### (57) ABSTRACT

A method of improving the training and performance of pre dictive models. A first method of operating an artificial intel ligence machine produces predictive model language docu ments describing improved predictive models that generate better business decisions from raw data record inputs. A sec ond method of operating an artificial intelligence machine including processors for predictive model algorithms pro duces and outputs better business decisions from raw data record inputs. Both methods enrich the raw data records their processors are fed by deleting data fields with data values that hew data fields from information sources then available that do benefit in the decision making of the artificial intelligence machine through improved accuracies of prediction.

#### METHOD OF OPERATING ARTIFICAL INTELLIGENCE MACHINES TO IMPROVE PREDICTIVE MODEL TRAINING AND PERFORMANCE

#### BACKGROUND OF THE INVENTION

[0001] 1. Field of the Invention

[0002] The present invention relates to ARTIFICIAL INTELLIGENCE MACHINES and more specifically to methods of improving the training and performance of pre dictive models these include by enriching the data records to produce better decisions.

[0003] 2. Background

[0004] Machine learning can use various techniques such as supervised learning, unsupervised learning and Reinforcement learning. In supervised learning the learner is supplied with labeled training instances (set of examples), where both the input and the correct output are given. For example, his torical stock prices are used to guesses future prices. Each example used for training is labeled with the value of inter est—in this case the stock price. A Supervised learning algo rithm learns from the labeled values using information such as the day of the week, the season, the company's financial data, the industry, etc. After the algorithm has found the best pattern it can, it uses that pattern to make predictions.

[0005] In unsupervised learning, data points have no labels associated with them. Instead, the goal of unsupervised learn ing is to identify and explore regularities and dependencies in data, e.g., the structure of the underlying data distributions. The quality of a structure is measured by a cost function which is usually minimized to infer optimal parameters char acterizing the hidden structure in the data. Reliable and robust inference requires aguarantee that the extracted structures are typical for the data source, e.g., similar structures have to be extracted from a second sample set of the same data source. [0006] Reinforcement learning maps situations to actions to maximize a scalar reward or reinforcement signal. The learner does not need to be directly told which actions to take, but instead must discover which actions yield the best rewards by trial and error. An action may affect not only the immediate reward, but also the next situation, and consequently all subsequent rewards. Trial and error search, and delayed reward, are two important distinguishing characteristics of reinforce ment learning.

[0007] Supervised learning algorithms use a known dataset to thereafter make predictions. The dataset training includes input data that produces response values. Supervised learning algorithms are used to build predictive models for new responses to new data. The larger the training datasets, the better will be the prediction models. Supervised learning includes classifications in which the data must be separated into classes, and regression for continuous-response. Common classification algorithms include Support vector machines (SVM), neural networks, Naive Bayes classifier and decision trees. Common regression algorithms include linear regression, nonlinear regression, generalized linear models, decision trees, and neural networks.

#### SUMMARY OF THE INVENTION

[0008] Briefly, method embodiments of the present invention improve the training and performance of predictive mod els included in artificial intelligence machines. A first method of operating an artificial intelligence machine produces pre

dictive model language documents describing improved pre dictive models that generate better business decisions from raw data record inputs. A second method of operating an artificial intelligence machine including processors for pre dictive model algorithms produces and outputs better busi ness decisions from raw data record inputs. Both methods enrich the raw data records their processors are fed by delet ing data fields with data values that have little benefit in decision making, and that derive and add new data fields from information sources then available that do benefit in the deci sion making of the artificial intelligence machine through improved accuracies of prediction.

[0009] The above and still further objects, features, and advantages of the present invention will become apparent upon consideration of the following detailed description of specific embodiments thereof, especially when taken in con junction with the accompanying drawings.

### BRIEF DESCRIPTION OF THE DRAWINGS

[0010] FIG. 1 is a flowchart of a method embodiment of the present invention that provides user-service consumers with data science as-a-service operating on artificial intelligence machines;

[0020] FIG. 8 is a flowchart diagram of an algorithm for using ordered rules and thresholds to decide amongst predic tion classes;

[0021] FIG. 9 is a flowchart diagram of a method that combines the methods of FIGS. 1-8 and their algorithms to arti ficial intelligence machines that provide an on-line service for scoring, predictions, and decisions to user-service consumers requiring data science and artificial intelligence services without their being required to invest in and maintain special ized equipment and software;

[0022] FIG. 10 is a flowchart diagram illustrating an artificial intelligence machine apparatus for executing an algo rithm for reconsideration of an otherwise final adverse deci sion, for example, in a payment authorization system a transaction request for a particular amount SX has already been preliminarily "declined" according to some other decision model;

[0023] FIG. 11 is a flowchart diagram of an algorithm for the operational use of Smart agents in artificial intelligence machines;

[0024] FIGS. 12-29 provide greater detail regarding the construction and functioning of algorithms that are employed in FIGS. 1-11:

[ $0025$ ] FIG. 12 is a schematic diagram of a neural network architecture used in a model;

[0026] FIG. 13 is a diagram of a single neuron in a neural network used in a model;

[0027] FIG. 14 is a flowchart of an algorithm for training a neural network;

[ $0028$ ] FIG. 15 is an example illustrating a table of distance measures that is used in a neural network training process;

[0029] FIG. 16 is a flowchart of an algorithm for propagating an input record through a neural network;

[0030] FIG. 17 is a flowchart of an algorithm for updating a training process of a neural network;

[0031] FIG. 18 is a flowchart of an algorithm for creating intervals of normal values for a field in a training table:

[0032] FIG. 19 is a flowchart of an algorithm for determin-

ing dependencies between each field in a training table;<br>[0033] FIG. 20 is a flowchart of an algorithm for verifying dependencies between fields in an input record;

[0034] FIG. 21 is a flowchart of an algorithm for updating a smart-agent technology;

[0035] FIG. 22 is a flowchart of an algorithm for generating a data mining technology to create a decision tree based on similar records in a training table;

[0036] FIG. 23 is an example illustrating a decision tree for a database maintained by an insurance company to predict a risk of an insurance contract based on a type of a car and a age of its driver,

[0037] FIG. 24 is a flowchart of an algorithm for generating a case-based reasoning technology to find a case in a database that best resembles a new transaction;

[0038] FIG. 25 is an example illustrating a table of global similarity measures used by a case-based reasoning technol Ogy.

[0039] FIG. 26 is an example illustrating a table of local similarity measures used by a case-based reasoning technol Ogy.

[0040] FIG. 27 is an example illustrating a rule for use with a rule-based reasoning technology;

0041 FIG. 28 is an example illustrating a fuzzy rule to

specify if a person is tall;<br>[0042] FIG. 29 is a flowchart of an algorithm for applying rule-based reasoning, fuzzy logic, and constraint programming to assess the normality/abnormality of and classify a transaction assess an activity; and

 $[0043]$  FIG. 30 is a flowchart diagram of an algorithm executed by an apparatus needed to implement a method embodiment of the present invention for improving predictive model training and performance by data enrichment of trans action records.

#### DETAILED DESCRIPTION OF THE INVENTION

[0044] Computer-implemented method embodiments of the present invention provide an artificial intelligence and machine-learning service that is delivered on-demand to user service consumers, their clients, and other users through net

work servers. The methods are typically implemented with special algorithms executed by computer apparatus and deliv ered to non-transitory storage mediums to the providers and user-service consumers who then sell or use the service them selves.

[0045] Users in occasional or even regular need of artificial intelligence and machine learning Prediction Technologies can get the essential data-science services required on the Cloud from an appropriate provider, instead of installing specialized hardware and maintaining their own software. Users are thereby freed from needing to operate and manage complex software and hardware. The intermediaries manage<br>user access to their particular applications, including quality, security, availability, and performance.

[0046] FIG. 1 represents a predictive model learning method 100 that provides artificial intelligence and machine learning as-a-service by generating predictive models from service-consumer-Supplied training data input records. A computer file 102 previously hashed or encrypted by a triple DES algorithm, or similar protection. It also possible to send a non-encrypted filed through an encrypted channel. Users of the platform would upload their data through SSL/TLS from a browser or from a command line interface (SCP or SFTP). This is then received by a network server from a service consumer needing predictive models. Such encode the supervised and/or unsupervised data of the service consumer that are essential for use in later steps as training inputs. The records 102 received represent an encryption of individual supervised and/or unsupervised records each comprising a predefined plurality of predefined data fields that communi cate data values, and structured and unstructured text. Such text often represents that found in webpages, blogs, auto mated news feeds, etc., and very often such contains errors and inconsistencies.

0047 Structured text has an easily digested form and unstructured text does not. Text mining can use a simple bag-of-words model. Such as how many times does each word occur. Or complex approaches that pull the context from language structures, e.g., the metadata of a post on Twitter where the unstructured data is the text of the post.

[0048] These records 102 are decrypted in a step 104 with an apparatus for executing a decoding algorithm, e.g., a stan dard triple-DES device that uses three keys. An example is illustrated in FIG. 2. A series of results are transformed into a set of non-transitory, raw-data records 106 that are collec tively stored in a machine-readable storage mechanism.

[0049] A step 108 cleans up and improves the integrity of the data stored in the raw-data records 106 with an apparatus for executing a data integrity analysis algorithm. An example is illustrated in FIGS. 3A, 3B, and 3C. Step 108 compares and corrects any data values in each data field according to user service consumer preferences like min, max, average, null, and default, and a predefined data dictionary of valid data values. Step 108 discerns the context of the structured and unstructured text with an apparatus for executing a contextual dictionary algorithm. Step 108 transforms each result into a set of flat-data records 110 that are collectively stored in a machine-readable storage mechanism.<br> **1995** ID Method 108 improves the training of predictive

models by converting and transforming a variety of inconsistent and incoherent Supervised and unsupervised training data for predictive models received by a network server as electronic data files, and storing that in a computer data storage mechanism. It then transforms these into another single, error-free, uniformly formatted record file in computer data storage with an apparatus for executing a data integrity analysis algorithm that harmonizes a range of supervised and unsupervised training data into flat-data records in which every field of every record file is modified to be coherent and wellpopulated with information.

[0051] The data values in each data field in the inconsistent and incoherent supervised and unsupervised training data are compared and corrected according to a user-service con sumer preference and a predefined data dictionary of valid data values. An apparatus for executing an algorithm substitutes data values in the data fields of incoming supervised and unsupervised training data with at least one value represent ing a minimum, a maximum, a null, an average, and a default. [0052] The context of any text included in the inconsistent and incoherent Supervised and unsupervised training data is discerned, recognized, detected, and discriminated with an apparatus for executing a contextual dictionary algorithm that employs a thesaurus of alternative contexts of ambiguous words for find a common context denominator, and to then mechanism for later access by a predictive model.

