ABSTRACT

Accurate characterization of near-surface soil water content is vital for guiding agricultural management decisions and for reducing the potential negative environmental impacts of agriculture. Characterizing the near-surface soil water content can be difficult, as this parameter is often both spatially and temporally variable, and obtaining sufficient measurements to describe the heterogeneity can be prohibitively expensive. Understanding the spatial correlation of near-surface soil water content can help optimize data acquisition and improve understanding of the processes controlling soil water content at the field scale. In this study, ground penetrating radar (GPR) methods were used to characterize the spatial correlation of water content in a three acre field as a function of sampling depth, season, vegetation, and soil texture. GPR data were acquired with 450 MHz and 900 MHz antennas, and measurements of the GPR groundwave were used to estimate soil water content at four different times. Additional water content estimates were obtained using time domain reflectometry measurements, and soil texture measurements were also acquired. Variograms were calculated for each set of measurements, and comparison of these variograms showed that the horizontal spatial correlation was greater for deeper water content measurements than for shallower measurements. Precipitation and irrigation were both shown to increase the spatial variability of water content, while shallowly-rooted vegetation decreased the variability. Comparison of the variograms of water content and soil texture showed that soil texture generally had greater small-scale spatial correlation than water content, and that the variability of water content in deeper soil layers was more closely correlated to soil texture than were shallower water content measurements. Lastly, cross-variograms of soil texture and water content were calculated, and co-kriging of water content estimates and soil texture measurements showed that geophysically-derived estimates of soil water content could be used to improve spatial estimation of soil texture.

Introduction

Accurate estimates of soil water content are important for maximizing crop yield, efficiently applying irrigation, and minimizing the potential environmental impacts of farming. Crop yield is partially influenced by soil water content; crop yield will decrease if the soil water content is below a crop-specific range (van Wijk, 1988; Williams et al., 1990; Dry et al., 2000). Crop yield is also affected by fertilization, and the soil must have a favorable water content to allow plants to fully absorb the nutrients in fertilizers and to achieve high nutrient efficiency (Fageria, 1992). Thus, crop yield can be maximized and nutrients can be applied most efficiently when the soil water content is well characterized across a field. In addition to crop yield, the quality

of some crops, such as wine grapes, partially depends on soil water content, so this parameter is regulated to ensure that it remains in the appropriate range. Monitoring of the soil water content is also needed to ensure efficient use of irrigation water, where the scheduling and volume of irrigation must be optimized to appropriately allocate limited water supplies. Finally, knowledge of the soil water content can help farmers reduce the potential negative environmental impacts of agriculture such as salinization or groundwater degradation (when excess irrigation carries fertilizers, pesticides, and salts into the saturated zone) (Rangeley, 1987).

The spatial and temporal variability of the near-surface soil water content has been well documented at a range of scales and using several different methods of measurement. Measurements of water content have been acquired at scales ranging from a single field to several hectares using gravimetric sampling, time domain reflectometry (TDR), capacitance sensors, and neutron probes (Bouten *et al.*, 1992; Grayson *et al.*, 1997; Famiglietti *et al.*, 1998; Western *et al.*, 1998; Western *et al.*, 1999; Petrone *et al.*, 2004; De Lannoy *et al.*, 2006). Some studies have used estimates of soil water content from remote sensing methods to explore water content variability on a larger scale (Vischel *et al.*, 2008), while other researchers have used data simultaneously acquired from ground-based and remote sensing techniques (Famiglietti *et al.*, 1999; Bosch *et al.*, 2006; Famiglietti *et al.*, 2008). Vertical measurements of soil water content have also been acquired to observe the changes in water content variability with depth (Hupet and Vanclooster, 2002; Bosch *et al.*, 2006; De Lannoy *et al.*, 2006). Collectively, the many studies of soil water content variability have shown that near-surface soil moisture is a function of spatially and sometimes temporally variable properties such as soil texture, soil depth, topography, vegetation, precipitation, evapotranspiration, and agricultural practices.

The variability of soil water content makes accurate characterization of this parameter difficult at large scales (Western and Blöschl, 1999). Conventional techniques for monitoring the soil water content (*i.e.*, gravimetric sampling, neutron probes, TDR, capacitance probes, and tensiometers) are point measurements, and it is often prohibitively expensive to collect sufficient measurements to accurately image the water content at large scales (Hillel, 1997; Vischel *et al.*, 2008). An alternative to conventional techniques is microwave remote sensing methods, which can rapidly acquire estimates of water content in the uppermost 0–5 cm of the subsurface over large areas (Famiglietti *et al.*, 2008). However, remote sensing techniques cannot provide water content estimates if significant vegetation is

Figure 1. The GPR groundwave travels in the shallow subsurface between the transmitting antenna (TX) and receiving antenna (RX). S is the separation distance between the GPR antennas, while v_1 is the velocity of the uppermost soil layer.

present (Famiglietti *et al.*, 1999), and the resolution of remote sensing estimates is typically between tens of meters to 50 km (Vischel *et al.*, 2008). Also, remote sensing data often require ground truth measurements of water content for calibration and validation (Famiglietti *et al.*, 1999).

