(-), 5'

TTCGAATTCTCCGTACGTGGTGAGGTCTTGGTGGACAAAGG-3'; P1min-2A-

RI(+),

5'CAAGAATTCTGACCACATACGGAGCTCAGGTGTCATCCAAAAAGTAGG-

3'; P1min-2A-RI(-), 5'

TTCGAATTCTCCGTACGTCGTAAGGTCTTCGTTGACAGTGG-3'.

**CD155tg mice: neuropathogenicity, vaccination, serum conversion.** Groups of 4-6, 6-8 week old *CD155* tg mice (Tg21 strain) were injected intracerebrally with purified virus ranging from  $10^2$  particles to  $10^9$  particles in 30 ul PBS to determine neuropathogenicity (S7). The lethal dose 50 ( $LD_{50}$ ) was calculated according to the method by the Reed and Muench (S8). Viral titers in the spinal cord and brain were quantified by plaque assay (data not shown).

To test PV-Min Z and PV-MinXY as a vaccine, three doses ( $10^8$  particles in 100ul of PBS) of these viruses were administered to 6-8 week old CD155tg mice via intraperitoneal injection once a week for three weeks. In parallel, a set of control mice received three mock vaccinations with 100 ul PBS. One week after the final vaccination, 30 ul of blood was extracted from the tail vein and subjected to low speed centrifugation after which the serum harvested (S9). Neutralizing antibodies against wt PV(M) in these sera were analyzed via micro-neutralization assay with 100 plaque forming units (PFU) of challenge virus, performed according to the recommendations of WHO (S9, 10). Two weeks after the final inoculations, the vaccinated and control mice were challenged with  $10^6$  PFU (a lethal dose) of wt PV(M) by intramuscular injection (9). All experiments utilizing CD155tg mice were undertaken in compliance with Stony Brook University's IACUC regulations as well as federal guidelines.

**Determination of RNA folding energies, exclusion of large (100bp) stable secondary structures.** To ensure that strong secondary structures do not affect translation efficiency, we scanned the capsid region of our designs using the program mfold (S11). We concentrated our search on 100-base long segments, having 80 bases overlap with each other. Any segments with lower binding energy than a threshold of - 30Kcal/mol would incur random synonymous substitutions at C - G binding locations, such that the binding energy of the segment could be elevated. The synonymous changes would be selected in such a way that the codon pair bias objective would be satisfied as well.

**Supporting Information.** The GenBank (<http://www.ncbi.nlm.nih.gov/Genbank/>) accession numbers for the codon-pair bias sequences presented in this paper are: P1-Min (EU095953) and P1-Max (EU095952).

