## 1 **Abstract**

2       Surface water bodies (lakes, reservoirs, and rivers) are key components of the water cycle and  
3 are important water resources. Water level and storage vary greatly under the impacts of climate  
4 change and human activities. Due to sparse in-situ monitoring networks, a comprehensive national-  
5 scale monitoring dataset of surface water bodies in China is not available. Over the last two decades,  
6 satellite altimetry has been used successfully for inland water monitoring. Here, we use CryoSat-2  
7 radar altimetry to monitor water level variations of large lakes, reservoirs and rivers across China  
8 and demonstrate its potential to complement available in-situ monitoring datasets for the country.

9       In this study, over 1000 lakes and reservoirs, and 6 large rivers are investigated. The results  
10 show that surface water varied greatly over the past 6 years, e.g. in the Tibetan Plateau, the Junggar  
11 Basin, the Northeast China Plain, and the central Yangtze River basin. Estimated changes in volume  
12 indicate that surface water variation contributes significantly to terrestrial storage variation,  
13 especially in the Qaidam Basin and the Tibetan Plateau. CryoSat-2 is capable of measuring  
14 regional-scale river level at high spatial resolution and competitive accuracy as demonstrated by  
15 comparison with available in-situ gauging data. The results are encouraging with RMSE values  
16 ranging from 0.24 to 0.35 m for the Heilongjiang-Amur River, 0.22 to 0.6 m for the Yellow River  
17 and 0.22 to 0.5 m for the Songhua River. Comparatively, accuracy is much lower over the Yangtze

18 and Pearl Rivers (RMSE ~ 2.6 m and ~ 3.3 m), probably due to intensive inland waterway  
19 navigation. CryoSat-2 shows great potential for monitoring surface water at national scale in China.

20 Keywords: CryoSat-2; Radar altimetry; Inland water; Water level; Storage variation; River height

## 21 **1. Introduction**

22 Remotely sensed water level, e.g. from radar altimetry or unmanned aerial vehicle (UAV), is  
23 increasingly used for surface water resource monitoring (Berry et al., 2005; Birkinshaw et al., 2010;  
24 Crétaux et al., 2016). The benefit of remotely sensed observations is that they are free and easy to  
25 access, and have a universal coverage (Jiang et al., 2017b). Therefore, we are able to monitor  
26 surface water at large scale for regions poorly gauged or not easy to reach and further advance  
27 water resource management and flood forecasting.

28 Because of the impacts of climate change and anthropogenic activities, water resource issues  
29 in China are more challenging and have received much attention (Jiang, 2009; Liu and Yang, 2012;  
30 Piao et al., 2010). Water storage, both surface- and subsurface water storage, have changed  
31 significantly in recent decades (Qiu, 2010). Construction of dams and reservoirs, groundwater  
32 exploitation, water diversion projects, land use change, etc., all altered the distribution of surface  
33 water storage and groundwater storage. The most dramatic example is that of groundwater over-  
34 exploitation in the North China Plain, which is considered the primary reason for groundwater  
35 depletion (Shi et al., 2011). Besides, lakes have been undergoing rapid change during the past  
36 decades (Ma et al., 2010). China's two largest freshwater lakes, Poyang and Dongting for example,  
37 are significantly altered in terms of the hydrological regime, and aquatic ecology by excessive  
38 human activities (e.g. artificial channel diversion, landscape modification, dam construction, etc.)  
39 (Lai et al., 2013; Yuan et al., 2015). Meanwhile, climate change also greatly affects distribution of  
40 water storage. For example, the Yangtze River shows a slight increase in annual runoff since 1960  
41 while the Yellow River shows a persistent decline (Piao et al., 2010). Terrestrial water storage  
42 (TWS) plays a critical role in local and regional ecological systems and socio-economic

43 development. However, annual water shortages exceed 50 km<sup>3</sup> across the country (Global Water  
44 Partnership, 2015). Therefore, monitoring the variations in TWS is important for water resources  
45 management and sustainable development.

46 Inland water bodies can be important components of TWS in certain regions of the globe and  
47 play a primary role in the global water cycle (Papa et al., 2010). Surface water stored in e.g.  
48 reservoirs, lakes, and rivers, has important influence on local climate, ecosystems, and human  
49 society. Many rivers, lakes, and reservoirs serve as important drinking water sources. Lake Taihu  
50 and Miyun Reservoirs, for instance, are the main drinking water sources for local people in Wuxi  
51 and Beijing, respectively, while rivers, like the Yangtze, Yellow, and Pearl serve hundreds of  
52 millions of people. Moreover, reservoirs have an important role in water supply and flood control  
53 and may become more critical with the increasing frequency and intensity of extreme weather  
54 events (Wang et al., 2016). In China, according to the *Bulletin of the First National Census for*  
55 *Water* (Ministry of Water Resources, 2013), there are 2865 lakes with a surface area greater than 1  
56 km<sup>2</sup> and the total lake surface area is about 78000 km<sup>2</sup>. Additionally, the number of reservoirs was  
57 98002 with a total storage capacity of 932.3 km<sup>3</sup> by 2011. However, the spatio-temporal distribution  
58 of surface water variation is very poorly known due to sparse in-situ monitoring networks and  
59 restricted access to monitoring datasets.

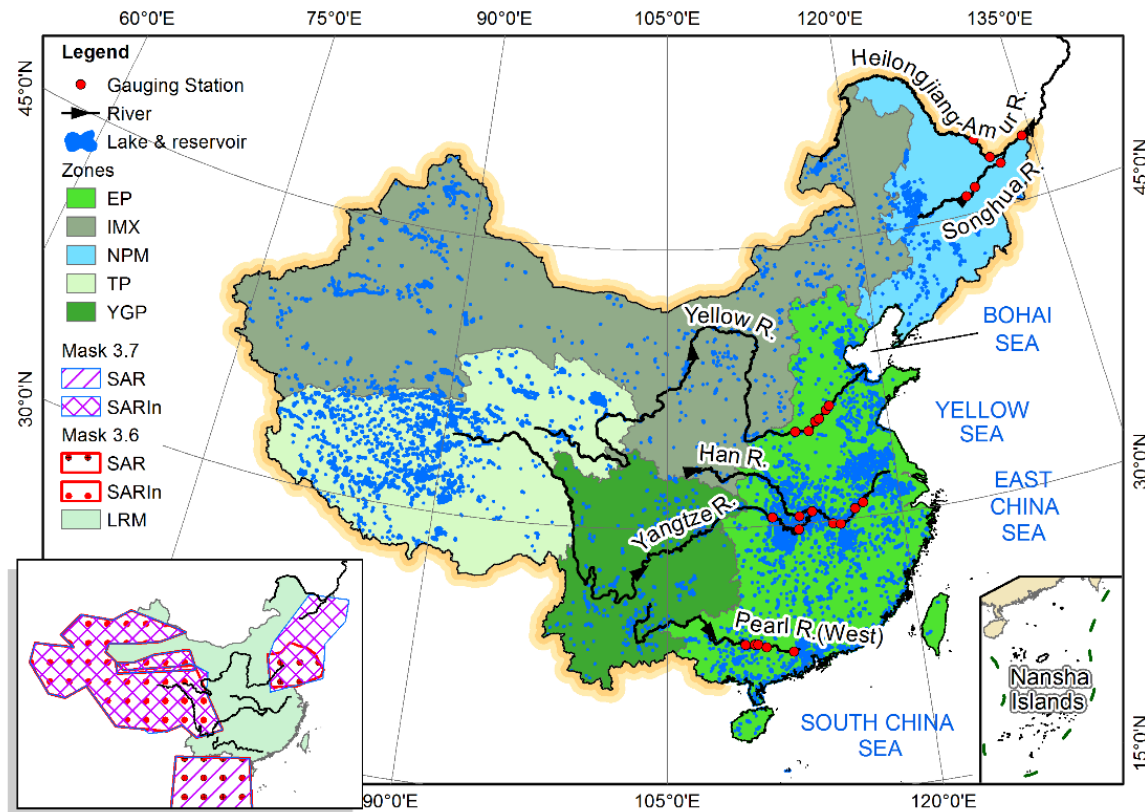

60 Traditionally, water storage measurements for lakes and reservoirs have relied on in-situ data,  
61 i.e. bathymetry and water level. However, in-situ observation at regional-continental scale is often  
62 time-consuming and expensive, especially in remote areas. Moreover, for China, existing  
63 monitoring datasets for most reservoirs and lakes are not publicly available. In this context, remote  
64 sensing technology makes it feasible to measure inland water bodies at regional scale. Satellite  
65 altimetry, as an alternative method for surface water level monitoring, has been widely used on  
66 inland water bodies (Berry et al., 2005; Birkett, 1995; Crétaux et al., 2016; Schwatke et al., 2015).