[0053] Further details regarding data clean-up are provided below in connection with FIGS. 3A, 3B, and 3C. Data cleaning herein deals with detecting and removing errors and inconsistencies from data in order to improve the quality of data. Data quality problems are present in single data collec tions, such as files and databases, or multiple data sources. For example,

#### Single-Source Data

#### 0054

-continued

level		data errors	
misspellings	attribute values	sorting on values often brings misspelled values next to correct values	
missing values	mill values attribute values + default values	percentage/number of null values presence of default value may indicate real value is missing	
varying value representations	attribute values	comparing attribute value set of a column of one table against that of a column of another table	
duplicates	cardinality + uniqueness attribute values	attribute cardinality = $\#$ rows should hold sorting values by number of occurrences; more than 1 occurrence indicates duplicates	

[0055] In a step 112, a test is made to see if a number of records 114 in the set of flat-data records 110 exceeds a predefined threshold, e.g., about one hundred million. The particular cutoff number to use is inexact and is empirically determined by what produces the best commercial efficiencies.

[0056] But if the number of records 114 is too large, a step 116 then samples a portion of the set of flat-data records 110. An example is illustrated in FIG. 4. Step 116 stores a set of samples 118 in a machine-readable storage mechanism for use in the remaining steps. Step 116 consequently employs an apparatus for executing a special sampling algorithm that limits the number of records that must be processed by the remaining steps, but at the same time preserves important training data. The details are described herein in connection with FIG. 4.

 $[0057]$  A modeling data 120 is given a new, amplified texture by a step 122 for enhancing, enriching, and concentrating the sampled or unsampled data stored in the flat-data records with an apparatus for executing a data enrichment algorithm. An example apparatus is illustrated in FIG. 4, which outputs training sets 420, 421, and 440; and test sets 422, 423, and 442; and blind sets 424, 425, and 444 derived from either the flat data 110 or sampled data 118. Such step 122 removes data that may exist in particular data fields that is less important to building predictive models. Entire data fields themselves are removed here that are predetermined to be unavailing to building good predictive models that follow.

[0058] Step 122 calculates and combines any data it has into new data fields that are predetermined to be more impor tant to building such predictive models. It converts text with an apparatus for executing a context mining algorithm, as suggested by FIG. 6. Even more details of this are suggested in my U.S. patent application Ser. No. 14/613,383, filed Feb. 4, 2015, and titled, ARTIFICIAL INTELLIGENCE FOR CONTEXT CLASSIFIER. Step 122 then transforms a plurality of results from the execution of these algorithms into a set of enriched-data records 124 that are collectively stored in a machine-readable storage mechanism.

[0059] A step 126 uses the set of enriched-data records 124 to build a plurality of smart-agent predictive models for each entity represented. Step 126 employs an apparatus for execut ing a smart-agent building algorithm. The details of this are shown in FIG. 6. Further related information is included in my U.S. Pat. No. 7,089,592 B2, issued Aug. 8, 2006, titled, SYSTEMS AND METHODS FOR DYNAMIC DETEC TION AND PREVENTION OF ELECTRONIC FRAUD, which is incorporated herein by reference. (Herein, Adjaoute 592.) Special attention should be placed on FIGS. 11-30 and the descriptions of Smart-agents in connection with FIG. 21 and the Smart-agent technology in Columns 16-18.

Unsupervised Learning of Normal and Abnormal Behavior

0060 Each field or attribute in a data record is represented by a corresponding Smart-agent. Each Smart-agent represent ing a field will build what-is-normal (normality) and what-is abnormal (abnormality) metrics regarding other smartagents.

[0061] Apparatus for creating smart-agents is supervised or unsupervised. When supervised, an expert provides information about each domain. Each numeric field is characterized by a list of intervals of normal values, and each symbolic field is characterized by a list of normal values. It is possible for a field to have only one interval. If there are no intervals for an attribute, the system apparatus can skip testing the validity of its values, e.g., when an event occurs.

[0062] As an example, a doctor (expert) can give the temperature of the human body as within an interval [35°C.: 41° C.], and the hair colors can be  $\{black, blood, red\}$ .

- 1) For each field "a" of a Table:<br>i) Retrieve all the distinct v
	- Retrieve all the distinct values and their cardinalities and create a list "La" of couples (vai, nai);
	- ii) Analyze the intermediate list "La" to create the list of intervals of normal values Ia with this method:
		- (a) If "a" is a symbolic attribute, copy each member of "La" into Ia when nai is Superior to a threshold
		- (b) If "a" is a numeric attribute:
			- 1. Order the list"La" starting with the smallest values "a":
			- 2. While La is not empty;<br>i. Remove the first e.
				- Remove the first element ea= (val, nal) of "La"
				- ii. Create an interval with this element:  $\mathbf{I}' = [\mathbf{v}\mathbf{a} \mathbf{1}, \mathbf{v}\mathbf{a} \mathbf{1}]$
				- iii. While it is possible, enlarge this interval with the first elements of "La" and remove them from "La":  $I' = [val,$ vak). The loop stops before the size of the interval vak-val becomes greater than a threshold  $\Theta_{dist}$
		- (c) given:  $na' = na1 + ... + nak$
		- (d) If na' is superior to a threshold  $\Theta$ min, Ia = I'
	- otherwise, ia = 0: iii) If Ia is not empty, save the relation (a, Ia).
	-

[0063] An unsupervised learning process uses the following algorithm:

[0064]  $\Theta_{man}$  represents the minimum number of elements an interval must include. This means that an interval will only be take into account if it encapsulates enough values, so its values will be considered normal because frequent;

the system apparatus defines two parameters that is modified: [0065] the maximum number of intervals for each attribute  $n_{max}$ 

[0066] the minimum frequency of values in each interval  $I_{Imin}$ 

 $\Theta_{min}$  is computed with the following method:

 $\Theta_{min} = f_{Imin}$ \*number of records in the table.

[0067]  $\Theta_{dist}$  represents the maximum width of an interval. This prevents the system apparatus from regrouping some numeric values that are too disparate. For an attribute a, lets call mina the smallest value of a on the whole table and maxa the biggest one. Then:

 $\Theta_{dist}$ =(maxa-mina)/ $n_{max}$ 

For example, consider a numeric attribute of temperature with the following values:

The first step is to sort and group the values into "La": "La"={  $(64, 1) (65, 1) (68, 1) (69, 1) (70, 1) (71, 1) (72, 2) (75, 2) (80, 1) (81, 1) (83, 1) (85, 1)$ }

Then the system apparatus creates the intervals of normal values:

0068] Consider  $f_{min}$ =10% and  $n_{max}$ =5 then  $\Theta_{min}$ =1.4 and  $\Theta_{dist}$  = (85–64)/5=4.2<br>[0069]  $\text{Ia}$  = {[64, 68] [69, 72] [75] [80, 83]}

The interval  $[85, 85]$  was removed because its cardinality  $(1)$ is smaller than  $\Theta_{min}$ .

[0070] When a new event occurs, the values of each field are verified with the intervals of the normal values it created, or that were fixed by an expert. It checks that at least one interval exists. If not, the field is not verified. If true, the value inside is tested against the intervals, otherwise a warning is generated for the field.

[0071] During creation, dependencies between two fields are expressed as follows:

[0072] When the field 1 is equal to the value v1, then the field 2 takes the value V2 in significant frequency p.

Example: when species is human the body\_temperature is 37.2° C. with a 99.5% accuracy.

[0073] Given cT is the number of records in the whole database. For each attribute X in the table:

Retrieve the list of distinct values for X with the cardinality of each value:

[0074] Lx={(x1, cx1), ... (xi, c<sub>xi</sub>), ... (xn, cxn)}<br>For each distinct value xi in the list:

Verify if the value is typical enough:  $(c_x/cT) > \Theta x$ ?

[0075] If true, for each attribute Y in the table,  $Y \neq X$ 

Retrieve the list of distinct values forY with the cardinality of each value:

[0076] Ly={(y1, cy1), ... (yj, c<sub>yj</sub>), ... (yn, cyn)}<br>For each value yj;<br>[0077] Retrieve the number of records c<sub>ij</sub> where (X=xi) and

(Y=yj). If the relation is significant, save it: if  $(c_j/c_{xi})>0xy$  then save the relation  $[(X=xi) \Rightarrow (Y=y)]$  with the cardinali- $\sum_{x_i}$ ,  $C_{y_i}$  and  $C_{ij}$ .

 $[0078]$  The accuracy of this relation is given by the quotient  $(c_{ij}/c_{xi})$ 

 $[0079]$  Verify the coherence of all the relations: for each relation  $[(X=xi) \Rightarrow (Y=yi)]$  (1)

[0080] Search if there is a relation  $[(Y=y)] \Rightarrow (X=xk)$ ] (2)

[0081] If xi $\neq$ xk remove both relations (1) and (2) from the model otherwise it will trigger a warning at each event since (1) and (2) cannot both be true.

[0082] To find all the dependencies, the system apparatus analyses a database with the following algorithm:

[0083] The default value for  $\Theta$ x is 1%: the system apparatus will only consider the significant value of each attribute.

[0084] The default value for  $\Theta$ xy is 85%: the system apparatus will only consider the significant relations found.

[0085] A relation is defined by:  $(Att_1=v_1) \Rightarrow (Att_2=v_2)(eq)$ . [0086] All the relations are stored in a tree made with four levels of hash tables, e.g., to increase the speed of the system apparatus. A first level is a hash of the attribute's name (Att1 in eq); a second level is a hash for each attribute the values that imply some correlations (V1 in eq); a third level is a hash of the names of the attributes with correlations (Att2 in eq) to the first attribute; a fourth and last level has values of the second attribute that are correlated  $(v2 \text{ in eq})$ .

Each leaf represents a relation. At each leaf, the system apparatus stores the cardinalities  $c_{xi}$ ,  $c_{vi}$  and  $c_{ij}$ . This will allow the system apparatus to incrementally update the relations during its lifetime. Also it gives:<br>[0087] the accuracy of a relation:  $c_{ij}/c_{xi}$ ;

[0088] the prevalence of a relation:  $c_y/cT$ ; <br>[0089] the expected predictability of a relation:  $c_y/cT$ .

[0090] Consider an example with two attributes,  $\tilde{A}$  and B:

	R
	∍
	า

There are ten records: cT=10. Consider all the possible relations:

With the defaults values for  $\Theta$ x and  $\Theta$ xy, for each possible relation, the first test  $(c_{x}/c_{T})>0x$  is successful (since  $0x=1\%$ ) but the relations (1) and (7) would be rejected (since Oxy=85%).

Then the system apparatus verifies the coherence of each remaining relation with an algorithm:

The system apparatus classifies the normality/abnormality of each new event in real-time during live production and detec tion.

[0091] For each event couple attribute/value  $(X, xi)$ :

Looking in the model for all the relations starting by  $[(X=x)^2]$  $\Rightarrow$  ...

- [0092] For all the other couple attribute/value  $(Y, Y_i)$ ,  $Y \neq X$ , of the event:
	- [0093] Look in the model for a relation  $[(X=x)]$  $\Rightarrow$  (Y=v)];
	- [0094] If  $y_i \neq v$  then trigger a warning " $[(X=x_i)]$  $\Rightarrow$  (Y=y<sub>i</sub>)] not respected".

Incremental Learning

[0095] The system apparatus incrementally learns with new events:

Increment cT by the number or records in the new table T.