## Supplementary Figures

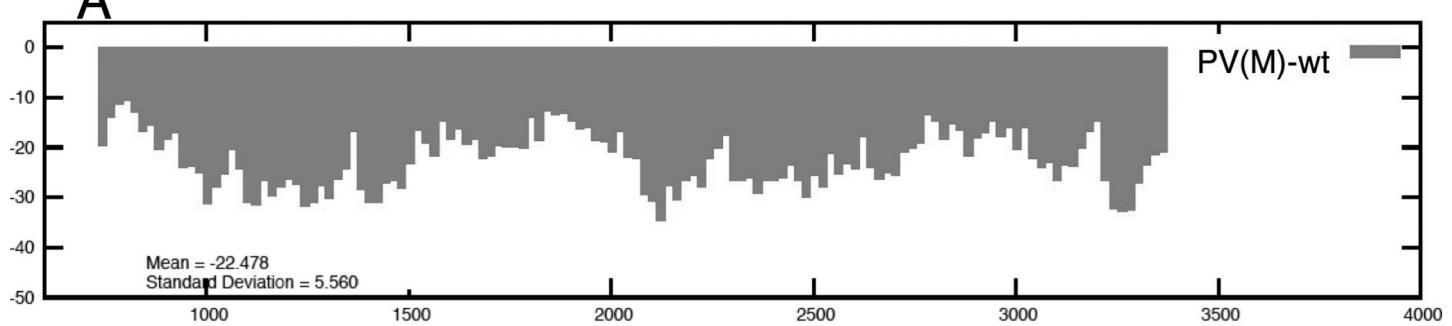

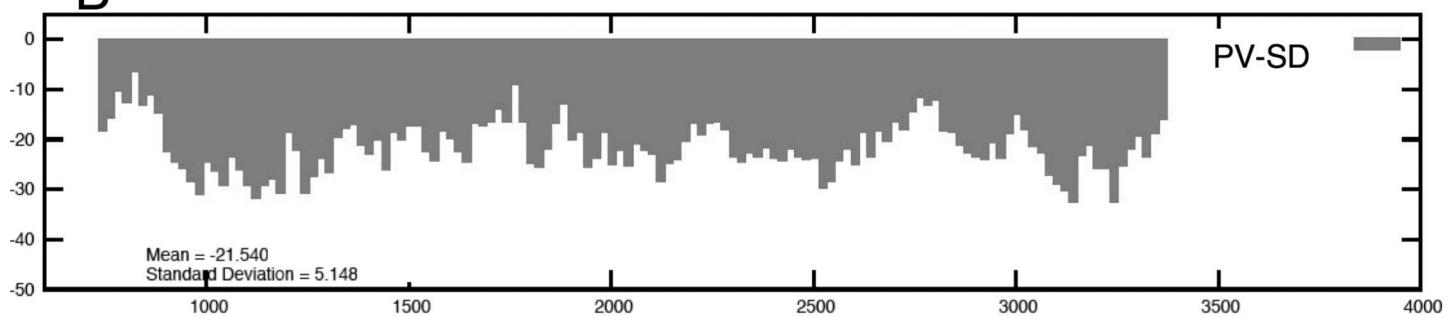

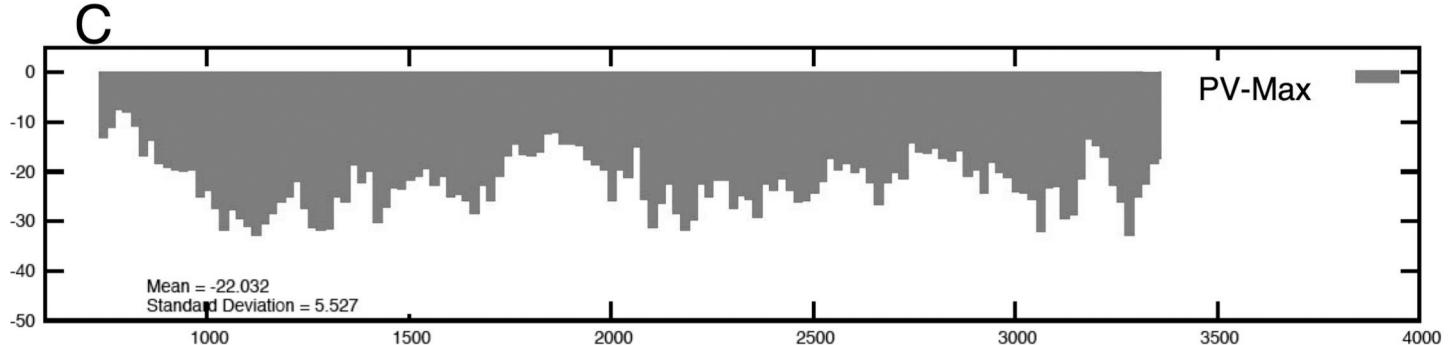

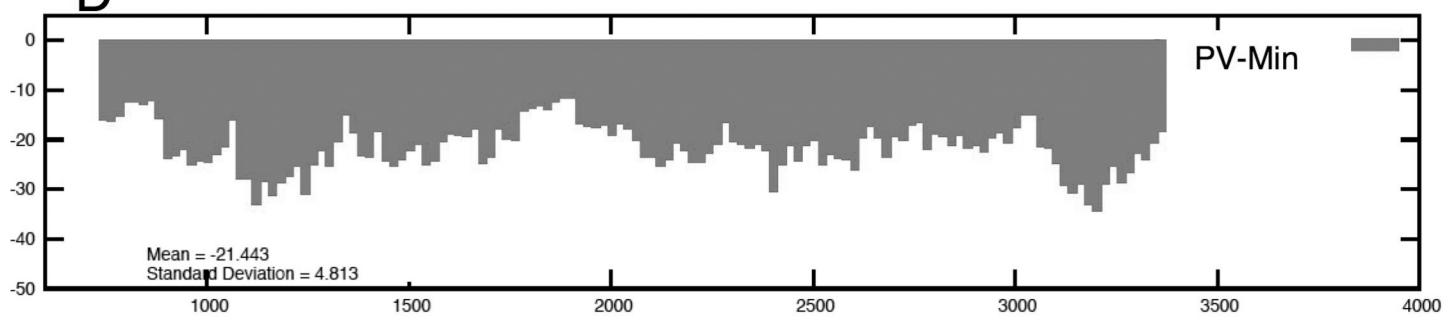

A

$$CPS = \ln \left( \frac{F(AB)_o}{\frac{F(A) \times F(B)}{F(X) \times F(Y)} \times F(XY)} \right)$$