67 Satellite altimeters obtain surface heights by measuring the two-way travel time of an  
68 electromagnetic pulse between the altimeter and the surface. Conventional radar altimeters have  
69 been operated for more than three decades. Among the previous and current altimetry missions,  
70 CryoSat-2 has advantages due to its dense ground tracks and Synthetic Aperture Interferometric  
71 Radar Altimeter (SIRAL) although the full repeat cycle is 369 days. The dense ground tracks make  
72 it possible to monitor smaller water bodies and lead to more frequent overpasses for large water  
73 bodies than previously (Nielsen et al., 2015). Meanwhile, the SIRAL instrument uses along-track  
74 beam formation to generate strips (~ 300 m) in SAR/SARIn mode which can be superimposed and  
75 averaged to reduce noise (Wingham et al., 2006). For example, Nielsen et al (2015) investigated  
76 the performance of CryoSat-2 data over small lakes (9 to 40 km<sup>2</sup>) and they found the RMSE values  
77 are only 8 cm or less, even for a lake of annual amplitude of 20-30 cm. Combined with multispectral  
78 satellite imagery, such as Landsat, MODIS, Sentinel-2/3, or SAR imagery (Sentinel-1), the  
79 dynamic water storage change can be monitored (Crétaux et al., 2015, 2016; Gao et al., 2012; Jiang  
80 et al., 2017a; Muala et al., 2014; Song et al., 2013; Zhang et al., 2014). In addition, satellite  
81 altimeters also offer the possibility to monitor river levels, flood evolution, and estimate river  
82 discharge, in particular for those areas where in-situ measurements are either unavailable or not  
83 accessible (Bercher et al., 2013; Michailovsky et al., 2012; Sulistioadi et al., 2015; Villadsen et al.,  
84 2014). For example, a recent study calibrated a hydrodynamic river model with CryoSat-2 water  
85 level in the Brahmaputra river. This study indicated that high spatial resolution CryoSat-2 data is  
86 very helpful in calibrating cross-sections without precise knowledge of river bathymetry (Schneider  
87 et al., 2017). A recent review of inland water applications of CryoSat-2 has been published by Jiang  
88 et al. (2017b).

89 Recently, several studies have used altimetry-derived surface water storage (SWS) changes to  
90 complement the terrestrial water storage variations obtained from GRACE (Forootan et al., 2014;  
91 Longuevergne et al., 2013; Moore and Williams, 2014; Ndehedehe et al., 2016). The work of Papa

92 et al. (2015) in the Ganges-Brahmaputra River basin shows that surface water storage variation  
93 contributes about 45% to GRACE-derived TWS variation. Given that the contribution of SWS to  
94 TWS can be considerable, especially on a regional scale in regions with significant reservoir and  
95 lake storage (e.g. China, Fig. 1), it is of major importance to study the spatio-temporal variations  
96 of SWS. This will enable estimation of different components (e.g. groundwater, soil moisture, and  
97 surface water) of TWS and their variations (Papa et al., 2015). Nevertheless, national-scale SWS  
98 variation in China is unknown till now. Key questions remain unanswered regarding the spatio-  
99 temporal dynamics of SWS in China, and the contribution of SWS to TWS.

100 The primary aim of this study is to demonstrate the value of CryoSat-2 radar altimetry data for  
101 monitoring surface water bodies of China. Specific key objectives are: (1) to monitor the surface  
102 water level (SWL) variation and estimate surface water storage changes (including lakes and  
103 reservoirs); (2) to identify the spatio-temporal dynamics of water levels of large rivers; (3) to  
104 evaluate the performance of CryoSat-2; and (4) to analyze relations between SWS and TWS change  
105 across time and space in China.

106

107 **Fig. 1.** Map of water bodies in China. Five geographic zones are highlighted; CryoSat-2 geographical masks  
 108 are also shown in the bottom left corner to present the coverage of different modes.

109 **2. Materials and methods**

110 **2.1. Study area and CryoSat-2 mode mask**

111 China has a large territory with a great diversity of physical and cultural geography. The  
 112 variation of surface water is affected by both natural and human factors. In this study, we divide  
 113 lakes and reservoirs into five zones, which consider climate conditions, geography, and  
 114 administrative boundaries (Ma et al., 2011; Wang and Dou, 1998). The zones are (Fig. 1): (1) the  
 115 Eastern Plain (EP) ( $2.07 \times 10^6$  km<sup>2</sup>), characterized by abundant rainfall and flat topography with  
 116 developed hydrologic systems; (2) Inner Mongolia and Xinjiang (IMX) ( $3.7 \times 10^6$  km<sup>2</sup>), where the  
 117 climate is arid or semiarid and the drainage system is poorly developed with less permanent runoff;  
 118 (3) Northeast Plain and Mountain (NPM) ( $0.81 \times 10^6$  km<sup>2</sup>), including the Three Northeast Provinces;  
 119 (4) the general Tibetan Plateau (TP) ( $1.95 \times 10^6$  km<sup>2</sup>) including both the Tibet Autonomous Region

120 and the Qinghai Province, characterized by cold and high altitude environments; and (5) Yunnan-  
121 Guizhou Plateau (YGP) ( $1.14 \times 10^6 \text{ km}^2$ ).

122 The radar altimeter onboard CryoSat-2 operates in three modes, i.e. low resolution mode  
123 (LRM), synthetic aperture mode (SAR), and SAR interferometric mode (SARIn). While the LRM  
124 is the same as a conventional pulse-limited radar altimeter, the SAR and SARIn utilize a  
125 Delay/Doppler radar altimeter with finer along-track spatial resolution (Keith Raney, 1998).  
126 Cryosat-2 is designed to automatically switch to the three modes according to a geographic mode  
127 mask, which divides the Earth's surface into different zones (European Space Agency and Mullar  
128 Space Science Laboratory, 2012). China is partially covered by all of the three modes (Fig. 1). The  
129 mode mask is subjected to changes from time to time and since 14 December 2015 (mask 3.7), a  
130 new SARIn mask was added over the Bohai Sea Rim and the Northeastern China. The coverage of  
131 three modes over China is displayed in Fig. 1. For more details about the small changes among  
132 different mask versions please refer to ESA CryoSat mission  
133 (<https://earth.esa.int/web/guest/missions/esa-operational-eo-missions/cryosat/>).

## 134 **2.2. Surface water extent**

135 There are several global surface water datasets available including the MODIS Water Mask  
136 (MOD44W) (Carroll et al., 2009), SRTM Water Body Dataset (SWBD, 2003), among others.  
137 Considering the resolution and timeliness, we use the dataset from Global Surface Water Explorer  
138 (<https://global-surface-water.appspot.com/>) (Pekel et al., 2016) to derive water body polygons. This  
139 water dataset, produced from Landsat imagery, maps the spatial and temporal distribution of water  
140 surfaces at the global scale over the past 32 years. Currently all of the mapped datasets are available  
141 to download (i.e. occurrence, change, seasonality, recurrence, transitions, and maximum extent). In  
142 our study, the water seasonality (2014-2015) dataset is used as input. The values from 1 to 12 stand  
143 for the number of months that one pixel is covered by water. In this study, pixels with value 12 are  
144 extracted. That means we use permanent water surface mask.

145 **2.3. CryoSat-2 data processing**

146 *2.3.1. Water level time series construction*

147 The ESA level 1b data product is retracked by an empirical sub-waveform retracker, called  
148 *Narrow Primary Peak Threshold* (NPPT) retracker (Jain et al., 2015). It has proven to provide valid  
149 water level and outperform the ESA L2 data (Jain et al., 2015; Nielsen et al., 2015; Villadsen et al.,  
150 2016). For lakes and reservoirs water level time series are constructed by the following steps:

151 Step 1. Point data are first selected with water masks.

152 Step 2. The obvious outliers are removed by comparing water level (h) with SRTM elevation  
153 (e) (Jarvis et al., 2008), i.e. data points are discarded if  $|h - e| > 20$  m.

154 Step 3. Water bodies with more than 5 crossings are retained.

155 Step 4. For each water body, the estimation of the along-track mean values and time series are  
156 calculated using the “R” package “tsHydro”, which is publicly available from Github  
157 (<https://github.com/cavios/tshydro>). This package is based on a state-space model proposed  
158 by Nielsen et al. (2015), where the observation part follows a mixture between a Cauchy and  
159 a Gaussian distribution. This considerably reduces the effect of outlying observations (Nielsen  
160 et al., 2017).

161 The data processing for rivers is different from that of lakes and reservoirs due to the river’s  
162 bendiness (sinuosity) which causes many crossovers per track at different reaches. The main  
163 procedures are described below:

164 The first two steps are the same as above.

165 Step 3. For each crossing track, a simple clustering is applied by checking the distance between  
166 two consecutive measurements. If the distance is larger than 1 km (the along-track distance  
167 between two consecutive samples is  $\sim 300$  m), we split this track into different parts to make  
168 sure that the measurements of each cluster are from the same reach.