An alternative to both conventional point measurement techniques and remote sensing is soil water content estimation using non-invasive geophysical techniques such as ground penetrating radar (GPR). GPR is a high-frequency electromagnetic technique that has been used to acquire accurate estimates of soil water content at a variety of scales (Huisman *et al.*, 2003). GPR groundwaves are especially useful for rapidly acquiring very high-resolution estimates of soil water content in the shallow subsurface over large areas (Lesmes *et al.*, 1999; Huisman *et al.*, 2001; Hubbard *et al.*, 2002; Galagedara *et al.*, 2003; Grote *et al.*, 2003; Huisman *et al.*, 2003; Galagedara *et al.*, 2004; Galagedara *et al.*, 2005a; Hubbard *et al.*, 2006). As shown in Fig. 1, groundwaves are boundary waves that are confined to the air-ground interface and travel directly between the transmitting and receiving antennas in the near subsurface (van Overmeeren *et al.*, 1997; Berktold *et al.*, 1998). The GPR groundwave travels at the velocity of an electromagnetic wave in the near-surface soil, and the groundwave velocity can be determined by measuring the separation distance between the transmitting and receiving antennas and recording the time needed for the groundwave to travel between the antennas (Huisman *et al.*, 2003; Galagedera *et al.*, 2005a; Hubbard *et al.*, 2006). The electromagnetic velocity is primarily influenced by the soil water content (Davis and Annan, 1989), and the velocity can be related

to the soil water content using either a site-specific petrophysical relationship or one of several petrophysical relationships available in the literature (Topp *et al.*, 1980; Roth *et al.*, 1990).

GPR groundwave methods can be used to collect many more water content estimates than could be obtained using conventional point measurement techniques, because GPR data can be acquired with a sampling increment as small as 1 cm, although a sampling increment of ~10 cm is more practical if data are to be acquired quickly. The large data sets generated using GPR can be used to more accurately characterize the soil water content distribution and to analyze the water content variability with unprecedentedly high resolution. (The resolution of data sets acquired with conventional point measurement techniques varies with the sampling increment, but few studies have been performed using point measurement techniques with a sampling increment of less than 5 m.) The improved statistical characterization possible with these large data sets can be used as input into stochastic hydrological and climate models, and could be used to improve water content characterization by increasing the accuracy of interpolated estimates between sampling points, to guide data acquisition campaigns for optimal sample locations, and to better understand the processes that influence near-surface soil water content. This research uses large data sets of soil water content derived from GPR groundwave data to explore the spatial correlation of soil water content as a function of sampling depth, season, vegetation, and soil texture.

Data Acquisition and Water Content Estimation

Data for this analysis were acquired at a three acre field within the Robert Mondavi vineyard in Napa Valley, California. The soils at this site range from sandy loam to clay loam and are primarily flood plain and alluvial fan deposits. Topographic variations across the site are negligible, and the water table is 3 to 4 m beneath the ground surface. Grapevines are planted across the field with a spacing of 1.2 m between each plant both perpendicular and parallel to the grapevine trellises. Winters are typically cool and moist, and summers are hot and dry, with very little precipitation between May and October. Irrigation is applied evenly across the field using a drip irrigation system during the summer months; the typical irrigation rate is 2.9 L/grapevine/day.

Near-surface soil water content estimates were acquired across the field site using GPR groundwave techniques in the common-offset mode, where the antennas were kept a set distance apart and moved in parallel along a traverse. The time needed for the

Figure 2. Site map showing GPR traverses (vertical lines) and time domain reflectometry measurement locations overlain on the normalized difference vegetation index data acquired in July 2000.

groundwave to travel from the transmitting to the receiving antenna was determined for each measurement, and these travel-time data were used to calculate electromagnetic velocity and then the water content at each measurement location. A detailed description of the data acquisition, interpretation, and validation procedures is given in Grote *et al.*, 2003. At this site, estimates of volumetric water content calculated from GPR groundwave data had a root mean squared error (RMSE) of 0.02 when compared to volumetric water content estimates obtained from gravimetric measurements, so the water content estimates derived from GPR data are assumed to be sufficiently accurate to support geostatistical analysis.

GPR groundwave data were acquired across the field site at four times, in May, August, and September of 2001 and in January of 2002. Data were acquired using a Sensors and Software PulseEkko 1000 GPR system with 450 MHz and 900 MHz antennas. Traverses were acquired across the field parallel to the grapevine trellises at 6 m intervals (each fifth row), and measurements were collected at 10-cm intervals along each traverse, for a total of approximately 20,000 water content estimates in each data set. Figure 2 shows the locations of the GPR traverses overlain on a site map of normalized difference vegetation index (NDVI) data, where darker and lighter NDVI colors indicate areas of weaker and stronger vegetation, respectively. (The variability in NDVI data was one of the factors used in selecting this field site, as a site with significant heterogeneity was desired.) An example of the soil water content distribution from one data set (900 MHz GPR data collected in Sept. 2001) is shown in Fig. 3. Each vertical "stripe" in this figure corresponds to a GPR
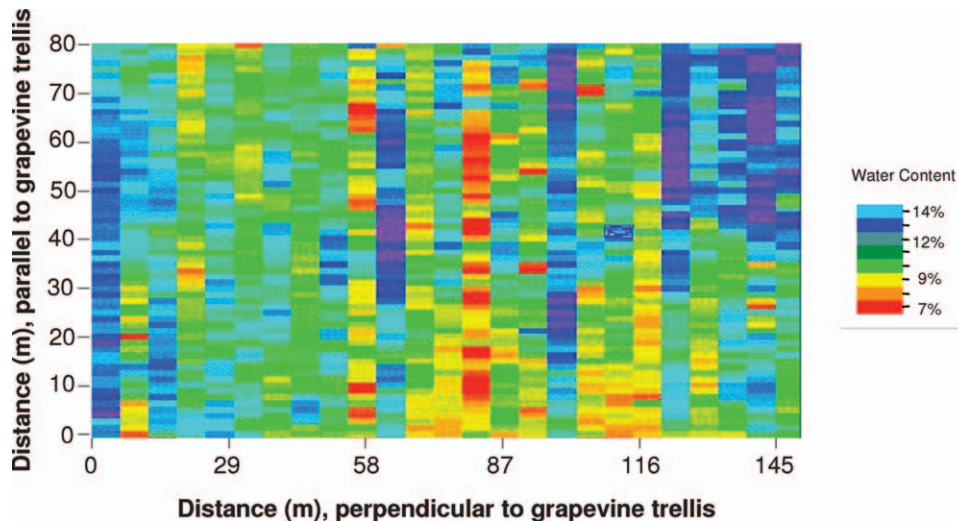