- For each relation  $[(X=x)) \Rightarrow (Y=y)$  previously created:<br>[0096] Retrieve its parameters:  $c_{xi}$ ,  $c_{yi}$  and  $c_{ij}$ 
	-
	- [0097] Increment  $c_{xi}$  by the number of records in Twhere  $X=x_i$ ;
	- [0098] Increment  $c_{y}$  by the number of records in Twhere  $Y=Y_j$ ;
	- $\begin{bmatrix} 0 & 0 & 0 \\ 0 & 0 & 0 \end{bmatrix}$  increment  $c_{ij}$  by the number of records in Twhere  $[(X=x_i) \Rightarrow (Y=Y_j)]$ ;<br>
	[0100] Verify if the relation is still significant:
	-

[0101] If  $(c_{x}/c_{x})<\theta_{x}$ , remove this relation;<br>If  $(c_{i}/c_{x})<\theta_{x}$ , remove this relation.

[0102] In FIG. 1, a step 127 selects amongst a plurality of smart-agent predictive models and updates a corresponding particular smart-agent's real-time profile and long-term profile. Such profiles are stored in a machine-readable storage mechanism with the data from the enriched-data records 124. Each corresponds to a transaction activity of a particular entity. Step 127 employs an apparatus for executing a smartagent algorithm that compares a current transaction, activity, behavior to previously memorialized transactions, activities and profiles such as illustrated in FIG. 7. Step 127 then trans forms and stores a series of results as Smart-agent predictive model in a markup language document in a machine-readable storage mechanism. Such Smart-agent predictive model markup language documents are XML types and best com municated in a registered file extension format, ".IFM", marketed by Brighterion, Inc. (San Francisco, Calif.).

[0103] Steps 126 and 127 can both be implemented by the apparatus of FIG. 11 that executes algorithm 1100.

[0104]  $\Delta$  step 128 exports the .IFM-type smart-agent predictive model markup language documents to a user-service consumer, e.g., using an apparatus for executing a data-sci ence-as-a-service algorithm from a network server, as illus trated in FIGS. 6 and 9.

[0105] In alternative method embodiments of the present invention, Method 100 further includes a step 130 for build ing a data mining predictive model (e.g. 612, FIG. 6) by applying the same data from the samples of the enriched-data records 124 as an input to an apparatus for generating a data mining algorithm. For example, as illustrated in FIG. 22. A data-tree result 131 is transformed by a step 132 into a data mining predictive model markup language document that is stored in a machine-readable storage mechanism. For example, as an industry standardized predictive model markup language (PMML) document. PMML is an XML based file format developed by the Data Mining Group (dmg. org) to provide a way for applications to describe and exchange models produced by data mining and machine learning algorithms. It supports common models such as logistic regression and feed-forward neural networks. Further information related to data mining is included in Adjaoute 592. Special attention should be placed on FIGS. 11-30 and the descriptions of the data-mining technology in Columns 18-20.

[0106] Method 100 further includes an alternative step 134 for building a neural network predictive model (e.g. 613, FIG. 6) by applying the same data from the samples of the enriched-data records 124 as an input to an apparatus for generating a neural network algorithm. For example, as illus trated in FIG. 12-17. A nodes/weight result 135 is trans formed by a step 136 into a neural-network predictive model markup language document that is stored in a machine-read able storage mechanism. Further information related to neu ral networks is included in Adjaoute '592. Special attention should be placed on FIGS. 13-15 and the descriptions of the neural network technology in Columns 14-16.

[0107] Method 100 further includes an alternative step 138 for building a case-based-reasoning predictive model (e.g. 614, FIG. 6) by applying the same data from the samples of the enriched-data records 124 as an input to an apparatus for generating a cased-based reasoning algorithm. As Suggested by the algorithm of FIG. 25-26. A cases result 139 is trans formed into a case-based-reasoning predictive model markup language document 140 that is stored in a machine-readable storage mechanism. Further information related to case based-reasoning is included in Adjaoute '592. Special attention should be placed on FIGS. 24-25 and the descriptions of the case-based-reasoning technology in Columns 20-21.

[0108] Method 100 further includes an alternative step 142 for building a clustering predictive model (e.g. 615, FIG. 6) by applying the same data from the samples of the enriched data records 124 as an input to an apparatus for generating a clustering algorithm. A clusters result 143 is transformed by a step 144 into a clustering predictive model markup language document that is stored in a machine-readable storage mecha nism.

[0109] Clustering here involves the unsupervised classification of observations, data items, feature vectors, and other patterns into groups. In Supervised learning, a collection of labeled patterns are used to determine class descriptions which, in turn, can then be used to label the new pattern. In the case of unsupervised clustering, the challenge is in grouping a given collection of unlabeled patterns into meaningful clus ters.

[0110] Typical pattern clustering algorithms involve the following steps:

[0111] (1) Pattern representation: extraction and/or selection;

[0112] (2) Pattern proximity measure appropriate to the data domain;

 $[0113]$  (3) Clustering, and

[0114] (4) Assessment of the outputs.

Feature selection algorithms identify the most effective sub sets of the original features to use in clustering. Feature extraction makes transformations of the input features into is used to obtain an appropriate set of features to use in clustering. Pattern representation refers to the number of classes and available patterns to the clustering algorithm. Pattern proximity is measured by a distance function defined on pairs of patterns.

[0115] A clustering is a partition of data into exclusive groups or fuzzy clustering. Using Fuzzy Logic, A fuzzy clustering method assigns degrees of membership in several clus ters to each input pattern. Both similarity measures and dis similarity measures are used here in creating clusters.

[0116] Method 100 further includes an alternative step 146 for building a business rules predictive model (e.g. 616, FIG. 6) by applying the same data from the samples of the enriched-data records 124 as an input to an apparatus for generating a business rules algorithm. As Suggested by the algorithm of FIG. 27-29. A rules result 147 is transformed by a step 148 into a business rules predictive model markup language document that is stored in a machine-readable stor

age mechanism. Further information related to rule-based reasoning is included in Adjaoute '592. Special attention should be placed on FIG. 27 and the descriptions of the rule-based-reasoning technology in Columns 20-21.

[0117] Each of Documents 128, 132, 136, 140, 144, and 146 is a tangible machine-readable transformation of a trained model and can be sold, transported, installed, used, adapted, maintained, and modified by a user-service con sumer or provider.

[0118] FIG. 2 represents an apparatus 200 for executing an encryption algorithm 202 and a matching decoding algorithm 204, e.g., a standard triple-DES device that uses two keys. The Data Encryption Standard (DES) is a widely understood and once predominant symmetric-key algorithm for the encryp tion of electronic data. DES is the archetypal block cipher an algorithm that takes data and transforms it through a series of complicated operations into another ciphertext bit string of the same length. In the case of DES, the block size is 64bits. DES also uses a key to customize the transformation, so that decryption can supposedly only be performed by those who know the particular key used to encrypt. The key ostensibly consists of 64bits; however, only 56 of these are actually used by the algorithm. Eight bits are used solely for checking parity, and are thereafter discarded. Hence the effective key length is 56 bits.

0119 Triple DES (3DES) is a common name in cryptog raphy for the Triple Data Encryption Algorithm (TDEA or Triple DEA) symmetric-key block cipher, which applies the Data Encryption Standard (DES) cipher algorithm three times to each data block. The original DES cipher's key size of 56-bits was generally sufficient when that algorithm was designed, but the availability of increasing computational power made brute-force attacks feasible. Triple DES provides a relatively simple method of increasing the key size of DES to protect against Such attacks, without the need to design a completely new block cipher algorithm.

[0120] In FIG. 2, algorithms 202 and 204 transform data in separate records in storage memory back and forth between private data (P) and triple encrypted data (C).

[0121] FIGS. 3A, 3B, and 3C represent an algorithm 300 for cleaning up the raw data 106 in stored data records, field by-field, record-by-record. What is meant by "cleaning up' is that inconsistent, missing, and illegal data in each field are removed or reconstituted. Some types of fields are very restricted in what is legal or allowed. A record 302 is fetched from the raw data 304 and for each field 306 a test 306 sees if the data value reported is numeric or symbolic. If numeric, a data dictionary 308 is used by a step 310 to see if such data value is listed as valid. If symbolic, another data dictionary 312 is used by a step 314 to see if such data value is listed as valid.

[0122] For numeric data values, a test  $316$  is used to branch if not numeric to a step 318 that replaces the numeric value. FIG. 3B illustrates such in greater detail. A test 320 is used to check if the numeric value is within an acceptable range. If not, step 318 is used to replace the numeric value.

[0123] For symbolic data values, a test 322 is used to branch if not numeric to a step 324 that replaces the symbolic value. FIG.3C illustrates such in greater detail. A test 326 is used to check if the symbolic value is an allowable one. If yes, a step 328 checks if the value is allowed in a set. If yes, then a return 330 proceeds to the next field. If no, step 324 replaces the symbolic value.

[0.124] If in step 326 the symbolic value in the field is not an allowed value, a step 332 asks if the present field is a zip code field. If yes, a step 334 asks if it's a valid zip code. If yes, the processing moves on to the next field with step 330. Other wise, it calls on step 324 to replace the symbolic value.

[0.125] If in step 332 the field is not an allowed value a zip code field, then a step 338 asks if the field is reserved for telephone and fax numbers. If yes, a step 340 asks if it's a valid telephone and fax number. If yes, the processing moves on to the next field with step 330. Otherwise, it calls on step 324 to replace the symbolic value.

[0126] If in step 338 the field is not a field reserved for telephone and fax numbers, then a step 344 asks if the present field is reserved for dates and time. If yes, a step 346 asks if it's a date or time. If yes, the processing moves on to the next field with step 330. Otherwise, it calls on step 324 to replace the symbolic value.

[0127] If in step 344 the field is not a field reserved for dates and time, then a step 350 applies a Smith-Waterman algo rithm to the data value. The Smith-Waterman algorithm does a local-sequence alignment. It's used to determine if there are any similar regions between two strings or sequences. For example, to recognize "Avenue" as being the same as "Ave."; and "St." as the same as "Street"; and "Mr." as the same as "Mister". A consistent, coherent terminology is then enforceable in each data field without data loss. The Smith-Waterman algorithm compares segments of all possible lengths and optimizes the similarity measure without looking at the total sequence. Then the processing moves on to a next field with step 330.

[0128] FIG. 3B represents what happens inside step 318, replace numeric value. The numeric value to use as a replace ment depends on any flags or preferences that were set to use a default, the average, a minimum, a maximum, or a null. A step 360 tests if user preferences were set to use a default value. If yes, then a step 361 sets a default value and returns to do a next field in step 330. A step 362 tests if user preferences were set to use an average value. If yes, then a step 361 sets an average value and returns to do the next field in step 330. A step 364 tests if user preferences were set to use a minimum value. If yes, then a step 361 sets a minimum value and returns to do the next field in step 330. A step 366 tests if user preferences were set to use a maximum value. If yes, then a step 361 sets a maximum value and returns to do the next field in step 330. A step 368 tests if user preferences were set to use a null value. If yes, then a step 361 sets a null value and returns to do the next field in step 330. Otherwise, a step 370 removes the record and moves on to the next record.