169 Step 4. For each cluster, a filtering is performed to get the mean value of each track: a  
170 measurement is discarded if  $|h - \mu| > 3\sigma$  ( $\mu$  is mean value and  $\sigma$  is the along-track standard  
171 deviation).

172 Step 5. The measurements (from step 4) are then interpolated to the closest in-situ station for  
173 validation purpose based on the local average slope.

### 174 2.3.2. Space-time interpolation

175 The dense ground tracks allow to map river level variations in both time and space (chainage).  
176 However, the initial point data are not easy to visually interpret and identify the spatio-temporal  
177 variation of water level. In order to have better visual interpretation, gridded water level data (time  
178 by chainage) are generated by interpolation as follows:

179 Step 1: A template grid (7 days by 10 km) is created for each year (2010 -2016).

180 Step 2: Cubic interpolation at each grid point is performed for each year using water level from  
181 step 4 in previous section, and then 7 gridded layers are obtained.

182 Step 3: For each grid point (6 - 7 values during 2010 - 2016), the median value (avoid the  
183 extremely dry/wet year) is used to generate a space-time map.

### 184 2.3.3. Trend and amplitude estimation

185 In order to estimate trends for lakes and reservoirs, a weighted linear regression model is used.  
186 Due to the seasonality of water level in most lakes and reservoirs, a linear-periodic model is fitted  
187 for those having a time series length of more than 15 points. Following Villadsen et al (Villadsen  
188 et al., 2015), this model is defined as:

$$189 \quad h(t) = a + bt + c \sin(2\pi t) + d \cos(2\pi t) \quad (1)$$

190 where  $t$  is the time in decimal years;  $a$  and  $b$  are the linear coefficients, and  $c$  and  $d$  are the  
191 periodic coefficients, respectively. From this model, the annual amplitude ( $H$ ) is estimated as:

$$192 \quad H = \sqrt{c^2 + d^2} \quad (2)$$

## 193 2.4. Water storage change

194 To assess the water storage changes in lakes and reservoirs, water extent ( $A$ ) and water level  
195 change ( $\Delta h$ ) are needed. Ideally, dynamic water extent datasets should be used to calculate accurate  
196 storage change. Due to the lack of such datasets, we assume that water extent is constant during the  
197 investigated period. Thus, water storage change can be obtained by multiplying  $A$  with  $\Delta h$ . The  
198 error induced by this assumption is about 2.5% after investigating 71 lakes in the Tibetan Plateau.

## 199 2.5. GRACE gravimetry

200 The Gravity Recovery and Climate Experiment (GRACE) mission measures the variations in  
201 gravitational field on a monthly scale, which can provide vertically integrated TWS change. The  
202 GRACE data used in this study is the latest version (RL05) L3 from the Center for Space Research  
203 (CSR), University of Texas at Austin, German Research Centre for Geosciences (GFZ), and Jet  
204 Propulsion Laboratory (JPL), respectively (<http://grace.jpl.nasa.gov/>). Each solution is processed  
205 by removal of atmospheric pressure/mass changes and the degree 2 and order 0 (C20) coefficients  
206 are substituted with those from Satellite Laser Ranging (Cheng et al., 2011) and degree 1  
207 coefficients with those from Swenson et al (Swenson et al., 2008). The data are further processed  
208 by multiplying by the scale factors at the grid scale to restore much of the energy removed by the  
209 de-stripping, Gaussian smoothing, and truncation to the land grids (Landerer and Swenson, 2012).  
210 As for the accuracy, the GRACE error estimates are based on measurement and leakage errors, and  
211 the total error in TWS for a given grid can be calculated as:

$$212 \quad Err = \sqrt{E_M^2 + E_L^2} \quad (3)$$

213 where  $Err$  is the total error,  $E_M$  and  $E_L$  are measurement and leakage errors, respectively. Finally,  
214 an ensemble mean solution is achieved by averaging the three solutions.

215 **2.6. Ancillary data**

216 Daily water level data of rivers are extracted from the *Hydrological Yearbook* published by  
217 the Chinese Ministry of Water Resources (MWR, 2014). The reservoir storage change data are  
218 extracted from *China Water Resources Bulletin* (<http://www.mwr.gov.cn/>) and *SongLiao Water*  
219 *Resources Bulletin* (<http://www.slwr.gov.cn/>). Precipitation data are downloaded from the China  
220 Meteorological Data Sharing Service System (<http://data.cma.cn/en>). Water level of 3 lakes is  
221 downloaded from the Third Pole Environment Database (<http://www.en.tpedatabase.cn/>).

222 **3. Results**

223 In this section, an overview of lakes and reservoirs is presented to show how much spatial  
224 detail CryoSat-2 can deliver, followed by detailed analysis of the temporal variations of these water  
225 bodies. Next, we show the CryoSat-2 derived water levels for 6 large Chinese river systems. Then,  
226 we evaluate the accuracy and precision of CryoSat-2 over inland water.

227 **3.1. Overview of monitored water bodies**

228 In total, 1334 lakes and reservoirs (> 5 km<sup>2</sup>) are visited by CryoSat-2 over China during 2010  
229 to 2016, providing basic water level information. After outlier removal, time series of 1163 water  
230 bodies are obtained. Table 1 lists the number of water bodies having different number of passes.  
231 Considering the estimates of linear trend and annual amplitude, only those having at least 10 passes  
232 are considered in this study. Overall, TP and EP are the two zones with the most lakes, accounting  
233 for 50% and 23% of the total number of water bodies, respectively (Table 2). Meanwhile, lakes in  
234 TP comparatively have more passes (avg. 25 passes per lake) due to their large sizes.

235 **Table 1.** Number of CryoSat-2 passes over water bodies

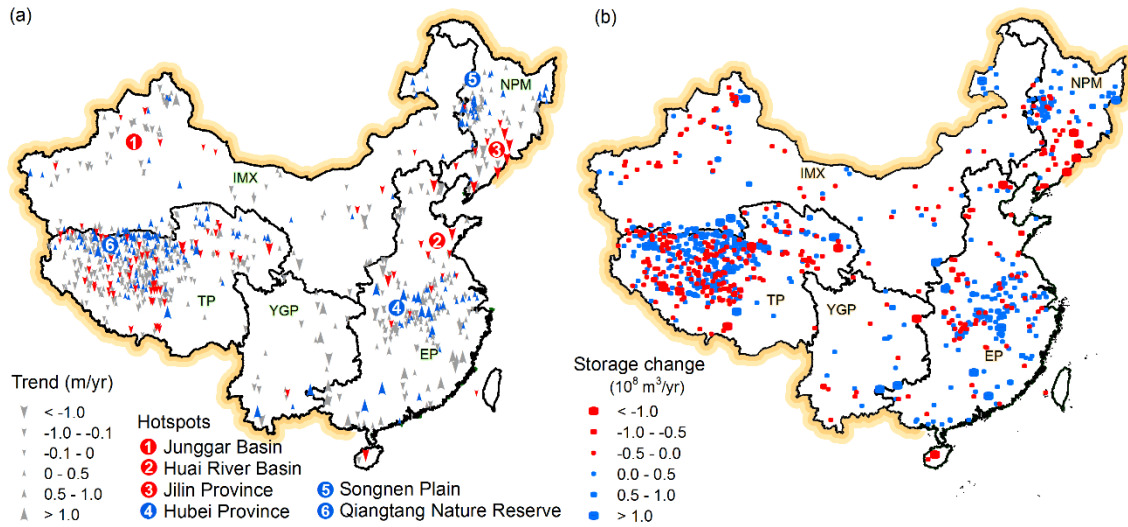

Number of passes	5	6	7	8	9	10	11	12	13	14	15	> 15
Number of water bodies	43	40	49	71	77	<b>92</b>	<b>64</b>	<b>73</b>	<b>52</b>	<b>35</b>	<b>37</b>	<b>530</b>

236 In zone TP, 56% of water bodies exhibit an upward trend and the rising rates of rising lakes  
 237 are far larger than the declining rates of declining lakes. At the national scale, surface water bodies  
 238 show a dominant increasing trend although some regions have an almost even split between rising  
 239 and declining lakes (Table 2). Out of the 1334 lakes and reservoirs surveyed by CryoSat-2, 288  
 240 lakes and reservoirs show a significant changing trend; of those, around 58% are located in region  
 241 TP.

242 **Table 2.** Statistics of water level and storage changes of water bodies in the five lake zones

Lake zone	Trend	Number (percentage)	Mean changing rate (m/yr)	Storage change rate ( $10^8 \text{ m}^3/\text{yr}$ )
EP	rising	142 (70%)	0.330	$9.5 \pm 23.6$
	declining	62 (30%)	-0.448	
IMX	rising	64 (52%)	0.302	$25.9 \pm 24.4$
	declining	58 (48%)	-0.219	
NPM	rising	60 (65%)	0.267	$-12.4 \pm 30.1$
	declining	33 (35%)	-0.573	
TP	rising	247 (56%)	0.228	$35.5 \pm 55.2$
	declining	194 (44%)	-0.117	
YGP	rising	14 (61%)	0.919	$5.4 \pm 25.4$
	declining	9 (39%)	-0.592	

243 Although water level changes vary zonally, several hotspots can be identified from the map of  
 244 changing rates (Fig. 2a). Specifically, water bodies in Junggar Basin, Huai River Basin, and Jilin  
 245 Province show a dominant declining trend. In contrast, those in Songnen Plain and North TP, i.e.  
 246 Qiangtang Reserve, show a marked rising trend.