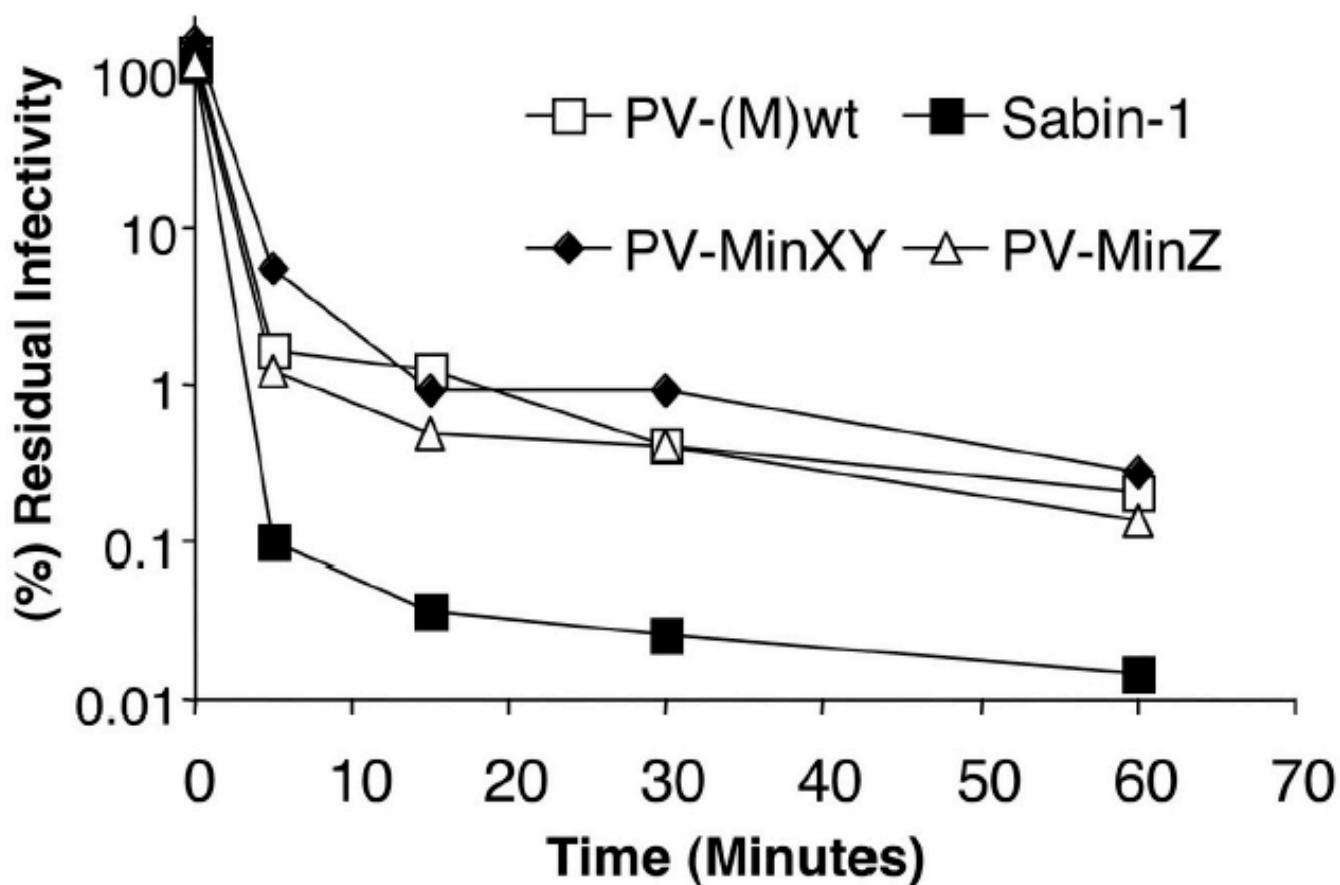

B

$$CPB = \sum_{i=1}^k \frac{CPS_i}{k-1}$$

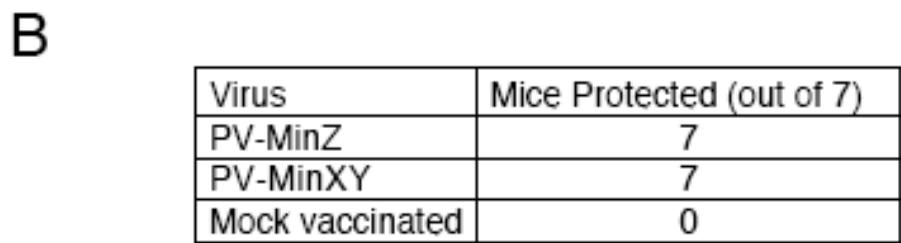

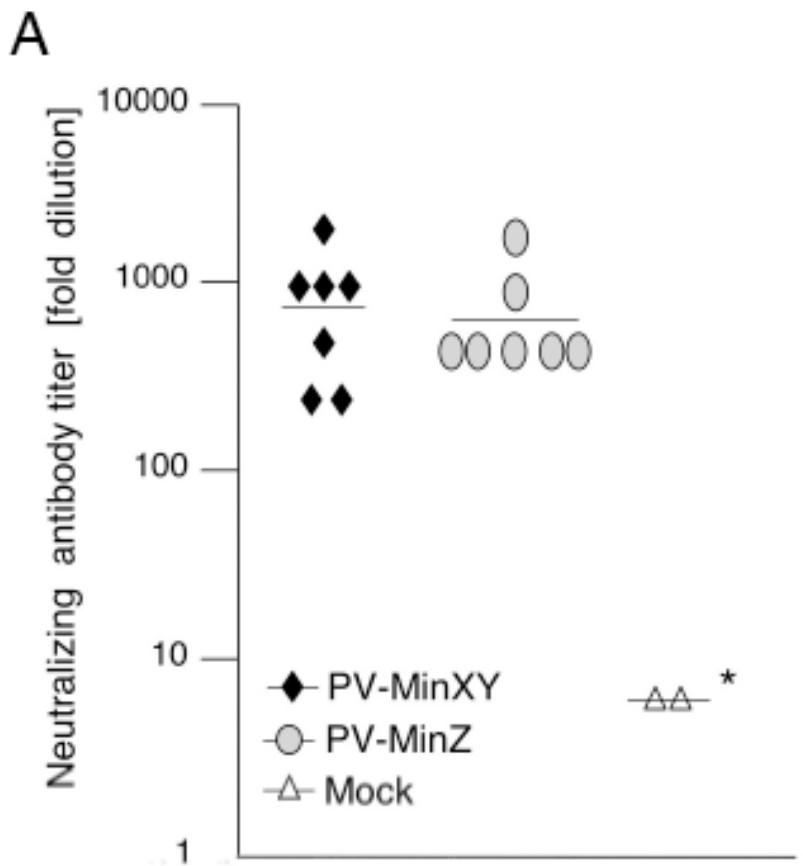

**Figure S1.** Equations used to determine codon-pair scores (CPS) and the codon-pair bias (CPB) of an entire open reading frame (ORF). (A) The equation used to calculate the CPS of a given codon pair independent of codon usage and amino acid bias, thus its relative expected frequency, where the codon pair AB encodes for amino acid pair XY and F denotes frequency (number of occurrences). This CPS score for a given pair determines if the pair is over-represented (+) or under-represented (-) in the human genome. (B) The equation used to calculate the CPB for an entire gene. CPB is the arithmetic mean of the individual codon pair scores of all pairs making up the ORF.