Figure 3. Water content estimates acquired over the three acre field site in Sept. 2001 using 900 MHz GPR groundwave data. Each vertical "stripe" corresponds to a GPR traverse, where a traverse parallel to the grapevine trellis was collected every 6 m with sampling every 10 cm along the traverse.

traverse; adjacent traverses show similar water content values in some areas of the field, but adjacent traverses can also have significantly different water contents in other portions of the field. The differences in water content observed in some adjacent traverses are related to near-surface vegetation, as is discussed in the next section. Although the absolute values of water content varied as a function of season and GPR frequency, and the influence of near-surface vegetation also varied with these parameters, the general pattern of water content observed in Fig. 3 (wettest in the northeast corner and western edge, driest near the south-central portion of the field) remained constant for all data sets. To supplement

the GPR-derived estimates of water content, 91 measurements of water content from TDR probes were obtained in an evenly spaced grid across the site in January 2002 (Fig. 2). TDR measurements were acquired using a SoilMoisture Trase System with two 15 cm waveguides placed 5 cm apart. In addition to the water content estimates obtained with GPR and TDR, 47 soil texture measurements (percent sand, silt, and clay) were acquired in the shallow subsurface (top 20 cm) and were used to characterize the soil texture distribution across the site. Figure 4 shows the distribution of soil texture, quantified as the percent sand, across the site.

X = soil texture measurement

Evaluation of Water Content Variability

The spatial correlations of soil water content from GPR and TDR data were evaluated by calculating experimental semi-variograms for each data set using GSLIB software (Deutsch and Journel, 1998). The experimental semi-variogram (γ) relates the variability of measurements to the distance between them and is calculated as follows (Rubin, 2003):

$$\gamma(h) = \frac{1}{2N(h)} \sum_{i=1}^{N(h)} [v(x_i) - v(x_i + h)]^2, \qquad (1)$$

where h is the distance between two measurements (the lag distance), $N(h)$ is the number of pairs of measurements separated by a distance h, and $v(x_i)$ is a measurement taken at location x_i. Although Eq. (1) is correctly referred to as the semi-variogram, common usage often refers to it simply as the variogram. This common terminology will be adopted for the remainder of this discussion. The main parameters used to describe a variogram are the sill, the correlation length (or range), the nugget, and the variogram shape (or model type). The sill is the variogram value (γ) at which the variogram plateaus (γ ceases to increase with increasing h). The correlation length describes the spatial continuity of the property being studied. The correlation length denotes the average distance over which correlations can be observed, while the range is the maximum distance over which correlations are observed. The correlation length is usually a function of the range and varies for different variogram models. The nugget measures the very small-scale variability of the property, or the variability between measurements acquired at very small lags. The nugget is often a function of both the property being measured and the minimum distance between measurements. The variogram model describes the shape of the variogram as the variability increases from the nugget to the sill. Properties with more spatial correlation at smaller lags are often better described by a Gaussian variogram model, while exponential or spherical variogram models better describe properties with less correlation at small lags. Variogram models can be linearly combined to describe multiple scales of correlation.

For the water content data sets acquired at this site, variogram models were fit to the experimental variograms using least squares regression techniques (Gambolati and Galeati, 1987), and similar variogram models were found to best describe the experimental variograms for each data set. The function that best characterized the water content variability for most of the data sets was a linear combination of an exponential model to describe the variability at small lags (less than

~10 m) and a Gaussian model to describe the larger-scale variability (Appendix A). Since the variogram model type did not change between different data sets, the primary focus of this paper is on differences observed in the experimental variograms as a function of sampling depth, season, vegetative cover, and soil texture.

Water Content Variability and Sampling Depth

While the lateral path of the GPR groundwave is well defined, the groundwave sampling depth is currently uncertain (Huisman *et al.*, 2003). Several researchers have used analytical models to estimate the groundwave sampling depth (Du, 1996; van Overmeeren *et al.*, 1997; Sperl, 1999; Galagedara *et al.*, 2005b), but these models vary significantly in their estimations (Fig. 5). All of the models shown in Fig. 5 are based upon relationships that correlate wavelength (λ) and the predicted sampling depth. For example, Galagedara *et al.* (2005b) estimates the sampling depth (z) as:

$$z = 0.6015\lambda + 0.0468. \qquad (2)$$

The wavelength equals the electromagnetic wave velocity divided by the central frequency, so the sampling depth is predicted to increase with increasing velocity and to decrease with increasing frequency. The wavelength varies with soil moisture, since the electromagnetic velocity is lower in wetter soils. Thus, the sampling depth is estimated to be less in wet soil than in relatively dry soil; if significant variations in water content are observed along a traverse, the sampling depths may vary along the traverse as well. Additionally, the central frequency of the GPR signal may change somewhat with soil moisture. GPR antennas emit and record energy

over a broad range of frequencies above and below the central frequency, and the frequencies recorded may decrease in wetter soils (higher frequency energy is more attenuated in wetter soil). Thus, the wavelength may not change as much in wetter soils as would be expected if the frequency remained constant (as assumed in Fig. 5).