247

248

249

**Fig. 2.** Distribution of lake/reservoir changing rates (a) (Solid red and blue arrows indicate significant trends at the 5% level) and storage change (b)

250

### 3.2. Variations of lakes and reservoirs

251

#### 3.2.1. Annual fluctuation of water level

252

Overall, annual amplitudes of lakes are relatively smaller than amplitudes of reservoirs. For example, annual amplitudes of lakes in TP are between 0-1.5 m and the average is  $0.52 \pm 0.45$  m, while those of reservoirs located in the lower portions of the Yangtze River basin and Northeast Plain are larger than 5 m (Fig. 3). This is mainly due to human regulation. In fact, reservoirs did not show a very clear annual fluctuation pattern in recent years (Fig. 3).

257

In many cases, annual fluctuations of larger lakes are lower compared to smaller ones. An example is given in Fig. 3 from region TP. We can see that Zhari NamCo ( $1072 \text{ km}^2$ ) has a smaller annual fluctuation compared to Aru Co ( $113 \text{ km}^2$ ) and Gyaring Lake ( $538 \text{ km}^2$ ).

259

**Fig. 3.** Level changes of four lakes in TP lake region (a-c) and very large reservoirs (storage capacity >  $1 \times 10^9 \text{ m}^3$ ) in NPM lake region (d-f)

260  
261  
262

### 263 3.2.2. Surface water storage changes

264 The surface water storage change varies greatly from region to region as shown in Fig. 2b.  
265 Region TP and IMX gained water storage while NPM lost water storage in the period 2010-2016.  
266 Specifically, the estimated SWS changes in TP and IMX are  $35.5$  and  $25.9 \times 10^8 \text{ m}^3/\text{yr}$ , respectively  
267 (Table 2). It is obvious that in the northwest of IMX, i.e. the Junggar Basin and south of NPM,  
268 SWS loss was dominant. EP and YGP exhibited slightly increasing SWS trends although some  
269 lakes/reservoirs experienced declining trends.

270 Some lakes show very significant storage changes and play a dominant role in the regional  
271 surface water storage variation. For instance, Hulun Lake, Poyang Lake, and many lakes in the  
272 Tibetan Plateau have annual average storage increases exceeding  $1 \times 10^8 \text{ m}^3/\text{yr}$  (Table D1).

273 Reservoirs have relatively smaller areas but larger storage capacity than lakes, thus play a  
274 dominant role in seasonal SWS. However, at intra-annual scale, large reservoirs did not vary greatly  
275 due to human intervention. For instance, Three Gorges reservoir did not show a significant  
276 changing trend.

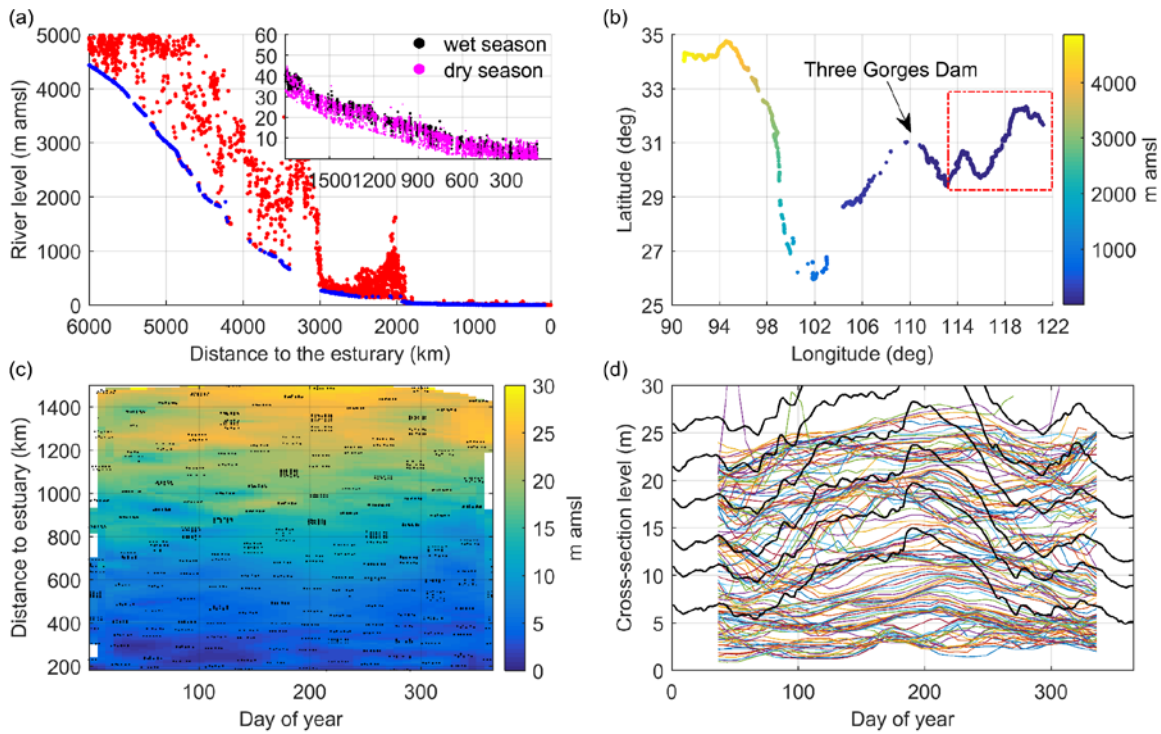

277 **3.3. Water level of large rivers**

278 We investigated 6 large rivers, i.e. the mainstream of the Yangtze River and its tributary - Han  
279 River, the Yellow River, the Pearl River (the west part, i.e. West River), and the Heilongjiang-  
280 Amur River and its tributary - Songhua River. The following sections will present the water level  
281 variation in detail.

282 *3.3.1. The Yangtze River*

283 Figure 4 shows the river level profile of the Yangtze River. Data quality over the upper part is  
284 relatively poor due to the narrow valley, canyons, and gorges in the mountainous areas. The lower  
285 reach after the Three Gorges Dam is relatively flat, especially downstream of river kilometer 1900  
286 (measured from the estuary) (Fig. 4a). The level drops from above 4500 m to a few hundred meter  
287 along the upper course while the lower part is very flat. The fluctuation of water level of the lower  
288 reach is about 10 m and decreases close to the estuary (inset of Fig. 4a), which is confirmed by the  
289 available in-situ measurement. The lower flat reach has more CryoSat-2 crossings and the  
290 interpolated space-time map generally captures the high flow around day of year 200 (Figs. 4c &  
291 4d). However, the data over some sections are sparse and annual mean level is over-/under-  
292 estimated due to the uneven seasonal data sampling. As shown in Fig. 4c, the heights of several  
293 hotspots are presented along the chainage, such as those located around river km 1000. Despite all  
294 these limitations, the interpolated water level profile still presents the general annual flow pattern  
295 (Fig. 4d). Nevertheless, from these graphs, much hydrological information (e.g. river level profile,  
296 water level slope, flow regime) are provided by CryoSat-2. This indicates that CryoSat-2 can  
297 potentially facilitate river modeling.