**A****B****C****D**

**Figure S2. Synthetic P1s have similar folding energy to wild-type, ensuring absences of large, stable secondary RNA structure.** To ensure that strong secondary structures do not affect translation efficiency, we scanned the capsid region of our designs using the program mFold (S11). We concentrated our search on 100-base long segments, having 80 bases overlap with each other. Any segments with lower binding energy than a threshold of -30Kcal/mol would incur random synonymous substitutions at C - G binding locations, such that the binding energy of the segment could be elevated. The synonymous changes would be selected in such a way that the codon pair bias objective would be satisfied as well. Nevertheless, only a few changes resulted thus altering the original codon pair selections of our algorithm. All constructs thus have a similar mean folding energy (A) PV(M)-wt, mean -22.478, (B) PV-SD, mean -21.540, (C) PV-Max, mean -22.032, (D) PV-Min, mean -21.443.

**Figure S3.** The heat inactivation profile of the synthetic viruses is unchanged. To rule out that large scale codon-pair bias modification alters the gross morphology of virions, as one might expect if capsid proteins were misfolded, the thermal stability of PV-MinXY and PV-MinZ was tested. An equal number of particles were incubated at 50°C and the remaining infectivity quantified after given periods of time via plaque assay. If the capsids of the synthetic viruses were destabilized we would expect increased loss of viability at 50°C in comparison to PV(M)-wt. This was not the case. The thermal inactivation kinetics of both synthetic viruses was identical to the wt. In contrast, the Sabin-1 virus carries numerous mutations in the genome region encoding the capsid, which, fittingly, rendered this virus less heat stable as compared to wt PV1(M).

**Figure S4.** Induction of neutralizing antibodies by PV-MinZ and PV-MinXY and protection after challenge. Since PV-MinZ and PV-MinXY encode exactly the same proteins as wild-type virus, they might provoke a protective immune response. Alternatively, the relatively poor translation of the mutant mRNAs might prevent such a response. To distinguish these possibilities, PV-MinZ and PV-MinXY were administered to groups of eight *CD155tg* mice at a dose of  $10^8$  particles once a week for three weeks via intraperitoneal injection. (A) Ten days after the final injection the protective antibodies of the seven surviving mice in each group were measured via micro-neutralization assay, and a robust immune response was detected, as indicated (878 for PV-MinXY, 805 for PV-MinZ) (S9, 10). (B) Subsequent challenge of the vaccinated mice with an otherwise lethal dose of wild-type poliovirus via intramuscular injection did not lead to death or signs of paralysis or paresia; in contrast, all mock vaccinated mice succumbed to challenge. (\*) No virus neutralization for mock-vaccinated animals was detected at the lowest tested dilution of 1:8.

## Supplementary Tables

**Table S1.** Calculated codon pair scores (CPS) for all 3721 possible codon pair combinations (excluding Stop codons) in the human ORFeome. Column A, amino acid pair; Column B, codon pair; Column C, expected number of occurrences of the codon pair within the human ORFeome; Column D, observed number of occurrences of this codon pair within the ORFeome; Column E, ratio of observed occurrences over expected occurrences; Column F, the natural log of the ratio in column E corresponds to the codon pair score (CPS) for the codon pair in column B.

**Table S2**

<u>P1-Region</u>	<u>Codon Pair Bias</u>
PV-Max	+0.246
PV(M)-wt	-0.034
PV-SD	-0.095
PV-AB	-0.096
PV-MinZ	-0.205
PV-MinXY	-0.391
PV-Min	-0.474

**Table S2.** Includes the Codon-pair Bias of various designed as well as the natural nucleotide encodings of the poliovirus P1 protein. The table includes two viruses previously constructed PV-AB and PV-SD (S4). The virus PV-SD, had 937 mutations in synonymous codons in the P1 region and was constructed by randomly shuffling the existing codons (S4). In PV-SD neither codon bias nor codon pair bias was significantly altered and PV-SD grew with a wt phenotype (S4). The second virus PV-AB used only rare codons (S4), yet its CPB was not altered drastically either, thus despite derivatives of PV-AB having an attenuated phenotype the attenuation was not due to codon pairing. These two viruses indicate that the attenuation observed in PV-Min derivative viruses was not a result of random changes in synonymous codons.