[0129] FIG. 3C represents what happens inside step 324, replace symbolic value. The symbolic value to use as a replacement depends on if flags were set to use a default, the average, or null. A step 374 tests if user preferences were set to use a default value. If yes, then a step 375 sets a default value and returns to do the next field in step 330. A step 376 tests if user preferences were set to use an average value. If yes, then a step 377 sets an average value and returns to do the next field in step 330. A step 378 tests if user preferences were set to use a null value. If yes, then a step 379 sets a null value and returns to do the next field in step 330. Otherwise, a step 380 removes the record and moves on to a next record.

[0130] FIG. 4 represents the apparatus for executing sampling algorithm 116. A sampling algorithm 400 takes cleaned, raw-data 402 and asks in step 404 if method embodiments of the present invention data are supervised. If so, a step 406 creates one data set "C1" 408 and a "Cn" 410 for each class. Stratified selection is used if needed. Each application carries its own class set, e.g., Stocks portfolio managers use buy-sell hold classes; loans managers use loan interest rate classes; risk assessment managers use fraud-no\_fraud-suspicious classes; marketing managers use product-category-to-suggest classes; and, cybersecurity uses normal behavior-abnor mal behavior classes. Other classes are possible and useful. For all classes, a step 412 and 413 asks if the class is abnormal (e.g., uncharacteristic). If not, a step 414 and 415 down sample and produce sampled records of the class 416 and 417. Then a step 418 and 419 splits the remaining data into separate training sets 420 and 421, separate test sets 422 and 423,

and separate blind sets 424 and 425.<br>[0131] If in step 404 method embodiments of the present invention data was determined to be unsupervised, a step 430 creates one data set with all the records and stores them in a memory device 432. A step 434 down-samples all of them and<br>stores those in a memory device 436. Then a step 438 splits the remaining data into separate a training set 440, a separate test set 442, and a separate blind set 444.

[0132] Later applications described herein also require data cleanup and data enrichment, but they do not require the split training sets produced by sampling algorithm 400. Instead they process new incoming records that are cleaned and enriched to make a prediction, a score, or a decision, record one at a time.

[0133] FIGS. 5A and 5B together represent an apparatus 500 with at least one processor for executing a specialized data enrichment algorithm that works both to enrich the profiling criteria for smart-agents and to enrich the data fields for all the other general predictive models. They all are intended to work together in parallel with the Smart-agents in opera tional use.

[0134] In FIG. 5A, a plurality of training sets, herein 502 and 502, for each class C1... Cn are input for each data field of a record in a step 506. Such supervised and unsupervised training sets correspond to training sets 420, 421, and 440 (FIG. 4). More generally, flat data 110, 120 and sampled data 118 (FIG. 1). A step 508 asks if there are too many distinct data values, e.g., more than a threshold data value stored in memory. For example, data that is so random as to reveal no information and nothing systemic. If so, a step 510 excludes that field and thereby reduces the list of fields. Otherwise, a step 512 asks if there is a single data value. Again, if so such field is not too useful in later steps, and step 510 excludes that field as well. Otherwise, a step 514 asks if the Shannon entropy is too small, e.g., less than a threshold data value stored in memory. The Shannon entropy is calculable using a conventional formula:

$$
H(X) = \sum_{i=1}^{n} p(x_i)I(x_i) = \sum_{i=1}^{n} p(x_i) \log_b \frac{1}{p(x_i)} = -\sum_{i=1}^{n} p(x_i) \log_b p(x_i),
$$

[0135] The entropy of a message is its amount of uncertainty. It increases when the message is closer to random, and decreases when it is less random. The idea here is that the less likely an event is, the more information it provides when it occurs. If the Shannon entropy is too small, step 510 excludes that field. Otherwise, a step 516 reduces the number of fields in the set of fields carried forward as those that actually provide useful information. [0136] A step 517 asks if the field type under inspection at that instant is symbolic or numeric. If symbolic, a step 518 provides AI behavior grouping. For example, colors or the names of boys. Otherwise, a step 520 does a numeric fuzzi-<br>fication in which a numeric value is turned into a membership of one or more fuzzy sets. Then a step 522 produces a reduced set of transformed fields. A step 524 asks if the number of criteria or data fields remaining meets a predefined target number. The target number represents a judgment of the optimum spectrum of profiling criteria data fields that will be needed to produce high performance Smart-agents and good predictive models.

 $[0137]$  If yes, a step 526 outputs a final list of profiling criteria and data fields needed by the smart-agent steps 126 and 127 in FIG. 1 and all the other predictive model steps 130, 131, 134, 135, 138, 139, 142,143, 146, and 147.

[0138] If not, the later steps in Method 100 need richer data to work with than is on-hand at the moment. The enrichment provided represents the most distinctive advantage that embodiments of the present invention have over conventional methods and systems. A step 528 (FIG. 5B) begins a process to generate additional profiling criteria and newly derived data fields. A step 530 chooses an aggregation type. A step 532 chooses a time range for a newly derived field or profiling criteria. A step 534 chooses a filter. A step 536 chooses con straints. A step 538 chooses the fields to aggregate. A step 540 chooses a recursive level.

[0139] A step  $542$  assesses the quality of the newly derived field by importing test set classes C1... Cn 544 and 546. It assesses the profiling criteria and data field quality for large enough coverage in a step 548, the maximum transaction/ event false positive rate (TFPR) below a limit in a step 550, the average TFPR below a limit in a step 552, transaction/ event detection rate (TDR) above a threshold in a step 554, the transaction/event review rate (TRR) trend below a threshold in a step 556, the number of conditions below a threshold in a step 560, the number of records is above a threshold in a step 562, and the time window is optimal a step 564.

[0140] If the newly derived profiling criteria or data field has been qualified, a step 566 adds it to the list. Otherwise, the newly derive profiling criteria or data field is discarded in a step 568 and returns to step 528 to try a new iteration with updated parameters.

[0141] Thresholds and limits are stored in computer storage memory mechanisms as modifiable digital data values that are non-transitory. Thresholds are predetermined and is "tuned" later to optimize overall operational performance. For example, by manipulating the data values stored in a computer memory storage mechanism through an adminis trator's console dashboard. Thresholds are digitally com pared to incoming data, or newly derived data using conven tional devices.

#### Using the Data Science

[0142] Once the predictive model technologies have been individually trained by both supervised and unsupervised data and then packaged into a PMML Document, one or more of them can be put to work in parallel render a risk or a decision score for each new record presented to them. At a minimum, only the Smart-agent predictive model technology will be employed by a user-consumer. But when more than one predictive model technology is added in to leverage their respective synergies, a decision engine algorithm is needed to single out which predicted class produced in parallel by sev eral predictive model technologies would be the best to rely O.

[0143] FIG. 6 is a flowchart diagram of a method 600 for using the PMML Documents (128, 132, 136, 140, 144, and 148) of FIG. 1 with an algorithm for the run-time operation of parallel predictive model technologies.

[0144] Method 600 depends on an apparatus to execute an algorithm to use the predictive technologies produced by method 100 (FIG. 1) and exported as PMML Documents.<br>Method 600 can provide a substantial commercial advantage in a real-time, record-by-record application by a business. One or more PMML Documents 601-606 are imported and put to work in parallel as predictive model technologies 611 616 to simultaneously predicta class and its confidence in that class for each new record in a raw data record input 618 that are presented to them.

[0145] It is important that these records receive a datacleanup 620 and a data-enrichment, as were described for steps 108 and 122 in FIG. 1. A resulting enriched data 624 with newly derived fields in the records is then passed in parallel for simultaneous consideration and evaluation by all the predictive model technologies 611-616 present. Each will transform its inputs into a predicted class 631-636 and a confidence 641-646 stored in a computer memory storage mechanism.

[0146] A record-by-record decision engine 650 inputs user strategies in the form of flag settings 652 and rules 654 to decision on which to output as a prevailing predicted class output 660 and to compute a normalized confidence output 661. Such record-by-record decision engine 650 is detailed here next in FIG. 7.

Typical examples of prevailing predicted classes 660:

[0147] Method 600 works with at least two of the predictive models from steps 128, 132, 136, 140, 144, and 148 (of FIG. 1). The predictive models each simultaneously produce a score and a score-confidence level in parallel sets, all from a particular record in a plurality of enriched-data records. These combine into a single result to return to a user-service consumer as a decision.

[0148] Further information related to combining models is included in Adjaoute 592. Special attention should be placed on FIG. 30 and the description in Column 22 on combining the technologies. There, the neural network, Smart-agent, data mining, and case-based reasoning technologies all come together to produce a final decision, such as if a particular electronic transaction is fraudulent, in a different application, if there is network intrusion.

[0149] FIG. 7 is a flowchart diagram of an apparatus with an algorithm 700 for the decision engine 650 of FIG. 6. Algo rithm 700 chooses which predicted class 631-636, or a com posite of them, should be output as prevailing predicted class 660. Switches or flag settings 652 are used to control the decision outcome and are fixed by the user-service consumer in operating their business based on the data science embod [0150] A step 702 inspects the rule type then in force. Compiled flag settings rules are fuzzy rules (business rules) developed with fuzzy logic. Fuzzy rules are used to merge the predicted classes from all the predictive models and technologies 631-636 and decide on one final prediction, herein, prevailing predicted class 660. Rules 654 are either manually written by analytical engineers, or they are automatically generated when analyzing the enriched training data 124 (FIG. 1) in steps 126, 130, 134, 138, 142, and 146.

[0151] If in step 702 it is decided to follow "compiled" rules', thena step 704 invokes the compiled flag settings rules and returns with a corresponding decision 706 for output as prevailing predicted class 660.

[0152] If in step 702 it is decided to follow "smart agents", then a step 708 invokes the smart agents and returns with a corresponding decision 710 for output as prevailing predicted class 660.

[0153] If in step 702 it is decided to follow "predefined rules', then a step 712 asks if the flag settings should be applied first. If not, a step 714 applies a winner-take-all test to all the individual predicted classes 631-636 (FIG. 6). A step tests if one particular class wins. If yes, a step 718 outputs that winner class for output as prevailing predicted class 660.

[0154] If not in step 716, a step 720 applies the flag settings to the individual predicted classes  $631-636$  (FIG. 6). Then a step  $722$  asks there is a winner rule. If yes, a step  $724$  outputs that winner rule decision for output as prevailing predicted class 660. Otherwise, a step 726 outputs an "otherwise" rule decision for output as prevailing predicted class 660.

[0155] If in step 712 flag setting are to be applied first, a step 730 applies the flags to the individual predicted classes 631 636 (FIG. 6). Then a step 732 asks if there is a winner rule. If yes, then a step 734 outputs that winner rule decision for output as prevailing predicted class 660. Otherwise, a step 736 asks if the decision should be winner-take-all. If no, a step 738 outputs an "otherwise" rule decision for output as prevailing predicted class 660.

[0156] If in step 736 it should be winner-take-all, a step 740 applies winner-take-all to each of the individual predicted classes 631-636 (FIG. 6). Then a step 742 asks if there is now a winner class. If not, step 738 outputs an "otherwise' rule decision for output as prevailing predicted class 660. Other wise, a step 744 outputs a winning class decision for output as prevailing predicted class 660.