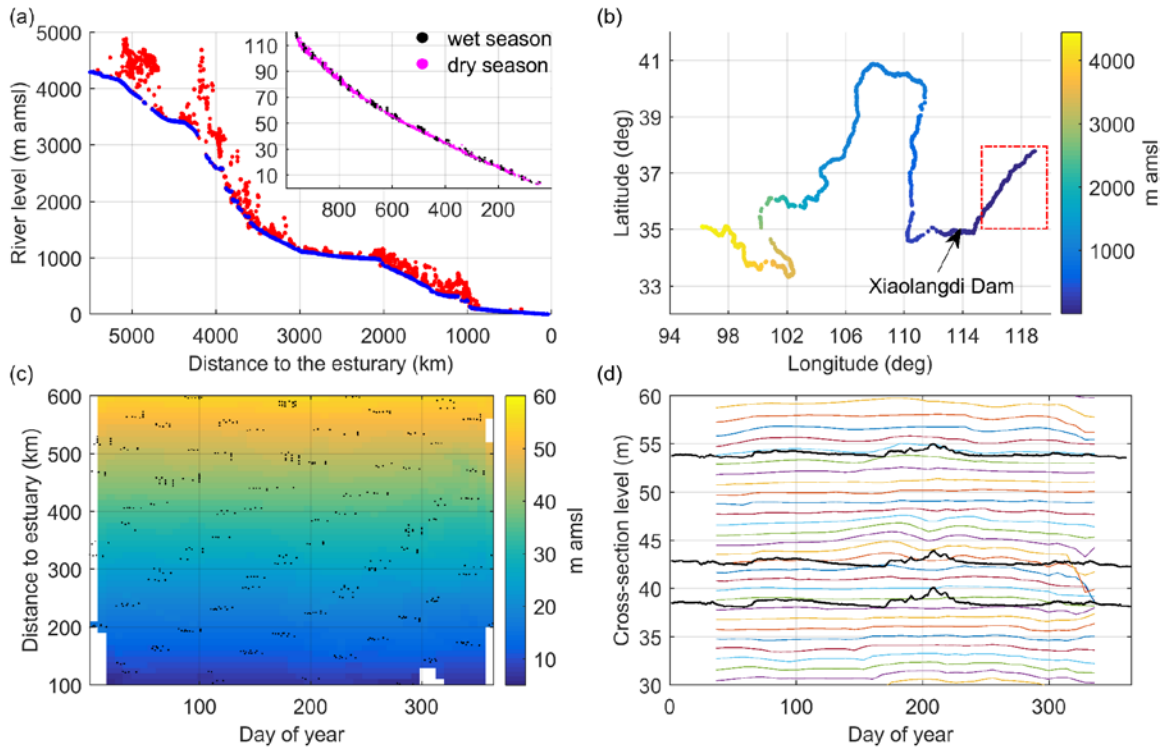

298

299 **Fig. 4.** The Yangtze River height profile: (a) CryoSat-2 data distribution along river course (red points are  
 300 outliers); (b) map of river profile with colored heights; (c) spatio-temporal distribution of CryoSat-2 river  
 301 water level (location is indicated by red rectangle in b; black dots indicate retracked water level); and (d)  
 302 interpolated sectional level against in-situ data (black lines) corresponding to c.

### 303 3.3.2. The Yellow River

304 In contrast to the data of the Yangtze River, the data quality and derived river height profile  
 305 of the Yellow River are much less noisy, especially in the downstream portion, where the river  
 306 flows through a flat plain area. (Figs. 5a and 5b). The river slope is quite consistent throughout the  
 307 last 800 km and the slope is very gentle at 0.1‰ (0.1 m/km) although the local surface slope is  
 308 varying between 0.05 and 0.15 m/km. The fluctuation of water level is small (~ 1- 2 m) downstream  
 309 of Xiaolangdi Dam and the flow regime cannot be clearly seen from the space-time interpolation  
 310 map due to the small inter-annual variation (Fig. 5c). However, for most of the cross sections, the  
 311 annual variation of water level is reasonable compared to that of the Yangtze River, and the pattern  
 312 is generally in agreement with in-situ data (Fig. 5d).

313

314

Fig. 5. The same as Fig. 4 but for the Yellow River.

315

### 3.3.3. The Heilongjiang-Amur River

316

Data quality over this region is very good, especially for the Songhua River where many valid

317

measurements are obtained. From the profile of river level versus chainage (Fig. 6d), we can see

318

that the slope of the Songhua River is just about 0.1‰ (0.1 m/km), similar to the Yellow River.

319

The river level profiles are very well presented at high spatial resolution (Fig. 6), which is not

320

possible using any of the previous altimetry missions. This is a unique capability of Cryosat-2 due

321

to its dense ground tracks. Fig. 7 shows in detail the water level maps of river reach where in-situ

322

data are available. Generally, the space-time river level maps of Heilongjiang-Amur and its largest

323

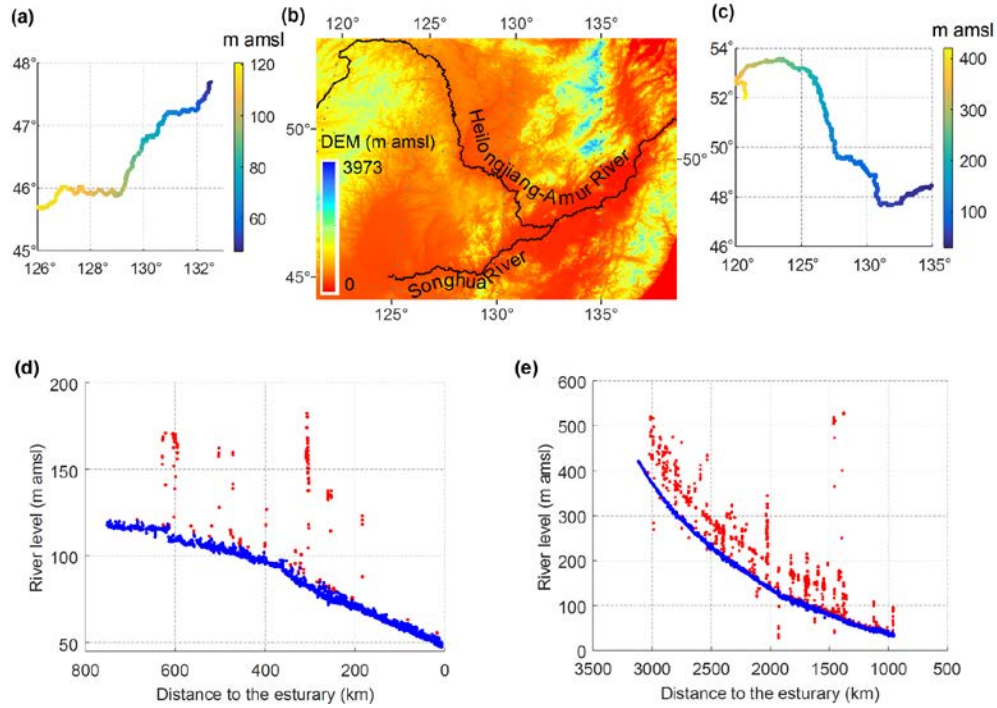

tributary, Songhua River, are captured well and are in agreement with in-situ measurements (see

324

details in section 3.4). High and low flow periods are very well observed. These river level graphs

325

reflect the high spatial coverage of CryoSat-2 data and a satisfactory data quality.

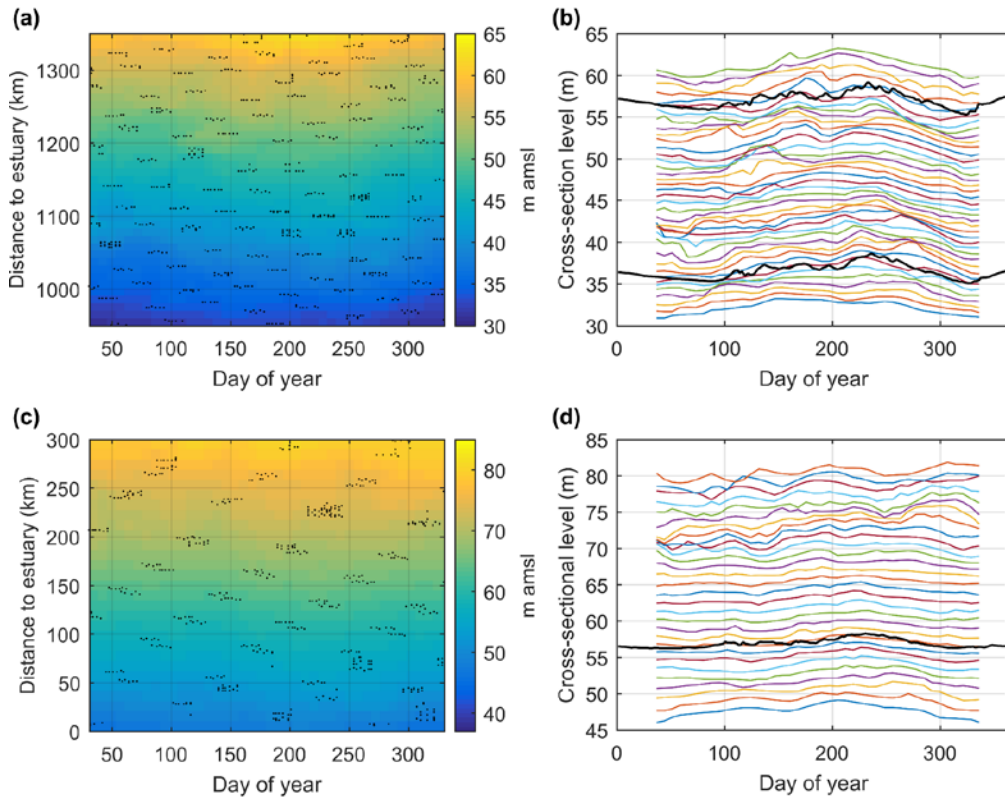

326

327

328

**Fig. 6.** River level and the longitudinal profile of Songhua River (a and d) and Heilongjiang-Amur River (c and e), and the SRTM DEM (b) in this region. Outliers are in red in d and e.