Experimental results from several researchers have indicated that the sampling depth is a function of GPR frequency (Du and Rummel, 1994; Chanzy et al., 1996; Hubbard et al., 2002; Grote et al., 2003), but the exact relationship between frequency and sampling depth is again unclear. Comparison of the sampling depths estimated from experimental results with the sampling depths predicted using the analytical models shows that no single model describes the experimental data well, so the most accurate analytical model is still uncertain. If the models predicting the smallest sampling depth (Sperl, 1999) and the largest sampling depth (full waveform approximation (Du, 1996)) are considered for the 900 MHz antennas for the driest data set (August, where average velocity for 900 MHz data is ~0.15 m/ns), the sampling depth estimates range from 6 cm to 16 cm. For the 450 MHz data from August, the range of predicted sampling depths is 8 cm to 27 cm. For the wettest data set (January, where the average velocity for the 900 MHz is ~0.08 m/ns), the predicted sampling depth ranges from 4 cm to 9 cm for the 900 MHz data and from 6 cm to 18 cm for the 450 MHz data. The actual sampling depth probably falls within the range of predicted depths, but a comparison of gravimetric water content measurements acquired simultaneously with GPR estimates of water content at different times at this site suggests that the deeper sampling depths may be more likely, especially for the 900 MHz data (Grote et al., 2003). Gravimetric water content measurements were acquired simultaneously with the GPR data over depth intervals of 0 to 10 cm, 10 to 20 cm, and 0 to 20 cm. For both the 450 and 900 MHz data, the best correlation between GPR-derived and gravimetric estimates of soil water content occurred in the 0 to 20 cm interval, and the least correlation was observed for the 10 to 20 cm interval. These correlations suggest that the sampling depth is likely greater than 10 cm for both the 900 MHz and 450 MHz data.

A comparison of water content estimates acquired with the 450 and 900 MHz antennas showed that the water content estimates varied with GPR frequency; these differences are attributed to the different penetration depths of these frequencies. Measurements of water content obtained with the 900 MHz antennas had lower mean water contents during the drier months (Aug. and Sept.) than estimates from the 450 MHz data, but the mean water content was approximately equal for both frequencies during the Jan. campaign, when the soil was

Figure 6. a) Experimental variograms and variogram models for water content estimates from GPR and TDR data acquired in January 2002. b) Normalized experimental variograms of water content estimates from GPR and TDR data acquired in January 2002. Normalization was performed by dividing the variogram value by the variance of the data set.

near saturation. A smaller-scale study of water content measurements obtained using GPR and gravimetric techniques in Nov. 2001 showed an opposite trend when data were acquired immediately after precipitation; these data showed higher water content values in the 900 MHz GPR data than in the 450 MHz data, and the gravimetric measurements also showed a decrease in saturation with increasing depth (Grote et al., 2003).

Geostatistical analysis of water content estimates acquired with multiple GPR frequencies can provide information on how near-surface soil water content variability changes with depth. For each of the data sets acquired in this study, the shallower 900 MHz data showed less correlation than the deeper 450 MHz data; the 900 MHz data consistently had higher standard deviations, and the experimental variograms had higher sills (Figs. 6 and 7). Also, the 900 MHz variograms typically had shorter ranges than variograms calculated from 450 MHz data (Fig. 7 and Table 2). The higher variability of the 900 MHz data may reflect the spatial variability of surface processes such as precipitation and
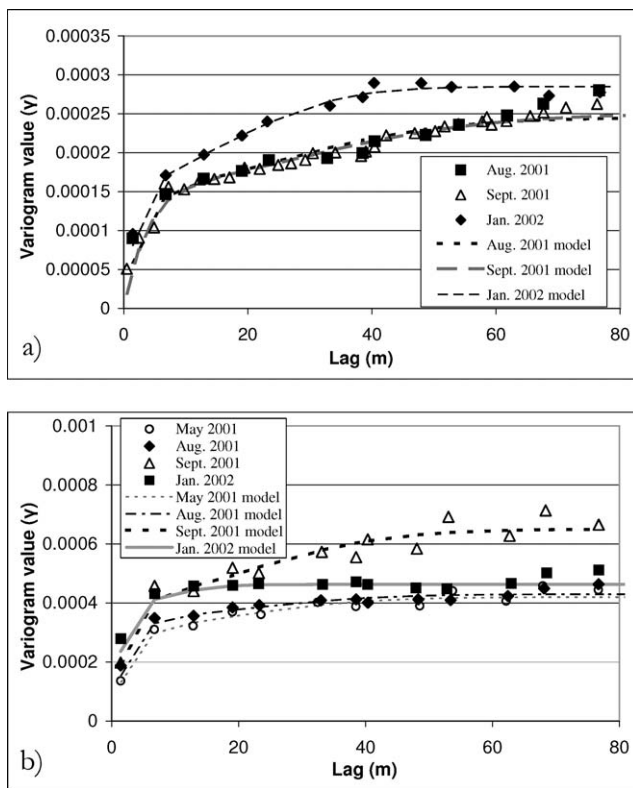

Figure 7. a) Experimental variograms and variogram models for water content estimates from 450 MHz GPR data. b) Experimental variograms and variogram models for water content estimates from 900 MHz GPR data.

irrigation, while lateral redistribution of soil water (largely controlled by soil texture at this site) may reduce the effects of these processes on the deeper water content measurements. The water content in deeper soil is also less affected by diurnal variations in temperature and evapotranspiration.