[0157] Compiled flag settings rules in step 704 are fuzzy rules, e.g., business rules with fuzzy logic. Such fuzzy rules are targeted to merge the predictions 631-636 into one final prediction 660. Such rules are either written by analytical engineers or are generated automatically by analyses of the training data.

[0158] When applying flag settings to the individual predictions, as in step 730, an algorithm for a set of ordered rules that indicate how to handle predictions output by each pre diction technology. FIG. 8 illustrates this further.

[0159] FIG. 8 shows flag settings 800 as a set of ordered rules 801-803 that indicate how to handle each technology prediction  $631-636$  (FIG. 6). For each technology  $611-616$ , there is at least one rule  $801-803$  that provides a corresponding threshold 811-813. Each are then compared to prediction confidences 641-646.

[0160] When a corresponding incoming confidence  $820$  is higher or equal to a given threshold 811-813 provided by a rule 801-803, the technology 611-616 associated with rule 801-803 is declared "winner" and its class and confidence are used as the final prediction. When none of the technologies 611-616 win, an "otherwise rule' determines what to do. In this case, a clause indicates how to classify the transaction (fraud/not-fraud) and it sets the confidence to zero.

Consider the following example:

A first rule, e.g., 801, looks at a Smart-agent confidence (e.g., 641) of 0.7, but that is below a given corresponding threshold (e.g., 811) of 0.75 so inspection continues.

[0.161] A second rule (e.g.,  $802$ ) looks at a data mining confidence (e.g., 642) of 0.8 which is above a given threshold (e.g., 812) of 0.7. Inspection stops here and decision engine 650 uses the Data Mining prediction (e.g., 632) to define the final prediction (e.g., 660). Thus it is decided in this example that the incoming transaction is fraudulent with a confidence of 0.8.

0162. It is possible to define rules that apply only to spe cific kinds of predictions. For example, a higher threshold is associated with predictions of fraud, as opposed to prediction classes of non-frauds.

[0163] A winner-take-all technique groups the individual predictions 631-636 by their prediction output classes. Each Prediction Technology is assigned its own weight, one used when it predicts a fraudulent transaction, another used when it predicts a valid transaction. All similar predictions are grouped together by Summing their weighted confidence. The sum of the weighted confidences is divided by the sum of the weights used in order to obtain a final confidence between 0.0 and 1.0.

For example:

Here in the Example, two prediction technologies (e.g., 611 and  $612$ ) are predicting (e.g.,  $631$  and  $632$ ) a "fraud" class for the transaction. So their cumulated weighted confidence here is computed as:  $2*0.7+1*0.8$  which is 2.2, and stored in computer memory. Only case-based-reasoning (e.g., 614) predicts (e.g., class 634) a "valid' transaction, so its weighted confidence here is computed as: 1\*0.4, and is also stored in computer memory for comparison later.

[0164] Since the first computed value of 2.2 is greater than the second computed value of 0.4, this particular transaction in this example is decided to belong to the "fraud' class. The confidence is then normalized for output by dividing it by the sum of the weights that where associated with the fraud (2 and 1). So the final confidence (e.g., 661) is computed by 2.2/(2+ 1) giving: 0.73.

[0165] Some models 611-616 may have been trained to output more than just two binary classes. A fuzzification can provide more than two slots, e.g., for buy/sell/hold, or declined/suspect/approved. It may help to group classes by type of prediction (fraud or not-fraud).

For example:

[0166] In a first example, similar classes are grouped together. So fraud= $2*0.6+1*0.5=1.7$ , and valid= $2*0.7=1.4$ . The transaction in this example is marked as fraudulent.

[0167] In a second example, all the classes are distinct, with the following equation:  $2*0.6$  "00"+1\*0.5 "01"+2\*0.7 "G" so the winner is the class "G" and the transaction is marked as valid in this example.

[0168] Embodiments of the present invention integrate the constituent opinions of the technologies and make a single prediction class. How they integrate the constituent predictions 631-636 depend on a user-service consumers' selec tions of which technologies to favor and how to favor, and such selections are made prior to training the technologies, e.g., through a model training interface.

[0169] A default selection includes the results of the neural network technology, the Smart-agent technology, the data mining technology, and the case-based reasoning technology. Alternatively, the user-service consumer may decide to use any combination of technologies, or to select an expert mode with four additional technologies: (1) rule-based reasoning technology; (2) fuzzy logic technology; (3) genetic algorithms technology; and (4) constraint programming technol Ogy.

[0170] One strategy that could be defined by a user-service consumer-consumer assigns one vote to each predictive tech nology 611-616. A final decision 660 then stems from a majority decision reached by equal votes by the technologies within decision engine 650.

[0171] Another strategy definable by a user-service consumer-consumer assigns priority values to each one of technologies 611-616 with higher priorities that more heavily determine the final decision, e.g., that a transaction is fraudu lent and another technology with a lower priority determines that the transaction is not fraudulent, then method embodi ments of the present invention use the priority values to dis

criminate between the results of the two technologies and determine that the transaction is indeed fraudulent.

[0172] A further strategy definable by a user-service consumer-consumer specifies instead a set of meta-rules to help choose a final decision 660 for output. These all indicate an output prediction class and its confidence level as a percent age (0-1000, or 0-1.0) proportional to how confident the system apparatus is in the prediction.

[0173] FIG. 9 illustrates a method 900 of business decision making that requires the collaboration of two businesses, a service provider 901 and a user-consumer 902. The two businesses communicate with one another via secure Internet between network servers. The many data records and data files passed between them are hashed or encrypted by a triple DES algorithm, or similar protection. It also possible to send a non-encrypted filed through an encrypted channel. Users of the platform would upload their data through SSL/TLS from a browser or from a command line interface (SCP or SFTP). [0174] The service-provider business 901 combines method 100 (FIG. 1) and method 600 (FIG. 6) and their constituent algorithms. It accepts supervised and unsupervised training data 904 and strategies 906 from the user service consumer business 902. Method 100 then processes such as described above with FIGS. 1-8 to produce a full set of fully trained predictive models that are passed to method 600.

[0175] New records from operations 906 provided, e.g., in real-time as they occur, are passed after being transformed by encryption from the user-service consumer business 902 to the service provider business 901 and method 600. An on going run of scores, predictions, and decisions 908 (produced by method 600 according to the predictive models of method 100 and the strategies 905 and training data 904) are returned to user-service consumer business 902 after being trans formed by encryption.

0176 With some adjustment and reconfiguration, method 900 is trained for a wide range of uses, e.g., to classify fraud/ no-fraud in payment transaction networks, to predict buy/sell/ hold in stock trading, to detect malicious insider activity, and to call for preventative maintenance with machine and device failure predictions.

0177 Referring again to FIG. 9, another method of oper ating an artificial intelligence machine to improve their deci sions from included predictive models begins by deleting with at least one processor a selected data field and any data values contained in the selected data field from each of a first series of data training records stored in a memory of the artificial intelligence machine to exclude each data field in the first series of data training records that has more than a threshold number of random data values, or that has only one repeating data value, or that has too small a Shannon entropy, and using an information gain to select the most useful data fields, and then transforming a Surviving number of data fields in all the first series of data training records into a corresponding reduced-field series of data training records stored in the memory of the artificial intelligence machine.

[0178] A next step includes adding with the at least one processor a new derivative data field to all the reduced-field series of data training records stored in the memory and initializing each added new derivative data field with a new data value, and including an apparatus for executing an algo rithm to either change real scaler numeric data values into fuzzy values, or if symbolic, to change a behavior group data value, and testing that a minimum number of data fields survive, and if not, then to generate a new derivative data field and fix within each an aggregation type, a time range, a filter, a set of aggregation constraints, a set of data fields to aggre gate, and a recursive level, and then assessing the quality of a newly derived data field by testing it with a test set of data, and then transforming the results into an enriched-field series of data training records stored in the memory of the artificial intelligence machine.

[0179] A next step includes verifying with the at least one processor that each predictive model if trained with the enriched-field series of data training records stored in the memory produces decisions having fewer errors than the same predictive model trained only with the first series of data training records.

[0180] A further step includes recording a data-enrichment descriptor into the memory to include an identity of selected data fields in a data training record format of the first series of data training records that were subsequently deleted, and which newly derived data fields were subsequently added, and how each newly derived data field was derived and from which information sources.

[0181] A next step includes causing the at least one processor of the artificial intelligence machine to start extracting decisions from a new series of data records of new events by receiving and storing the new series of data records in the memory of the artificial intelligence machine.

[0182] A further step includes causing the at least one processor to fetch the data-enrichment descriptor and use it to select which data fields to delete and then deleting all the data values included in the selected data fields from each of a new series of data records of new events. Each data field deleted matches a data field in the first series of data training records had more than a threshold number of random data values, or that had only one repeating data value, or that had too small a Shannon entropy.

0183) A next step includes adding with the at least one processor a new derivative data field to each record of the new series of data records stored in the memory according to the data-enrichment descriptor, and initializing each added new derivative data field with a new data value stored in the memory. Each new derivative data field added matches a new derivative data field added to the enriched-field series of data training records in which real scaler numeric data values were changed into fuzzy values, or if symbolic, were changed into a behavior group data value stored in the memory, and were tested that a minimum number of data fields survive, and if not, then that generated a new derivative data field and fixed within each an aggregation type, a time range, a filter, a set of aggregation constraints, a set of data fields to aggregate, and a recursive level.

[0184] The method concludes by producing and outputting a series of predictive decisions with the at least one processor that operates at least one predictive model algorithm derived from one originally built and trained with records having a same record format described by the data-enrichment descriptor and stored in the memory of the artificial intelli gence machine.

[0185] FIG. 10 represents an apparatus for executing an algorithm 1000 for reclassifying a decision 660 (FIG. 6) for business profitability reasons. For example, when a payment card transaction for a particular transaction amount SX has already been preliminarily "declined" and included in a decision 1002 (and 660, FIG. 6) according to some other decision model. A test 1004 compares a dollar transaction "threshold amount-A"  $1006$  to a computation  $1008$  of the running average business aparticular user has been doing with the account involved. The rational for doing this is that valuable custom ers who do more than an average amount (threshold-A 1006) of business with their payment card should not be so easily or trivially declined. Some artificial intelligence deliberation and reconsideration is appropriate.

[0186] If, however test 1004 decides that the accountholder has not earned special processing, a "transaction declined" decision 1010 is issued as final (transaction-declined 110). Such is then forwarded by a financial network to the merchant point-of-sale (POS).

[0187] But when test 1004 decides that the accountholder has earned special processing, a transaction-preliminarily approved decision 1012 is carried forward to a test 1014. A threshold-B transaction amount 1016 is compared to the transaction amount SX. Essentially, threshold-B transaction amount 1016 is set at a level that would relieve qualified accountholders of ever being denied a petty transaction, e.g., under S250, and yet not involve a great amount of risk should the "positive' scoring indication from the "other decision model" not prove much later to be "false". If the transaction amount SX is less than threshold-B transaction amount 1016, a "transaction approved" decision 1018 is issued as final. Such is then forwarded by the financial network to the mer chant CP/CNP, unattended terminal, ATM, online payments, etc.