329

330

331

332

**Fig. 7.** Water level maps of the Heilongjiang-Amur River (a and b) and its tributary - Songhua River (c and d). a and c show the interpolation maps of certain reach (black dots are retracked measurements); and b and d are the corresponding sectional water level profiles (black lines are plotted using in-situ data).

333 **3.4. Evaluation of CryoSat-2 derived water level**

334 *3.4.1. Comparison with in-situ data*

335 Because information on the reference system of the Chinese in-situ station network is not  
 336 publicly available, water level anomaly time series of both altimetry and in-situ data are computed.  
 337 Then the RMSE and coefficient of determination ( $R^2$ ) are calculated. CryoSat-2 performs quite well  
 338 over the 3 lakes for which in-situ records are available, i.e. Zhari Namco (1070 km<sup>2</sup>), Dawa Co  
 339 (250 km<sup>2</sup>), and Bam Co (120 km<sup>2</sup>). The corresponding RMSEs are 0.14 m, 0.21 m, and 0.26 m,  
 340 respectively.

341 Table 3 shows the performance of CryoSat-2 at different locations for 6 rivers. In general, the  
 342 performance of CryoSat-2 LRM is comparable over the Yellow River, Songhua River, and  
 343 Heilongjiang-Amur River with respect to the RMSE. This result is also comparable to that of SAR  
 344 in the Amazon River reported by Villadsen et al. (2016). Moreover, the performance of LRM over  
 345 these rivers is clearly better than that for the Yangtze River and Pearl River although the last two  
 346 rivers are much wider than other Chinese rivers. This also explains the poor interpolation result of  
 347 the Yangtze River in previous section.

348 **Table 3. Validation of virtual stations of CryoSat-2 against in-situ data.**

River	Station Name	Position (km)	Mode <sup>s</sup>	Width (km)	Number of measurements	RMSE (m)	R <sup>2</sup>

### 350 3.4.2. Evaluation of precision

351 To evaluate the water level data quality, we have calculated the standard deviation (SD) of the  
352 along-track measurements. The SD gives a measure of how precise the observations are along each  
353 track. Over lakes, LRM and SARIn perform almost equally well and the median SD is below 0.1  
354 m as expected due to the large area of water surface.

355 Because rivers are normally much narrower than lakes, we considered the tracks with two or  
356 more measurements. Table 4 shows the along-track SD of water level for the 6 rivers during  
357 different seasons. It is obvious that SDs of the Yangtze River and the Pearl River are very large  
358 compared to those of other rivers. And the downstream of the Yangtze is strikingly high, especially  
359 in the dry season (Table 4). We will discuss the possible reasons in Discussion. Moreover, the  
360 SAR/SARIn modes do not outperform LRM significantly (Table 4).

361

362

363

364  
365

**Table 4. The precision of CryoSat-2 in terms of the along-track deviation (median SD in bracket)  
(Units: m)**

River	SD of Wet season	SD of Dry season	SD of All	SD of LRM	SD of SAR/SARIn
All	0.33 (0.18)	0.40 (0.20)	0.37 (0.19)		SAR

369 **4. Discussion**

370 First, the performance of CryoSat-2 over inland water is discussed. Next, the comparison  
 371 between surface water storage and terrestrial water storage is discussed at a regional scale followed  
 372 by a discussion of water ‘hotspot’.

373 **4.1. Performance of CryoSat-2 over inland water**

374 CryoSat-2 works pretty well over lakes in this study although the validation is conducted  
 375 against very few lakes with ground truth. The RMSE is generally around 20 cm and is smaller for  
 376 large lakes. This is in agreement with recent published result (Nielsen et al., 2017). On the other  
 377 hand, the accuracy of river water level is good in terms of the RMSE in the order of 40 cm. While  
 378 as reported in section 3.4, the performance over the Yangtze River and Pearl River is relatively  
 379 poor. Performance is worse over the downstream of the Yangtze River compared to the upstream.  
 380 A possible reason for the poor performance is that waveforms are polluted by ships using the inland  
 381 transport waterway. Waveforms show several peaks probably returning from different scatterers on  
 382 the river (Fig. A1). One evidence is that the performance over a branch (i.e. Han river) of the  
 383 Yangtze River is better even though river width is smaller (Table 4). This limitation suggests that

384 more specific retracking or ad hoc outlier filtering algorithm are required for altimetry data  
385 processing over heavily navigated rivers. Moreover, the relief impacts the data quality greatly. This  
386 is due to the closed-loop tracking problem (Biancamaria et al., 2017; Dehecq et al., 2013). This is  
387 quite clear from the upper part of Yangtze River and Yellow River in mountainous regions (Figs.  
388 4 and 5).

#### 389 **4.2. Effect of SWS on TWS**

390 Figure 8 illustrates the TWS changes observed by GRACE during the period of 2003-2016.  
391 The three solutions from different centers agree relatively well, especially in region YGP (Fig. 8f).  
392 Monthly TWS anomalies vary significantly among these five zones. IMX experienced a decreasing  
393 trend although the fluctuation range is small (approx. 11 mm) compared to YGP (Figs. 8c and 8f).  
394 NPM had a special fluctuation pattern compared to other regions. Between 2008 and 2014, NPM  
395 had twice large positive increases and two droughts in the TWS anomaly, which is likely related to  
396 extreme precipitation and drought events (Cong et al., 2016) (see precipitation in Fig. B1).  
397 Comparatively, TWS anomaly is the largest for YGP with a magnitude of 30 mm and shows a very  
398 regular pattern (Fig. 8f).

399  
400  
401

**Fig. 8.** Regionally averaged time series of equivalent water level anomalies with errors (grey shade) in different regions

402  
403  
404  
405  
406  
407  
408

From the perspective of multi-year average, four hotspots can be identified. One region of pronounced TWS loss is the North China Plain, which is also reported by several studies (Feng et al., 2013; Mo et al., 2016). Three regions of TWS increase are located in northern TP, northern NPM, and south of EP, respectively. Among these, the average anomaly of the first hotspot (i.e. northern TP) is 37.6 mm and the increasing rate is 11.9 mm/yr. Moreover, the north of NPM and the south of EP also have net accumulation in TWS, and the corresponding increasing rates are 6.9 and 10.9 mm/yr, respectively (see the map of TWS change in Fig. C1).

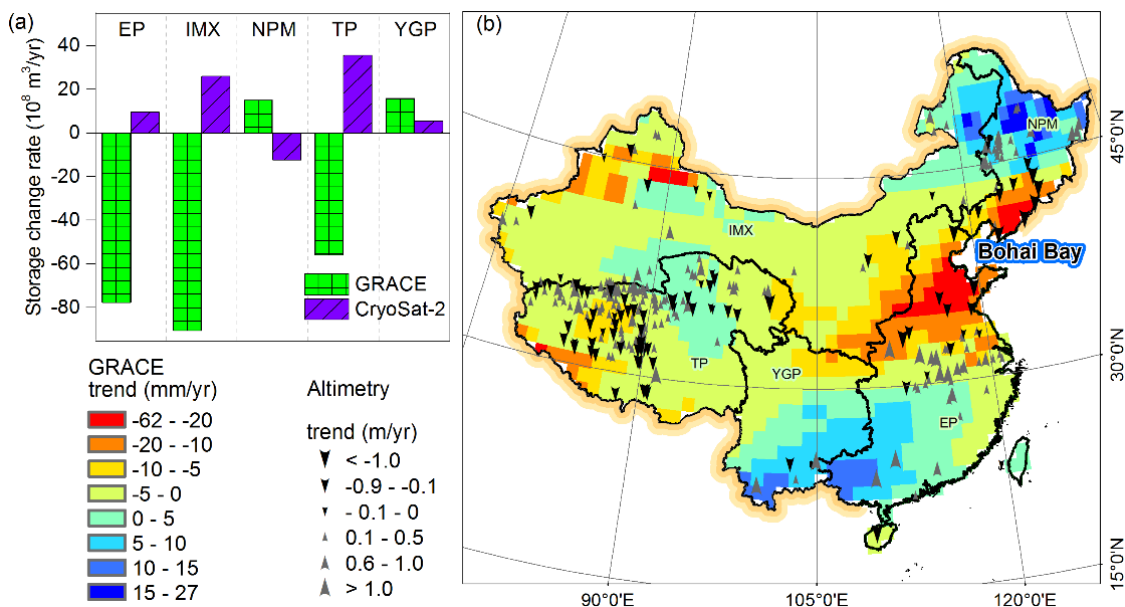

409  
410  
411

On a regional scale, the contributions of SWS to TWS are relatively small for IMX and EP, although in the latter 204 lakes and reservoirs are investigated. It indicates that the changes of water bodies are very inhomogeneous, and cancel each other out to produce negligible net effect (Fig. 9a