Although the shallower sampling depth of the 900 MHz data may explain the higher variability observed in this data set, it is important to note that the sample volume for the 900 MHz data is smaller than that of the 450 MHz data. The sample volume is approximately the antenna separation multiplied by the sampling depth, and the antenna separations for the 900 MHz and 450 MHz data are 17 cm and 25 cm, respectively. Thus, the 900 MHz antennas have a smaller lateral sampling distance as well as a probable shallower sampling depth. The larger sample volume of the 450 MHz data is expected to result in reduced variability, so the difference in variability between the two frequencies could be caused by the different sample volumes rather than by different sampling depths. Although the sample volume probably influences the water content variability, analysis of the water content estimates from TDR data acquired in Jan. 2002 indicate

that sampling depth probably has a greater impact on water content variability than does sample volume at this site. The TDR probes are 15 cm long, so the sampling depth of the TDR is similar to the estimated sampling depth of the 450 MHz GPR data. However, the sample volume for the TDR probes is much less, as the two TDR prongs are separated by only 5 cm, and the area between and immediately adjacent to the prongs has the greatest influence on the TDR response (Topp *et al.*, 1996). Estimates of soil water content obtained from the TDR data and the 450 MHz GPR data are very similar, and the experimental variogram of water content estimated from TDR data shows variability between that of the 450 MHz and 900 MHz GPR data, as shown in Fig. 6(a). If each of these variograms is normalized by the variance of the water content estimates, the variograms from the 450 MHz GPR and TDR data are very similar, while the variogram from the 900 MHz data shows less spatial correlation (Fig. 6(b)). Since the TDR data have a sampling depth that is similar to the estimated sampling depth of the 450 MHz data, these results indicate that variability decreases with depth regardless of sample volume.

The decrease in variability with depth observed in this experiment was similar to the findings of other researchers. Hupet and Vanclooster (2002) found that total variability decreased with depth, with the greatest variability occurring in their shallowest sampling interval (0 to 20 cm). They calculated variograms from water content measurements acquired at different times and depths, and they found that for soil water content measured in intervals from the surface to 75-cm depth, the variograms showed no spatial correlation (pure nugget model). Variograms for water content measurements at 100-cm and 125-cm depth showed the expected trend of the variogram values increasing with lag. The authors attributed the lack of spatial correlation in the shallower soils to the effects of vegetation at the site, where vegetation was believed to be the primary factor controlling soil moisture patterns. The authors noted that spatial correlations of shallow water content might exist at smaller lags than those investigated in this project (minimum lag was ~15 m). In another study, Bosch *et al.* (2006) used much shallower samples, but also found that the total variability of the soil at 0 to 3 cm depth was greater than that at 3 to 6 cm depth. These authors attributed the increased variability at shallow depths to changes in soil texture and microtopography. In contrast, De Lannoy *et al.* (2006) collected deeper water content measurements (at approximately 30 cm intervals to a depth of 180 cm) and found that spatial variability generally increased with depth; the changes in variability with depth were attributed to changes in the hydraulic properties of soils

Table 1. Means and standard deviations of volumetric water content for estimates derived from 450 MHz and 900 MHz GPR data in rows with and without crop cover for each data campaign. 450 MHz data were not acquired in May 2001.

Campaign	Central frequency (MHz)	Mean water content in rows with crop cover	Mean water content in rows without crop cover	Standard deviation of water content in rows with crop cover	Standard deviation of water content in rows without crop cover

across the site. The deeper measurements acquired by De Lannoy et al. (2006) might have been less influenced by surficial processes than the shallower measurements acquired in other studies.

Water Content Variability and Seasonal Water Content Fluctuations

Many studies have shown that water content variability changes as a function of the mean soil water content, although a clear relationship between the variability and the mean has not been defined. In some studies, the spatial variability of near-surface water content was found to be greater in drier soils (Famiglietti et al., 1999; Hupet and Vanclooster, 2002; Bosch et al., 2006), while other studies showed variability to be greater in wetter soils (Bell et al., 1980; Famiglietti et al., 1998). De Lannoy et al. (2006) observed that the relationship between soil water content variability and the mean water content changed with depth, where shallower measurements (uppermost 10 cm) exhibited greater spatial variability at higher moisture contents, while deeper measurements (50 cm and below) showed variability increasing at lower moisture contents. Owe et al. (1982) and Famiglietti et al. (2008) observed maximum near-surface water content variability in moderately wet soils, with decreased variability in both dry and very wet soils. Peters-Lidard and Pan (2002) suggested that these observations can be explained by soil texture heterogeneity, where soil moisture variability increases as the soil dries out if the mean soil water content is between the field capacity of the soil and full saturation (the soil is initially very wet), but the variability will decrease with drying if the water content is initially less than the field capacity of the soil.

Other studies of water content variability have considered variograms calculated using water content measurements in wet and in dry soils. Western et al. (1998) found that less correlation was observed in wet soil (higher sills and correlation lengths of 35 m to 50 m)

than in drier soil (lower sills and correlation lengths of 50 m to 60 m). The changes in the variograms with mean soil moisture are attributed to lateral redistribution of water during different seasons. When the soil was dry, the soil moisture distribution was relatively uniform (lower sill), because the hydraulic properties of the soil were limiting evapotranspiration (soil properties were assumed to be the main factor controlling soil moisture patterns), and lateral redistribution of water was less significant. When the soil was wet, lateral redistribution of water content caused by topographic variations contributed to higher variability. In another study, De Lannoy et al. (2006) observed variability that partially follows the pattern described by Western et al. (1998). De Lannoy et al. observed that for shallow water content measurements (uppermost 10 cm), the variogram range and sill both increase with increasing soil moisture (range varies from 200 m to over 300 m) and decrease during dry periods. When the soil was very dry, the variogram shape was best fit by a pure nugget model, suggesting that either there was very little spatial structure of water content under these conditions or that the measurement error was greater than the spatial variability of water content.