[0188] If the transaction amount \$X is more than threshold-B transaction amount 1016, a transaction-preliminarily approved decision 1020 is carried forward to a familiar trans action pattern test  $1022$ . An abstract  $1024$  of this account's transaction patterns is compared to the instant transaction. with a new baby as evidenced in purchases of particular items, then all future purchases that could be associated are reason ably predictable. Or, in another example, if the accountholder seems to be on business in a foreign country as evidenced in purchases of particular items and travel arrangements, then all future purchases that could be reasonably associated are to be expected and scored as lower risk. And, in one more example, if the accountholder seems to be a professional of specific things and arrangements, then these future purchases too could be reasonably associated are be expected and scored as lower risk.

[0189] So if the transaction type is not a familiar one, then a "transaction declined" decision  $1026$  is issued as final. Such is then forwarded by the financial network 106 to the mer-<br>chant (CP and/or CNP) and/or unattended terminal/ATM. Otherwise; a transaction-preliminarily-approved decision 1028 is carried forward to a threshold-C test 1030.

[0190] A threshold-C transaction amount 1032 is compared to the transaction amount SX. Essentially, threshold-C transaction amount 1032 is set at a level that would relieve qualified accountholders of being denied a moderate transac tion, e.g., under S2500, and yet not involve a great amount of risk because the accountholder's transactional behavior is within their individual norms. If the transaction amount SX is less than threshold-C transaction amount 1032, a "transaction approved" decision 1034 is issued as final (transaction-approved). Such is then forwarded by the financial network 106 to the merchant (CP and/or CNP) and/or unattended terminal/ ATM.

0191) If the transaction amount SX is more than thresh old-C transaction amount 1032, a transaction-preliminarily approved decision 1036 is carried forward to a familiar user device recognition test 1038. An abstract 1040 of this account's user devices is compared to those used in the instant transaction.

[0192] So if the user device is not recognizable as one employed by the accountholder, then a "transaction declined decision 1042 is issued as final. Such is then forwarded by the financial network 106 to the merchant (CP and/or CNP) and/or unattended terminal/ATM. Otherwise; a transaction-preliminarily-approved decision 1044 is carried forward to a threshold-D test 1046.

[0193] A threshold-D transaction amount 1048 is compared to the transaction amount SX. Basically, the thresh old-D transaction amount 1048 is set at a higher level that would avoid denying substantial transactions to qualified accountholders, e.g., under S10,000, and yet not involve a great amount of risk because the accountholder's user devices are recognized and their instant transactional behavior is within their individual norms. If the transaction amount SX is less than threshold-D transaction amount 1032, a "transaction approved' decision 1050 is issued as final. Such is then for warded by the financial network 106 to the merchant (CP and/or CNP) and/or unattended terminal/ATM.

[0194] Otherwise, the transaction amount \$X is just too large to override a denial if the other decision model decision 1002 was "positive', e.g., for fraud, or some other reason. In such case, a "transaction declined' decision 1052 is issued as final (transaction-declined 110). Such is then forwarded by the financial network 106 to the merchant (CP and/or CNP) and/or unattended terminal/ATM.

[0195] In general, threshold-B 1016 is less than threshold-C 1032, which in turn is less than threshold-D 1048. It could be that tests 1022 and 1038 would serve profits better if swapped in FIG. 10. Embodiments of the present invention would therefore include this variation as well. It would seem that threshold-A 1006 should be empirically derived and driven by business goals.

[0196] The further data processing required by technology 1000 occurs in real-time while merchant (CP and CNP, ATM and all unattended terminal) and users wait for approved/ declined data messages to arrive through financial network. The consequence of this is that the abstracts for this-ac count's-running-average-totals 1008, this account's-transaction-patterns 1024, and this-account's-devices 1040 must all be accessible and on-hand very quickly. A simple look-up is preferred to having to compute the values. The Smart agents and the behavioral profiles they maintain and that we've described in this Application and those we incorporate herein by reference are up to doing this job well. Conventional methods and apparatus may struggle to provide this informa tion quickly enough.

[0197] FIG. 10 represents for the first time in machine learning an apparatus that allows a different threshold for each customer. It further enables different thresholds for the same customer based on the context, e.g., a Threshold-1 while traveling, a Threshold-2 while buying things familiar with his purchase history, a Threshold-3 while in same area where they live, a Threshold-4 during holidays, a Threshold-5 for nights, a Threshold-6 during business hours, etc.

[0198] FIG. 11 represents an algorithm that executes as Smart-agent production apparatus 1100, and is included in the build of smart-agents in steps 126 and 127 (FIG. 1), or as step 611 (FIG. 6) in operation. The results are either exported as an ..IFM-type XML document in step 128, or used locally as in method 600 (FIG. 6). Step 126 (FIG. 1) builds a population of smart-agents and their profiles that are represented in FIG. 11 as smart-agents S1 1102 and Sn 1104. Step 127 (FIG. 1) initialized that build. Such population can reach into the mil lions for large systems, e.g., those that handle payment trans action requests nationally and internationally for millions of cardholders (entities).

[0199] Each new record 1106 received, from training records 124, or from data enrichment 622 in FIG. 6, is inspected by a step 1108 that identifies the entity unique to the record that has caused to record to be generated. A step 1110 gets the corresponding Smart-agent that matches this identi fication from the initial population of Smart-agents 1102, 1102 it received in step 128 (FIG. 1). A step 1112 asks if any were not found. A step 1114 uses default profiles optimally defined for each entity, and to create and initialize smartagents and profiles for entities that do not have a match in the initial population of smart-agents 1102, 1102. A step 1116 uses the matching Smart-agent and profile to assess record 1106 and issues a score 1118. A step 1120 updates the match ing Smart-agent profile with the new information in record 1106.

[0200] A step 1122 dynamically creates/removes/updates and otherwise adjusts attributes in any matching smart-agent profile based on a content of records 1106. A step 1124 adjusts an aggregation type (count, Sum, distinct, ratio, aver age, minimum, maximum, standard deviation, . . . ) in a matching smart-agent profile. A step 1126 adjusts a time range in a matching smart-agent profile. A step 1128 adjusts a filter based on a reduced set of transformed fields in a matching Smart-agent profile. A step 1130 adjusts a multi dimensional aggregation constraint in a matching smartagent profile. A step 1132 adjusts an aggregation field, if needed, in the matching Smart-agent profile. A step 1134 adjusts a recursive level in the matching Smart-agent profile. [0201] FIGS. 12-29 provide greater detail regarding the construction and functioning of algorithms that are employed in FIGS. 1-11.

#### Neural Network Technology

[0202] FIG. 12 is a schematic diagram of the neural network architecture used in method embodiments of the present invention. Neural network 1200 consists of a set of processing elements or neurons that are logically arranged into three layers: (1) input layer 1201; (2) output layer 1202; and (3) hidden layer 1203. The architecture of neural network 1200 is similar to a back propagation neural network, but its training, utilization, and learning algorithms are different. The neurons in input layer 1201 receive input fields from a training table. Each of the input fields are multiplied by a weight such as weight "Wij" 1204 a to obtain a state or output that is passed along another weighted connection with weights "V<sub>j</sub>t"  $1205$ between neurons in hidden layer 1202 and output layer 1203. The inputs to neurons in each layer come exclusively from output of neurons in a previous layer, and the output from these neurons propagate to the neurons in the following layers.

[ $0203$ ] FIG. 13 is a diagram of a single neuron in the neural network used in method embodiments of the present inven tion. Neuron 1300 receives input "i' from a neuron in a previous layer. Input "i" is multiplied by a weight "Wih" and processed by neuron 1300 to produce state "s'. State "s' is then multiplied by weight " $V_{hi}$ " to produce output "i" that is processed by neurons in the following layers. Neuron 1300 contains limiting thresholds 1301 that determine how an input is propagated to neurons in the following layers.

[0204] FIG. 14 is a flowchart of an algorithm 1400 for training neural networks with a single hidden layer that builds incrementally during a training process. The hidden layers may also grow in number later during any updates. Each training process computes a distance between all the records in a training table, and groups some of the records together. In a first step, a training set "S" and input weights "bi' are initialized. Training set "S" is initialized to contain all the records in the training table. Each field "i" in the training table is assigned a weight "bi" to indicate its importance. The input weights "bi" are selected by a client. A distance matrix D is created. Distance matrix D is a square and symmetric matrix of size NxN, where N is the total number of records in training set "S". Each element "Dij" in row "i" and column "j" of distance matrix D contains the distance between record "i" and record "j" in training set "S". The distance between two records in training set "S" is computed using a distance measure.

[0205] FIG. 15 illustrates a table of distance measures 1500 that is used in a neural network training process. Table 1500 lists distance measures that is used to compute the distance between two records Xi and Xj in training set "S". The default distance measure used in the training process is a Weighted Euclidean distance measure that uses input weights "bi' to assign priority values to the fields in a training table.

 $[0206]$  In FIG. 14, a distance matrix D is computed such that each element at row "i" and column "j" contains  $d(Xi, Xj)$ between records  $Xi$  and  $Xi$  in training set "S". Each row "i" of distance matrix D is then sorted so that it contains the dis tances of all the records in training set "S" ordered from the closest one to the farthest one.

[0207] A new neuron is added to the hidden layer of the neural network the largest subset "Sk" of input records having the same output is determined. Once the largest subset "Sk" is determined, the neuron group is formed at step 97. The neu ron group consists of two limiting thresholds, Blow and Ohigh, input weights "Wh', and output weights "Vh', such that  $\Theta$ low=Dk, "j" and  $\Theta$ high=Dk, l, where "k" is the row in the sorted distance matrix D that contains the largest Subset "Sk" of input records having the same output, "j" is the index of the first column in the subset "Sk" of row "k', and 1 is the index of the last column in the subset "Sk" of row "k'. The input weights "Wh" are equal to the value of the input record in row "k" of the distance matrix  $D$ , and the output weights "Vh" are equal to zero except for the weight assigned between the created neuron in the hidden layer and the neuron in the output layer representing the output class value of any records belonging to subset "Sk". A subset "Sk" is removed from training set 'S', and all the previously existing output weights "Vh' between the hidden layer and the output layer are doubled. Finally, the training set is checked to see if it still contains input records, and if so, the training process goes back. Otherwise, the training process is finished and the neu ral network is ready for use.

[0208] FIG. 16 is a flowchart of an algorithm 1600 for propagating an input record through a neural network. An input record is propagated through a network to predict if its output signifies a fraudulent transaction. A distance between the input record and the weight pattern "Wh' between the input layer and the hidden layer in the neural network is computed. The distance 'd' is compared to the limiting thresholds low and high of the first neuron in the hidden layer. If the distance is between the limiting thresholds, then the weights "Wh" are added to the weights "Vh" between the hidden layer and the output layer of the neural network. If there are more neurons in the hidden layer, then the propagation algorithm goes back to repeat steps for the other neurons in the hidden layer. Finally, the predicted output class is determined according to the neuron at the output layer that has the higher weight.