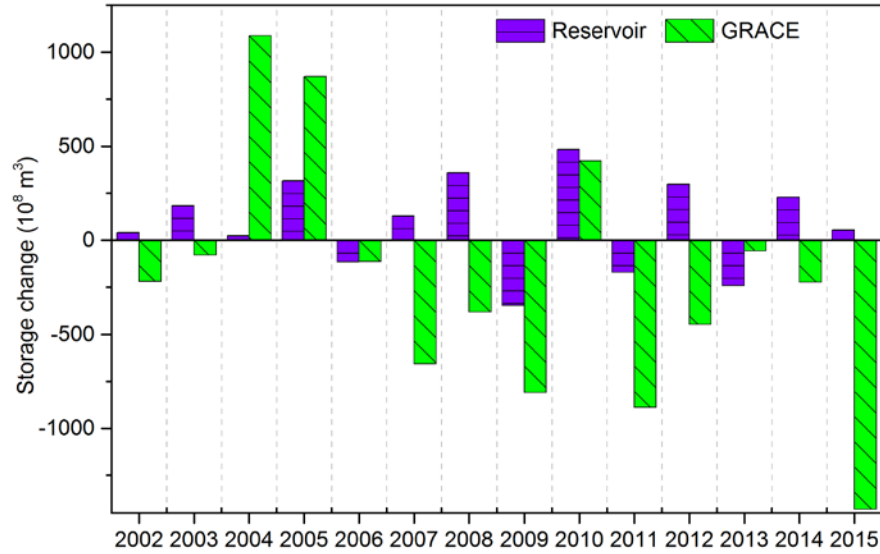

412 and Table 2). Moreover, the change rates of SWS and TWS in all zones except YGP are opposite.  
 413 Especially in TP, the SWS increment effectively mitigates total storage loss.

414 On the other hand, SWS changes agree well with TWS changes in northwest and central IMX,  
 415 and regions around the Bohai Bay Rim, where both are decreasing (Fig. 9b). In central IMX, i.e.  
 416 the Inner Mongolia, lakes are shrinking and the number of lakes is also decreasing according to  
 417 Tao et al (2015), who attributed it to intensive human activities (e.g. coal mining) as well as drier  
 418 and warmer climate.

419  
 420 **Fig. 9.** Storage change rates by zones (a) and distribution of the changing trend of water level (b) (only 288  
 421 with a significant trend shown) inferred from GRACE and altimetry for the period of 2010 – 2016

422 As an important part of SWS, reservoir storage change has a marked impact on TWS change  
 423 at national scale (Fig. 10). For certain years, both reservoir storage change and TWS change have  
 424 the same pattern, i.e. increase or decrease, and even similar magnitude for 2006 and 2010, which  
 425 means that the reservoir storage changes dominated the TWS change.

426

427

**Fig. 10.** Comparison of annual changes between reservoir storage and TWS at national scale

428

Therefore, SWS should not be ignored when estimating groundwater storage change from

429

GRACE especially in the areas with significant lake and reservoir storage.

430

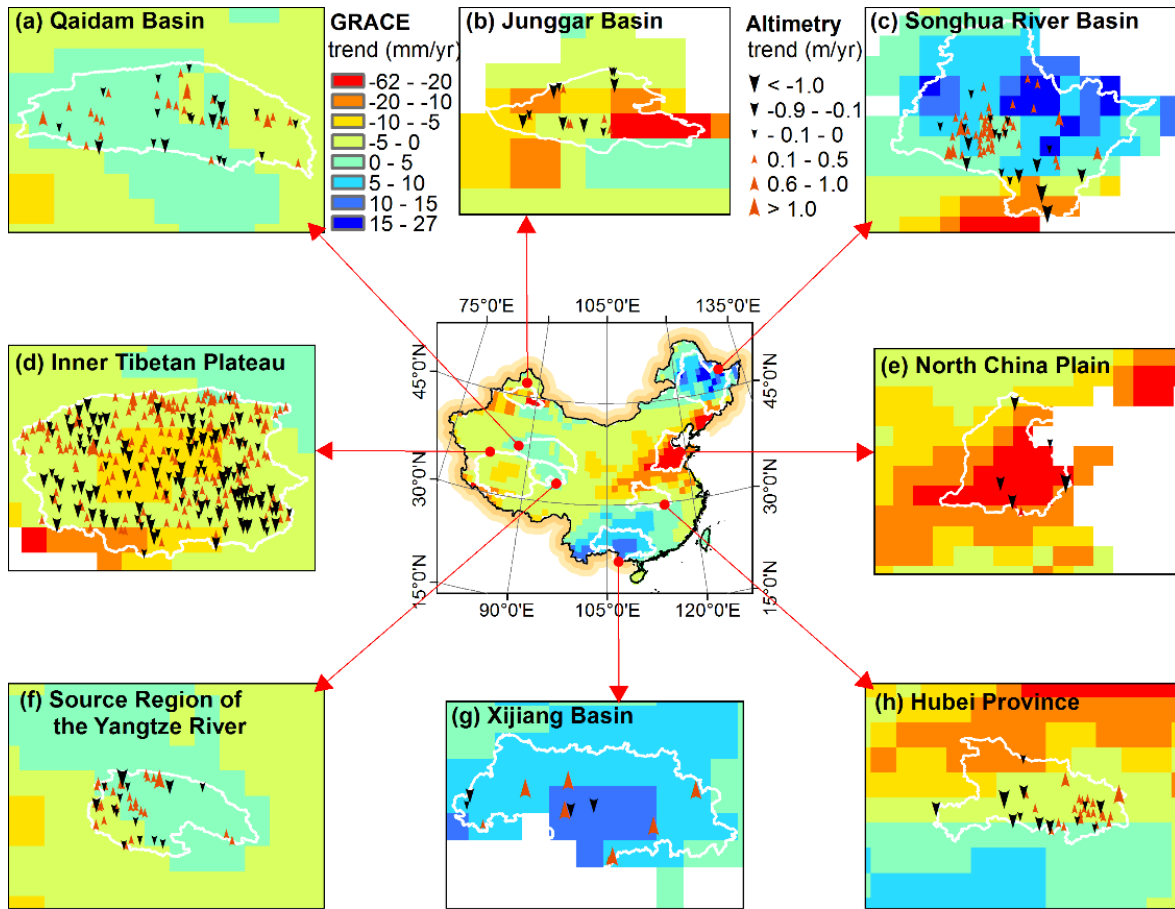

#### **4.3. Hotspots showing significant surface water dynamics**

431

As mentioned before, water storage is rapidly changing in some hotspots in China (Fig. 11).

432

We will discuss the variations in SWS and TWS for eight hotspot regions below.

**Fig. 11.** Hotspots of regional storage change over the period of 2010-2016.

433

434

435

436

437

438

439

440

441

442

443

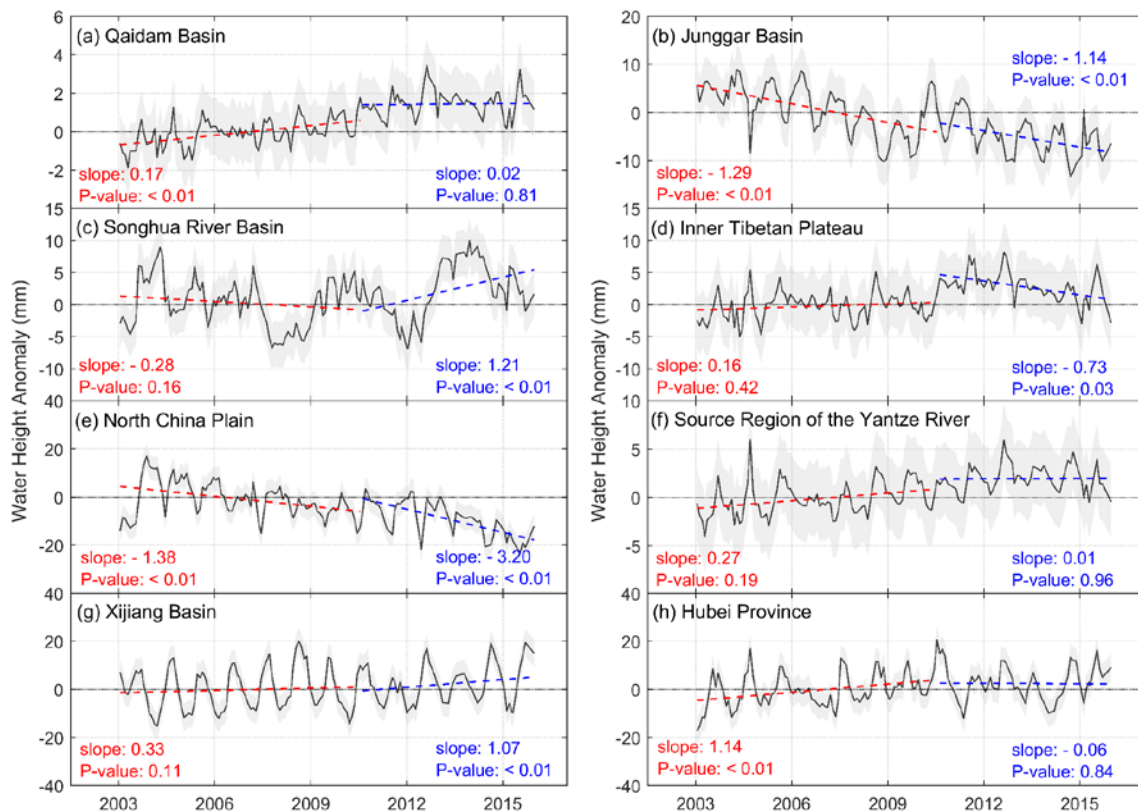

444

445

Qaidam Basin: Although the lakes in Qaidam Basin do not show uniform rising (Fig. 11a), nine of the 12 large lakes ( $> 100 \text{ km}^2$ ) are expanded. Therefore, the net SWS change is positive. However, the TWS change is very small during 2010-2016 (Figs. 11a and 12a); that is, other storage components (e.g. soil moisture storage, groundwater storage, snow, and ice, etc.) are decreasing at the similar rate as lake storage increasing. Thus, the SWS contribution is nearly 50% of TWS change. This is different from previous study where the contribution from lakes is estimated as 1.1% during 2003 - 2012 (Jiao et al., 2015).