The results of this experiment are different from those in both of the variogram studies described above. In this study, GPR data acquired at four different times were used to calculate variograms of soil water content. The May (when only 900 MHz data were collected) and Aug. data sets were acquired during the dry season, and no irrigation or precipitation had occurred for at least a week prior to data acquisition; the soil water content was quite low during these data acquisition campaigns (Table 1). The Sept. data set was acquired two days after drip irrigation was applied at the base of each grapevine, creating a wet zone in the soil immediately surrounding the vine. January data were acquired during the wet winter, and light precipitation occurred the day prior to data acquisition. The experimental

Table 2. Variogram model parameters for each campaign. In each entry, a linear combination of an exponential model (E) and Gaussian model (G) was used. The first parameter listed after the letter representing the model type is the sill for that model, while the second parameter is the correlation length.

variograms of water content for each of these data acquisition campaigns are shown in Fig. 7(a) for the 450 MHz data and Fig. 7(b) for the 900 MHz data. For the 450 MHz data, the variograms for the Aug. and Sept. data sets are very similar, indicating that the spatial correlation of water content may be temporally stable in dry soils. The sills for the drier campaigns (Aug. and Sept.) are not reached in the experimental variograms, but the variances of all three data sets are similar. The estimated ranges of the variograms calculated from the Aug. and Sept. data sets (~100 m) are considerably higher than the range of the variogram calculated from wet soil in Jan. (~70 m). The relatively small range observed in the wetter soil may reflect different rates of evaporation or infiltration as a function of soil texture or may indicate variations in porosity. (During the dry season, the soil may have already lost enough moisture that evapotranspiration was limited, and GPR techniques are not well suited to detect variations in porosity in more uniformly dry soils.) Factors other than soil texture are less likely to be significant at this site, since topography is negligible and agricultural practices are uniform across the site.

A slightly different pattern of variability is observed in the water content estimates obtained from the 900 MHz GPR data. For these data, the estimates obtained in Sept. had the highest sill and the longest range (~90 m). The high sill observed in Sept. may be caused by drip irrigation, which created wet zones immediately adjacent to the vines and therefore in-

creased the total water content heterogeneity. The effects of drip irrigation on near-surface water content appear to be very shallow, since the 900 MHz water content estimates were significantly influenced by the additional moisture, but the deeper 450 MHz estimates were not. Except for the unusually high variability of the 900 MHz Sept. data, the 450 MHz and 900 MHz data show similar trends for spatial correlation. The variograms from the 900 MHz data acquired in Jan. again have similar sills to variograms calculated from May and Aug. data, and the range of the Jan. data (~30 m) is less than the ranges of the drier data sets (~80 m). A comparison of the 900 MHz variograms from Sept. and Jan. indicates that both irrigation and precipitation increase water content variability, but the variability caused by precipitation that is relatively evenly distributed across the field is less than the variability caused by irrigation applied immediately adjacent to each vine.

If the seasonal variability observed at the Mondavi site is interpreted using the explanation of Peters-Lidard and Pan (2002), the relatively high variability of the wet Jan. soil could indicate that the soil was between the field capacity and full saturation, but closer to field capacity. This seems likely, as the mean water content in Jan. was high. The explanation also seems to describe the drier data sets (May and Aug.), since it seems likely that the mean water contents at these times were already below field capacity, and thus lower variability would be expected with increased drying.

Water Content Variability and Shallowly-rooted Vegetation

The effects of transpiration on mean soil water content are well documented, but the influence of vegetation on water content variability is not clear. Hupet and Vanclooster (2002) calculated variograms from water content measurements acquired in a field of maize. Analysis of these variograms showed little spatial correlation of water content at shallow depths, and the authors attributed the high spatial variability of shallow water content to the spatially variable vegetation, and thus variable root water uptake and evapotranspiration across the field. De Lannoy *et al.* (2006) also noted that the high water content variability they observed in wet, shallow soils may be partially caused by vegetation which causes variable interception of precipitation. Wilson *et al.* (2004) noted that vegetation was probably responsible for some of the water content heterogeneity that was not explained by topographic effects. Or and Rubin (1993) performed a modeling study that showed that the spatial distribution of water content was greatly influenced by the behavior of shallow vegetation, even at depths extending below the root zone.

At the Mondavi site, near-surface vegetation appears to affect both the mean and the variability of soil water content. The water content distribution in Fig. 3 exhibits a striped pattern, where adjacent traverses sometimes have significantly different water contents. The traverses were separated by 6 m, and considerable differences in water content between adjacent traverses caused by soil heterogeneity over this distance is possible, but would not explain the striped pattern observed in the water content data. Instead, the striped pattern probably reflects the water usage of shallowly-rooted vegetation. At this site, "crop cover" of zorrow fescue grass was planted in every other row to reduce erosion and to decrease the near-surface soil water content to the optimal level for wine-grape production. The crop cover emerges in January and begins to go dormant in May. Although weeds and wild grasses grow in the rows without crop cover, the effects of the crop cover on near-surface water content are much more significant than the effects of incidental vegetation. The rows with crop cover had slightly lower mean water content values than the rows without crop cover during the dry months, but crop cover did not appear to significantly affect the soil water content when the near-surface soil was close to saturation in Jan. (Table 1). The influence of crop cover on near-surface water content also appears to be a function of depth, since rows with and without crop cover show greater differences in water content for the shallower 900 MHz data than for the deeper 450 MHz data.

The effects of crop cover on the near-surface water content variability at this site seem to be different from the effects of vegetation observed by other researchers. Table 1 shows that the standard deviations of water content in rows with crop cover were less than those in rows without crop cover for all data sets except the 900 MHz data collected in Jan. To explore the influence of crop cover on the spatial correlation of water content, separate experimental variograms were calculated for rows with and without crop cover. Experimental variograms for data acquired using both GPR frequencies in Sept. 2001 in rows with and without crop cover are shown Fig. 8. These variograms show that rows with crop cover had lower sills than rows without crop cover, but that crop cover affected the range differently for the 900 MHz and 450 MHz data. For the 900 MHz data, the ranges with and without crop cover were 75 and 100 m, respectively, while the 450 MHz data showed a range of 95 m with crop cover and 60 m without. These variograms also indicate that the effects of crop cover are most significant on very shallow water content measurements (900 MHz), as the differences between variograms calculated from rows with and without crop cover are much greater for the 900 MHz data than for the deeper 450 MHz data. Inspection of variograms calculated with and without crop cover for the other data sets shows that crop cover has the greatest effect on water content variability when the soil is dry and the fescue roots may be actively removing soil water from wetter zones, causing the near-surface soil to be more uniformly dry across the field. Data acquired in Jan. under nearly saturated conditions when the crop cover was emerging show only minor differences between rows with and without crop cover (Fig. 9), but water content variability is slightly higher in rows with crop cover for this data set. The slight increase in variability in rows with crop cover may be caused by variable transpiration of the newly emergent crop cover when the soil water content is high or by changes in water content caused by alteration of the soil structure as a result of new root growth.