[0209] FIG. 17 is a flowchart of an algorithm 1700 for updating the training process of a neural network. The train ing process is updated whenever a neural network needs to learn some new input record. Neural networks are updated automatically, as soon as data from a new record is evaluated by method embodiments of the present invention. Alterna tively, the neural network may be updated offline.

[0210] A new training set for updating a neural network is created. The new training set contains all the new data records that were not utilized when first training the network using the training algorithm illustrated in FIG. 14. The training set is checked to see if it contains any new output classes not found in the neural network. If there are no new output classes, the updating process proceeds with the training algorithm illus trated in FIG. 14. If there are new output classes, then new neurons are added to the output layer of the neural network, so that each new output class has a corresponding neuron at the output layer. When the new neurons are added, the weights from these neurons to the existing neurons at the hidden layer of the neural network are initialized to Zero. The weights from the hidden neurons to be created during the training algorithm are initialized as 2h, where "h" is the number of hidden neurons in the neural network prior to the insertion of each new hidden neuron. With this initialization, the training algorithm illustrated in FIG. 14 is started to form the updated neural network technology.

[0211] Evaluating if a given input record belongs to one class or other is done quickly and reliably with the training, propagation, and updating algorithms described.

#### Smart-Agent Technology

[0212] Smart-agent technology uses multiple smart-agents in unsupervised mode, e.g., to learn how to create profiles and clusters. Each field in a training table has its own Smart-agent that cooperates with others to combine some partial pieces of knowledge they have about data for a given field, and validate the data being examined by another smart-agent. The smartagents can identify unusual data and unexplained relation ships. For example, by analyzing a healthcare database, the Smart-agents would be able to identify unusual medical treat ment combinations used to combat a certain disease, or to identify that a certain disease is only linked to children. The Smart-agents would also be able to detect certain treatment combinations just by analyzing the database records with fields such as symptoms, geographic information of patients, medical procedures, and so on.

[0213] Smart-agent technology creates intervals of normal values for each one of the fields in a training table to evaluate if the values of the fields of a given electronic transaction are normal. And the technology determines any dependencies between each field in a training table to evaluate if the values of the fields of a given electronic transaction or record are coherent with the known field dependencies. Both goals can generate warnings.

[0214] FIG. 18 is a flowchart of an algorithm for creating intervals of normal values for a field in a training table. The algorithm illustrated in the flowchart is run for each field "a" in a training table. A list "La" of distinct couples ("vai", "nai") is created, where "vai" represents the  $i<sup>th</sup>$  distinct value for field "a" and "nai" represents its cardinality, e.g., the number of times value "vai" appears in a training table. At step 119, the field is determined to be symbolic or numeric. If the field is symbolic, each member of "La" is copied into a new list "Ia" whenever "nai" is superior to a threshold "Omin" that represents the minimum number of elements a normal interval must include. " $\Theta$ min" is computed as " $\Theta$ min"=fmin \*M, where M is the total number of records in a training table and fmin is a parameter specified by the user representing the minimum frequency of values in each normal interval. Finally, the relations (a, Ia) are saved in memory storage. Whenever a data record is to be evaluated by the smart-agent technology, the value of the field "a" in the data record is compared to the normal intervals created in "Ia' to determine if the value of the field "a" is outside the normal range of values for that given field.

[0215] If the field "a" is determined to be numeric, then the list "La" of distinct couples ("vai', nai) is ordered starting with the smallest value Va. At step 122, the first element e=(val, nal) is removed from the list "La', and an interval  $NI=[val, val]$  is formed. At step 124, the interval NI is enlarged to NI=[Val, vak] until Vak-Val> $\Theta$ dist, where  $\Theta$ dist represents the maximum width of a normal interval. Odist is computed as  $\Theta$ dist=(maxa-mina)/nmax, where nmax is a parameter specified by the user to denote the maximum num ber of intervals for each field in a training table. The values that are too dissimilar are not grouped together in the same interval.

[0216] The total cardinality "na" of all the values from "val" to "vak" is compared to " $\Theta$ min" to determine the final value of the list of normal intervals "Ia'. If the list "Ia' is not empty, the relations (a, Ia) are saved. Whenever a data record is to be evaluated by the smart-agent technology, the value of the field "a" in the data record is compared to the normal intervals created in "Ia' to determine if the value of the field 'a' is outside the normal range of values for that given field. If the value of the field "a" is outside the normal range of values for that given field, a warning is generated to indicate that the data record is likely fraudulent.

[0217] FIG. 19 is a flowchart of an algorithm 1900 for determining dependencies between each field in a training table. A list LX of couples (Vxi, nxi) is created for each field "x" in a training table. The values vxi in Lx for which (nxi/ nT)>0x are determined, where nT is the total number of records in a training table and  $\Theta$ x is a threshold value specified by the user. In a preferred embodiment,  $\Theta$ x has a default value of 1%. At step 132, a list Ly of couples (vyi, nyi) for each field y,  $Y \neq X$ , is created. The number of records nij where  $(x=xi)$  and  $(y=yj)$  are retrieved from a training table. If the relation is significant, that is if  $(nij/nxi)$   $\Theta$ xy, where  $\Theta$ xy is a threshold value specified by the user when the relation  $(X=x)$  $\Leftrightarrow$  (Y=yj) is saved with the cardinalities nxi, nyj, and nij, and accuracy (nij/nxi). In a preferred embodiment, 0xy has a default value of 85%.

[0218] All the relations are saved in a tree made with four levels of hash tables to increase the speed of the Smart-agent technology. The first level in the tree hashes the field name of the first field, the second level hashes the values for the first field implying some correlations with other fields, the third level hashes the field name with whom the first field has some correlations, and finally, the fourth level in the tree hashes the values of the second field that are correlated with the values of the first field. Each leaf of the tree represents a relation, and at each leaf, the cardinalities nxi, nyj, and nij are stored. This allows the Smart-agent technology to be automatically updated and to determine the accuracy, prevalence, and the expected predictability of any given relation formed in a training table.

0219 FIG. 20 is a flowchart of an algorithm 2000 for verifying the dependencies between the fields in an input record. For each field'x' in the input record corresponding to an electronic transaction, the relations starting with  $[(X=x)^2]$  $\Leftrightarrow$  ...] are found in the smart-agent technology tree. For all the other fields "y" in a transaction, the relations  $[(X=x)]$  $\leftrightarrow$  (Y=v)] are found in the tree. A warning is triggered anytime  $Y$  $\neq$ V. The warning indicates that the values of the fields in the input record are not coherent with the known field dependencies, which is often a characteristic of fraudulent transactions.

[0220] FIG. 21 is a flowchart of an algorithm 2100 for updating Smart-agents. The total number of records nT in a training table is incremented by a new number of input records to be included in the update of the Smart-agent tech nology. For the first relation  $(X=xi) \Leftrightarrow (Y=yi)$  previously created in the technology, the parameters nxi, nyj, and nij are retrieved, and, nxi, nyj, and nij are respectively incremented. The relation is verified to see if it is still significant for includ ing it in a Smart-agent tree. If the relation is not significant, then it is removed from the tree. Finally, a check is performed to see if there are more previously created relations  $(X=x)$  $\Leftrightarrow$  \*(Y=yj)] in the technology. If there are, then algorithm 2100 goes back and iterates until there are no more relations in the tree to be updated.

### Data Mining Technology

[0221] FIG. 22 represents one way to implement a data mining algorithm as in steps 130-132 (FIG. 1). More detail is incorporated herein by reference to Adjaoute '592, and especially that relating to its FIG. 22. Here the data mining algorithm and the data tree of step 131 are highly advantaged by having been trained by the enriched data 124. Such results in far superior training compared to conventional training with data like raw data 106.

0222 Data mining identifies several otherwise hidden data relationships, including: (1) associations, wherein one event is correlated to another event such as purchase of gour met cooking books close to the holiday season; (2) sequences, wherein one event leads to another later event such as purchase of gourmet cooking books followed by the purchase of gourmet food ingredients; (3) classification, and, e.g., the recognition of patterns and a resulting new organization of data such as profiles of customers who make purchases of gourmet cooking books; (4) clustering, e.g., finding and visu alizing groups of facts not previously known; and (5) fore casting, e.g., discovering patterns in the data that can lead to predictions about the future.

[0223] One goal of data mining technology is to create a decision tree based on records in a training database to facili tate and speed up the case-based reasoning technology. The case-based reasoning technology determines if a given input record associated with an electronic transaction is similar to any typical records encountered in a training table. Each record is referred to as a "case'. If no similar cases are found, 15

Mar. 10, 2016

a warning is issued to flag the input record. The data mining technology creates a decision tree as an indexing mechanism for the case-based reasoning technology. Data mining tech nology can also be used to automatically create and maintain business rules for a rule-based reasoning technology.

[0224] The decision tree is an "N-ary" tree, wherein each node contains a Subset of similar records in a training data base. (An N-ary tree is a tree in which each node has no more than N children.) In preferred embodiments, the decision tree is a binary tree. Each subset is split into two other subsets, based on the result of an intersection between the set of records in the subset and a test on a field. For symbolic fields, the test is if the values of the fields in the records in the subset are equal, and for numeric fields, the test is if the values of the value. Applying the test on a subset splits the subset in two others, depending on if they satisfy the test or not. The newly nated from in the tree. The data mining technology creates the subsets recursively until each subset that is a terminal node in the tree represents a unique output class.

[0225] FIG. 22 is a flowchart of an algorithm 2200 for generating the data mining technology to create a decision tree based on similar records in a training table. Sets "S", R, and U are initialized. Set "S" is a set that contains all the records in a training table, set R is the root of the decision tree, and set U is the set of nodes in the tree that are not terminal nodes. Both Rand U are initialized to contain all the records in a training table. Next, a first node Ni (containing all the records in the training database) is removed from U. The triplet (field, test, value) that best splits the subset Si associ ated with the node Ni into two subsets is determined. The triplet that best splits the subset Si is the one that creates the smallest depth tree possible, that is, the triplet would either create one or two terminal nodes, or create two nodes that, when split, would result in a lower number of children nodes than other triplets. The triplet is determined by using an impurity function such as Entropy or the Gini index to find the information conveyed by each field value in the database. The field value that conveys the least degree of information con tains the least uncertainty and determines the triplet to be used for splitting the subsets.

 $[0226]$  A node Nij is created and associated to the first subset Sij formed. The node Nij is then linked to node Ni, and named with the triplet (field, test, value). Next, a check is performed to evaluate if all the records in subset Sij at node Nij belong to the same output class  $c_{ij}$ . If they do, then the prediction of node Nij is set to  $c_{ij}$ . If not, then node Nij is added to U. The algorithm then proceeds to check if there are still subsets Sij to be split in the tree, and if so, the algorithm goes back. When all subsets have been associated with nodes, the algorithm continues for the remaining nodes in U until U is determined to be empty.