Inner Tibetan Plateau: TWS change during 2010-2016 is different from that during 2003-2009 in Inner Tibetan Plateau, i.e. the increasing rate slowed down and even reversed (Fig. 12d). Contrary to TWS, SWS do not show a significant difference between these two periods ( $35.5$  vs  $50.4 \times 10^8 \text{ m}^3/\text{yr}$ ). It is interesting that TWS has been decreasing over the recent six years while

446 SWS has been increasing (Fig. 12d). This may be due to acceleration of glaciers/snowpack melting  
 447 or groundwater storage change. According to Xiang et al (2016), groundwater storage has been  
 448 increasing during the period 2003-2009. If we assume that groundwater is steady after 2009, glacial  
 449 melt must have contributed large storage losses ( $- 68.9 \times 10^8 \text{ m}^3/\text{yr}$ ). Besides, permafrost and talik  
 450 are developed in this region, which affect soil moisture and groundwater (Muskett and Romanovsky,  
 451 2011). However, it is beyond the scope of this study to explain this variation. Nevertheless, lake  
 452 storage is an important component affecting TWS variation in this region.

453 **Fig. 12.** Monthly changes of TWS for eight hotspots during two periods, i.e. Apr. 2002- Dec. 2009 and Jan.  
 454 2010- Feb. 2016  
 455

456 SRYR: Lakes in SRYR have risen at a mean rate of 0.1 m/yr recently. However, the surplus  
 457 of TWS is a bit smaller than SWS (Fig. 13). The case is the same as that in Qaidam Basin where  
 458 SWS was increasing while TWS was decreasing slightly (Fig. 13).

459 Inner TP, Qaidam Basin, and SRYR all show that SWS is increasing but TWS is not increasing  
 460 as much as SWS or even decreasing. It appears that groundwater storage in these areas is decreasing.

461 Actually, however, groundwater storage in this region is increasing during the period of 2003-2009  
462 and the change is attributed to increased runoff recharge from melt water/precipitation (Xiang et  
463 al., 2016).

464 Junggar Basin and North China Plain are two hotspots showing consistent decline in TWS  
465 during 2003-2016 (Figs. 11b, 11e and 12b, 12e), and in the recent six years, the declining rates are  
466  $-11.8 \pm 2.4$  and  $-20.0 \pm 3.5$  mm/yr, respectively. However, for the former, SWS is decreasing  
467 although the contribution is very small due to limited number of lakes in this region (Fig. 12); thus  
468 TWS change is dominated by groundwater variation considering the very dry climate. This decrease  
469 is mainly caused by excessive extraction for piedmont agriculture (Zhao et al., 2015). Similarly, in  
470 North China Plain, SWS changes affect TWS variation very slightly, and the TWS change is mainly  
471 attributed to the groundwater over-exploitation (Shi et al., 2011).

472 TWS in Songhua River Basin has experienced several abrupt changes which are plausibly  
473 related to extreme precipitation events and droughts. In this region, although lakes exhibit slight  
474 increasing trends (Fig. 11c), SWS is declining owing to the decline of large reservoirs (Fig. B1).  
475 The declining rate of reservoir storage ( $-1.4 \times 10^8$  m<sup>3</sup>/yr) is almost the same as SWS estimated from  
476 CryoSat-2, which indicates that SWS change is dominated by reservoir storage. Water storage  
477 depends directly on precipitation in this region. This is justified by the fact that TWS change has  
478 very similar pattern to precipitation and total water resource given in the water resources *Bulletin*  
479 (<http://www.slwr.gov.cn/>) (Fig. B1). TWS from GRACE and total water resource from *Bulletin*  
480 both show a sharp peak in 2013, which is caused by the extreme precipitation in the summer of  
481 2013. This is verified by Wang et al. (2015) who found a considerable increase in groundwater  
482 tables after the flood event. One interesting finding is that GRACE disagrees with the total water  
483 resource *Bulletin* record and precipitation for 2004 (Fig. B1).

484 In the south China, Xijiang Basin, main part of Pearl River (c.a. 78%) shows a slight increase  
485 in TWS, especially during 2010-2016 at a rate of 8.6 mm/yr (Fig. 12g). The estimated SWS

486 changes contribute to the increasing trend. On the contrary, Hubei Province, exhibits TWS decrease  
 487 and SWS increase (Fig. 13). Due to human activities, lakes in Hubei have sharply decreased both  
 488 in area and size during the past century (Zhang et al., 2009). However, lake storage has a small  
 489 effect on TWS compared with reservoirs, such as Three Gorges Reservoir ( $393 \times 10^8 \text{ m}^3$ ) and  
 490 Huanglongtan Reservoir (capacity  $12.3 \times 10^8 \text{ m}^3$ ). Overall, SWS is increasing and playing a positive  
 491 role in maintaining the TWS balance.

492  
 493 **Fig. 13.** TWS and SWS changes in eight hotspots during 2010-2016

494 **5. Summary and Conclusions**

495 In this study, the value of CryoSat-2 for monitoring surface water at a national scale for China  
 496 is exploited. We (a) construct the water level time series of lakes and reservoirs in China at a  
 497 national scale; (b) assess the spatial variation of surface water bodies; (c) validate the performance  
 498 of CryoSat-2 over 6 rivers; (d) estimate the surface water storage changes and evaluated its impact  
 499 on terrestrial water storage change.

500 Water level variations of 1163 lakes and reservoirs across China during 2010 and 2016 are  
 501 investigated with CryoSat-2 data. The results show that 288 water bodies show a significant

502 changing trend. Water level of lakes varies regionally, specifically, water bodies in Junggar Basin  
503 and Huai River Basin show a dominant declining trend. In contrast, those in Songnen Plain, lower  
504 Yangtze River basin, and north Tibetan Plateau show a marked rising trend. And the rising rate is  
505 far beyond of the declining rate in the north Tibetan Plateau.

506 Six large rivers are investigated and the CryoSat-2 derived water level generally agree well  
507 with in-situ measurements, especially for the Yellow River, Songhua River, and Heilongjiang-  
508 Amur River with RMSE values ranging from 0.22 to 0.6 m, 0.22 to 0.5 m, and 0.24 to 0.35 m,  
509 respectively. Comparatively, data quality over the Yangtze River and Pearl River is poor because  
510 of the widely-distributed ships and the rugged topography.

511 The estimated surface water storage changes in Tibetan Plateau, and Inner Mongolia and  
512 Xinjiang are  $35.5$  and  $25.9 \times 10^8$  m<sup>3</sup>/yr, respectively. On the contrary, Northeast Plain and Mountain  
513 zone exhibited a decline. Surface water storage is one important component to TWS change, and  
514 plays an non-negligible role in TWS change, for instance, in the Tibetan Plateau and the Qaidam  
515 basin.

516 CryoSat-2 has great value for monitoring surface water bodies. It outperforms previous radar  
517 altimetry missions in terms of spatial coverage and resolution (SAR and SARIn modes). Besides,  
518 the performance of LRM is comparable to SAR and SARIn modes in terms of RMSE against in-  
519 situ data. However, new method is required to derive valid water levels for heavily navigated rivers  
520 such as the Yangtze and Pearl Rivers in China.

## 521 **Acknowledgements**

522 We wish to thank Dr. Jiayu Liu for supporting hydrometric data collection. We thank Raphael  
523 Schneider for many helpful discussions and input. ESA and NASA/JPL are acknowledged for  
524 providing CryoSat-2 data and GRACE data. We also want to thank Editor Aida Alvera-Azcarate

525 and the three anonymous reviewers for their valuable comments. The first author is funded by China  
526 Scholarship Council, which is greatly acknowledged.