The effects of vegetation on soil water content variability are probably determined by the state of vegetation and the mean soil moisture. For this site, even fairly dormant vegetation decreased the water content variability in shallow, dry soils. However, variability was slightly increased when the soil was wet and the vegetation was actively undergoing transpiration. This latter state may be more similar to the experiments performed by other researchers (Hupet and Vanclooster, 2002; De Lannoy *et al.*, 2006) who attributed high water content variability to vegetation.

Water Content Variability and Soil Texture

Several researchers have shown that soil water content variability is partially controlled by the variability of effective soil properties (Or and Rubin, 1993;
Figure 8. Experimental variograms of water content estimates from 450 MHz and 900 MHz GPR data acquired in Sept. 2001 for rows with and without crop cover.

Rubin and Or, 1993; Entekhabi and Rodriguez-Iturbe, 1994; Hupet and Vanclooster, 2002; Peters-Lidard and Pan, 2002; Ryu and Famiglietti, 2005; Teuling and Troch, 2005; De Lannoy et al., 2006; Famiglietti et al., 2008), but few studies have quantified the variability of soil texture. In this study, the influence of soil texture on near-surface soil water content variability was investigated by comparing experimental variograms for both

parameters. Forty-seven soil samples were collected across the field, and the percents of sand, silt, and clay were determined for each sample. To analyze the soil texture variability, the soil texture was quantified as the percent sand in each sample. The percent sand was chosen to quantify soil texture as the GPR responses to silts and clays at this site were very similar, and no additional information was gained by considering silts

Figure 9. Experimental variograms of water content estimates from 900 MHz GPR data acquired in Sept. 2001 and Jan. 2002 for rows with and without crop cover.
Figure 10. **a) Normalized experimental variograms of water content from 900 MHz GPR data acquired in rows without crop cover and of soil texture, where soil texture is quantified as the percent sand. Normalization was performed by dividing the variogram value by the variance of the data set. b) Normalized experimental variograms of water content from 450 MHz GPR data acquired in rows without crop cover and of soil texture.**

and clays separately. Thus, the soil could be divided into the coarse-grained fraction (sand) and the fine-grained fraction (silt and clay) without loss of information. To compare the spatial correlations of soil texture and water content, the experimental variograms were normalized by the variance for each data set (Fig. 10). The variograms of water content shown in Fig. 10 were calculated using only data acquired in rows without crop cover, since the influence of vegetation on near-surface water content may obscure the relationship between soil texture and water content variability. Inspection of the variograms in Fig. 10 shows that soil texture has greater spatial correlation than water content for lags up to ~35 m. Also, the variogram model that best fits the experimental soil texture variogram is Gaussian, which has greater correlation at small lags than the exponential model which best describes the first portion of the water content variograms. The relatively low spatial correlation of

water content in comparison to soil texture is especially apparent for the variograms generated from 900 MHz data (Fig. 10(a)), indicating that shallow water content measurements are significantly influenced by factors other than soil texture, even at a site with no significant topography or changes in agricultural practices. The variograms calculated using water content estimates from 450 MHz GPR data (Fig. 10(b)) are more similar to the soil texture variograms, especially for the data collected in Jan., when the soil was near saturation. These results indicate that deeper water content estimates may be more indicative of soil texture than very shallow measurements, and that the influence of soil texture on near-surface water content may be most significant when the soil is near saturation.

Using Geophysical Measurements of Water Content to Supplement Soil Texture Measurements

Geophysical techniques can be used to obtain a large number of water content estimates across a site, but soil texture measurements are typically more difficult to obtain. Measurements of soil texture usually involve collection of the soil sample followed by sieve analysis to determine the grain size distribution of the coarse-grained fraction of the soil. Further analysis using hydrometers or lasers to characterize the fine-grained fraction of the soil is usually necessary. These techniques are time consuming, so soil texture is a relatively expensive parameter to characterize over a large area.

During this experiment, soil texture measurements were made in conjunction with gravimetric water content measurements at three times. The gravimetric water content measurements were converted to volumetric water content estimates, and the soil texture was quantified as percent sand, silt, and clay. Figure 11 shows that the coarse-grained fraction of the soil (percent sand) correlates reasonably well with volumetric water content, and the greatest correlation occurs when the soil is near saturation (Jan.). This correlation suggests that water content measurements might be used to improve soil texture estimation.

To determine if the geophysically-derived estimates of water content could be used to improve soil texture estimation, estimates of the coarse-grained soil fraction (CGSF) calculated using ordinary kriging of the CGSF and using co-kriging of the CGSF and water content were made. To better understand the dependence of water content on soil texture (without additional variables), only soil samples acquired in rows without crop cover were used in variogram and kriging calculations. Thirty-one soil samples were acquired in these rows (sample locations shown in Fig. 12(a)), and
Figure 11. Correlations between volumetric water content estimates and soil texture measurements for three sampling campaigns.

these samples were used to calculate an experimental variogram and a variogram model using GS+software, which is a geostatistical analysis and mapping program. The variogram model was used to krige CGSF estimates across the site (Fig. 12(a)). Next, approximately half of the CGSF measurements were removed from the data file; the measurements removed were chosen so that the remaining measurements would offer the best possible spatial coverage of the field. Thus, when two samples were separated by only a small distance, one of the samples was removed. A new CGSF experimental variogram was calculated, and kriging was performed using the variogram model that best fit this new variogram. Figure 12(b) shows the CGSF estimates when kriging was performed using a subset of the soil texture measurements. Finally, a cross-variogram was calculated using the subset of CGSF measurements shown in Fig. 12(b) and the volumetric water content estimates from the 450 MHz GPR data acquired in Jan. Co-kriging of these two data sets was performed, and the resulting CGSF estimates are shown in Fig. 12(c). This analysis was then repeated using only the subset of data points which were initially removed (those shown in Fig. 12(a) but not in Fig. 12(b)) as the sampling points; Fig. 13(a) shows the CGSF estimates from kriging the second subset of soil texture measurements, while Fig. 13(b) shows the CGSF estimates from co-kriging this second soil texture subset with water content estimates.

Visual comparison of Figs. 12 and 13 shows that the CGSF maps developed using co-kriging with water content estimates (Figs. 12(c) and 13(b)) are significantly more similar to the map developed using all the CGSF measurements (Fig. 12(a)) than are the maps derived from only a subset of CGSF measurements (Figs. 12(b) and 13(a)). To quantify the improvement in CGSF estimation, the error of the kriged and co-kriged

estimates was evaluated by comparing the CGSF values obtained from estimation to the measured values omitted from the estimation calculations. When compared to the measured CGSF values, the root mean squared error (RMSE) of the CGSF estimates derived from co-kriging water content and a subset of CGSF values was 10% and 6% for the first and second data subsets, respectively, while the RMSE of CGSF derived from kriging only a subset of CGSF values was 12% and 7% for the first and second subsets, respectively. Cross-validation of the subset of CGSF measurements shown in Figs. 12 and 13 produced a RMSE of 6% and 7% for the first and second subsets, respectively, when co-kriging of CGSF and soil water content was performed, and a RMSE of 12% and 8% for the first and second subsets, respectively, when only kriging of the CGSF was used. The relatively modest reduction in RMSE obtained by co-kriging CGSF and water content may indicate that geophysically-derived water content can only slightly improve soil texture estimation, but may also reflect the small number of CGSF data points and the methodology used to choose which points to omit. When the entire map area is considered (Fig. 12(a)), the co-kriging of soil texture and water content seems to significantly improve the accuracy of the soil texture estimates.

Conclusions

In this study, GPR groundwave techniques were used to generate very high-resolution estimates of near-surface soil water content over a three acre field during four data acquisition campaigns. The large GPR data sets, combined with the flat topography and the uniform agricultural practices employed at this site, provided an unusual opportunity to study water content variability at the field scale as a function of measurement depth, season, vegetation, and soil texture. Geostatistical analyses showed that the spatial correlation changed with measurement depth, where shallow soils had greater variability than deeper soils. The higher variability in the shallower measurements may be caused by the heterogeneity of surficial processes such as precipitation and irrigation. Comparison of variograms of water content estimates acquired at different times under conditions of natural precipitation or evapotranspiration showed similar sills for dry and wet soil, but decreased correlation lengths in wet soils, which may reflect the heterogeneity of soil properties. Irrigation significantly increased the water content variability of very shallow soils, but did not notably affect deeper measurements. Shallowly-rooted vegetation such as crop cover reduced the mean water content and the variability of water content when the soil was dry and

crop evapotranspiration was high, but had little effect when the soil was near saturation and evapotranspiration demand was low. Finally, deeper water content estimates that were acquired when the soil was near saturation showed patterns of variability similar to those of soil texture, but shallower measurements and measurements acquired during the dry season were significantly influenced by factors other than soil texture.

Geophysical data were also used to improve soil texture estimation. Co-kriging of sparse soil texture measurements and high-resolution estimates of water content from GPR showed that GPR measurements could be used to improve soil texture estimation, but the improvement (quantified by RMSE) was relatively modest. Additional studies with a larger set of soil

texture measurements are needed to better understand how co-kriging may improve soil texture estimation.

The results of this research can be used to more effectively characterize water content variability for precision agriculture applications. Analysis of multi-frequency GPR data acquired at different times showed that water content variability related to soil texture is best characterized using deeper (*i.e.*, lower frequency GPR) measurements acquired when the soil is very wet, while variability related to irrigation can be better characterized using shallower (*i.e.*, higher frequency GPR) measurements. Geostatistical analysis also showed that crop cover can significantly reduce water content variability, suggesting that farmers may be able to use crop cover to make a single irrigation rate more effective for uniform crop growth. In addition to better

characterizing the soil water content variability, GPR measurements of water content can be used in conjunction with soil texture measurements to better characterize the soil texture distribution across a site, which might be used to identify sites suitable for potential agricultural development and to guide the planning of new vineyards or orchards.

APPENDIX A

A variogram model was fit to each experimental variogram using least squares regression techniques. A linear combination of an exponential and Gaussian model seemed to best fit the experimental variograms, so this combination was used to determine variogram model parameters. Table 2 gives the model parameters

for each variogram. The exponential model is defined as:

$$\gamma(h) = c\left(1 - \exp\left(-\frac{h}{l}\right)\right), \qquad (A\text{-}1)$$

where c is the sill and l is the correlation length. For the exponential model, the range is $\approx 3l$. The Gaussian model is defined as:

$$\gamma(h) = c\left(1 - \exp\left(-\frac{h^2}{l^2}\right)\right), \qquad (A\text{-}2)$$

where the range is $\approx 7l/4$.