0227 FIG. 23 represents a decision tree 2300 in an example for a database 2301 maintained by an insurance company to predict a risk of an insurance contract based on a type of a car and an age of its driver. Database 2301 has three fields: (1) age, (2) car type, and (3) risk. The risk field is the output class that needs to be predicted for any new incoming data record. The age and the car type fields are used as inputs. The data mining technology builds a decision tree, e.g., one that can ease a search of cases in case-based reasoning to determine if an incoming transaction fits any profiles of simi lar cases existing in its database. The decision tree starts with a root node NO (2302). Once the data records in database 2301 are analyzed, a test 2303 is determined that best splits database 2301 into two nodes, a node N1 (2304) with a subset 2305, and a node N2 (2306) with a subset 2307. Node N1 (2304) is a terminal node type, since all data records in subset 2305 have the same class output that indicates a high insur

ance risk for drivers that are younger than twenty-five. [0228] The data mining technology then splits a node  $N2$ (2306) into two additional nodes, a node N3 (2308) contain ing a subset 2309, and a node N4 (2310) containing a subset 2311. Both nodes N3 (2308) and N4 (2310) were split from node N2 (2306) based on a test 2312, that checks if the car type is a sports car. As a result, nodes N3 (2308) and N4 (2310) are terminal nodes, with node N3 (2308) signifying a high insurance risk and node N4 (2310) representing a low insurance risk.

[0229] The decision tree formed by the data mining technology is preferably a depth two binary tree, significantly reducing the size of the search problem for the case-based reasoning technology. Instead of searching for similar cases to an incoming data record associated with an electronic transaction in the entire database, the case-based reasoning technology only has to use the predefined index specified by the decision tree.

#### Case-Based Reasoning Technology

[0230] The case-based reasoning technology stores past data records or cases to identify and classify a new case. It reasons by analogy and classification. Case-based reasoning technologies create a list of generic cases that best represent the cases in its training table. A typical case is generated by computing similarities between all the cases in its training table and selecting those cases that best represent distinct cases. Whenever a new case is presented in a record, a deci sion tree is to determine if any input record it has on file in its database is similar to something encountered in its training table.

0231 FIG.24 is a flowchart of an algorithm for generating a case-based reasoning technology used later to find a record ing to a new transaction. An input record is propagated through a decision tree according to tests defined for each node in the tree until it reaches a terminal node. If an input record is not fully defined, that is, the input record does not contain values assigned to certain fields, and then the input record is propagated to a last node in a tree that satisfies all the tests. The cases retrieved from this node are all the cases belonging to the node's leaves.

[0232] A similarity measure is computed between the input record and each one of the cases retrieved. The similarity measure returns a value that indicates how close the input record is to a given case retrieved. The case with the highest similarity measure is then selected as the case that best represents the input record. The solution is revised by using a function specified by the user to modify any weights assigned to fields in the database. Finally, the input record is included in the training database and the decision tree is updated for learning new patterns.

[0233] FIG. 25 represents a table 2500 of global similarity measures useful by case-based reasoning technology. The table lists an example of six similarity measures that could be used in case-based reasoning to compute a similarity between cases. The Global Similarity Measure is a computation of the similarity between case values  $V_{1i}$  and  $V_{2i}$  and are based on local similarity measures  $\sin_i$  for each field  $y_i$ . The global similarity measures may also employ weights w, for different fields.

[0234] FIG. 26 is an example table of Local Similarity Measures useful in case-based reasoning. Table 2600 lists fourteen different Local Similarity Measures that is used by the global similarity measures listed. The local similarity measures depend on the field type and valuation. The field type is: (1) symbolic or nominal; (2) ordinal, when the values are ordered; (3) taxonomic, when the values follow a hierar chy; and (4) numeric, which can take discrete or continuous values. The Local Similarity Measures are based on a number of parameters, including: (1) the values of a given field for two cases,  $V_1$  and  $V_2$ ; (2) the lower (V<sub>1</sub> – and V<sub>2</sub> – ) and higher (V<sub>1</sub> + and  $V_2+$ ) limits of  $V_1$  and  $V_2$ ; (3) the set of all values that is reached by the field; (4) the central points of  $V_1$  and  $V_2$ , V1c and  $V2c$ ; (5) the absolute value "ec" of a given interval; and (6) the height "h" of a level in a taxonomic descriptor.

#### Genetic Algorithms Technology

0235 Genetic algorithms technologies include a library of genetic algorithms that incorporate biological evolution con cepts to find if a class is true, e.g., a business transaction is is used to analyze many data records and predictions generated by other predictive technologies and recommend its own efficient strategies for quickly reaching a decision.

Rule-Based Reasoning, Fuzzy Logic, and Constraint Programming Technologies

[0236] Rule-based reasoning, fuzzy logic, and constraint programming technologies include business rules, con straints, and fuzzy rules to determine the output class of a current data record, e.g., if an electronic transaction is fraudu lent. Such business rules, constraints, and fuzzy rules are derived from past data records in a training database or cre ated from predictable but unusual data records that may arise<br>in the future. The business rules is automatically created by the data mining technology, or they is specified by a user. The fuzzy rules are derived from business rules, with constraints specified by a user that specify which combinations of values for fields in a database are allowed and which are not.

[0237] FIG. 27 represents a rule 2700 for use with the rule-based reasoning technology. Rule 2700 is an IF-THEN rule containing an antecedent and consequence. The anteced ent uses tests or conditions on data records to analyze them. The consequence describes the actions to be taken if the data satisfies the tests. An example of rule 2700 that determines if a credit card transaction is fraudulent for a credit card belonging to a single user may include "IF (credit card user makes a purchase at 8 AM in New York City) and (credit card user makes a purchase at 8 AM in Atlanta) THEN (credit card number may have been stolen)". The use of the words "may have been" in the consequence sets a trigger that other rules need to be checked to determine if the credit card transaction is indeed fraudulent or not.

[0238] FIG. 28 represents a fuzzy rule 2800 to specify if a person is tall. Fuzzy rule 2800 uses fuzzy logic to handle the concept of partial truth, e.g., truth values between "com pletely true" and "completely false" for a person who may or may not be considered tall. Fuzzy rule 2800 contains a middle ground, in addition to the binary patterns of yes/no. Fuzzy rule 2800 derives here from an example rule such as

0239) "IF height >6 ft., THEN person is tall'.

Fuzzy logic derives fuzzy rules by "fuzzification" of the antecedents and "de-fuzzification" of the consequences of business rules.

[0240] FIG. 29 is a flowchart of an algorithm 2900 for applying rule-based reasoning, fuzzy logic, and constraint programming to determine if an electronic transaction is fraudulent. The rules and constraints are specified by a user service consumer and/or derived by data mining technology. The data record associated with a current electronic transac tion is matched against the rules and the constraints to deter mine which rules and constraints apply to the data. The data is tested against the rules and constraints to determine if the transaction is fraudulent. The rules and constraints are updated to reflect the new electronic transaction.

[0241] The present inventor, Dr. Akli Adjaoute and his Company, Brighterion, Inc. (San Francisco, Calif.), have been highly successful in developing fraud detection com puter models and applications forbanks, payment processors, and other financial institutions. In particular, these fraud detection computer models and applications are trained to follow and develop an understanding of the normal transac tion behavior of single individual accountholders. Such train ing is sourced from multi-channel transaction training data or single-channel. Once trained, the fraud detection computer models and applications are highly effective when used in real-time transaction fraud detection that comes from the same channels used in training.

[0242] Some embodiments of the present invention train several single-channel fraud detection computer models and applications with corresponding different channel training data. The resulting, differently trained fraud detection com puter models and applications are run several in parallel so each can view a mix of incoming real-time transaction mes sage reports flowing in from broad diverse sources from their unique perspectives. One may compute a "hit" the others will miss, and that's the point.

[0243] If one differently trained fraud detection computer model and application produces a hit, it is considered herein a warning that the accountholder has been compromised or has gone rogue. The other differently trained fraud detection computer models and applications should be and are sensi tized to expect fraudulent activity from this accountholder in the other payment transaction channels. Hits across all chan nels are added up and too many is reason to shut down all payment channels for the affected accountholder.

[0244] In general, a method of cross-channel financial fraud protection comprises training a variety of real-time, risk-scoring fraud model technologies with training data selected for each from a common transaction history. This then can specialize each member in the monitoring of a selected channel. After training, the heterogeneous real-time, risk-scoring fraud model technologies are arranged in parallel<br>so that all receive the same mixed channel flow of real-time transaction data or authorization requests.

[0245] Parallel, diversity trained, real-time, risk-scoring fraud model technologies are hosted on a network server platform for real-time risk scoring of a mixed channel flow of real-time transaction data or authorization requests. Risk thresholds are directly updated for particular accountholders in every member of the parallel arrangement of diversity trained real-time, risk-scoring fraud model technologies when any one of them detects a suspicious or outright fraudu lent transaction data or authorization request for the accountholder. So, a compromise, takeover, or suspicious

activity of an accountholder's account in any one channel is thereafter prevented from being employed to perpetrate a fraud in any of the other channels.<br>[0246] Such method of cross-channel financial fraud pro-

tection can further include building a population of real-time, long-term, and recursive profiles for each accountholder in each of the real-time, risk-scoring fraud model technologies. Then during real-time use, maintaining and updating the real time, long-term, and recursive profiles for each accountholder in each and all of the real-time, risk-scoring fraud model technologies with newly arriving data.

[0247] If during real-time use a compromise, takeover, or suspicious activity of the accountholder's account in any one channel is detected, then updating the real-time, long-term, and recursive profiles for each accountholder in each and all of the other real-time, risk-scoring fraud model technologies are included in a final risk score calculation 728 for the current transaction or authorization request.

[0248] Fifteen-minute vectors are a way to cross pollenate risks calculated in one channel with the others. The 15-minute vectors can represent an amalgamation or fuzzification of transactions in all channels, or channel-by channel. Once a 15-minute vector has aged, it is shifted into a 100-minute shift register means. These vectors represent velocity counts that is very effective in catching fraud as it is occurring in real time.

[0249] In every case, embodiments of the present invention include adaptive learning that combines three learning tech niques to evolve the artificial intelligence classifiers. First is the automatic creation of profiles, or Smart-agents, from his torical data, e.g., long-term profiling. The second is real-time learning, e.g., enrichment of the Smart-agents based on real time activities. The third is adaptive learning carried by incre mental learning algorithms.

[0250] For example, two years of historical credit card transactions data needed over twenty seventerabytes of data base storage. A Smart-agent is created for each individual card in that data in a first learning step, e.g., long-term profiling. Each profile is created from the card's activities and transactions that took place over the two year period. Each profile for each smart-agent comprises knowledge extracted field-byfield, such as merchant category code (MCC), time, amount for an mcc over a period of time, recursive profiling, zip codes, type of merchant, monthly aggregation, activity during the week, weekend, holidays, Card not present (CNP) versus card present (CP), domestic versus cross-border, etc. this profile will highlights all the normal activities of the smartagent (specific payment card).

[0251] Smart-agent technology learns specific behaviors of each cardholder and creates a Smart-agent to follow the behavior of each cardholder. Because it learns from each activity of a cardholder, the Smart-agent updates its profiles and makes effective changes at runtime. It is the only tech nology with an ability to identify and stop, in real-time, pre viously unknown fraud schemes. It has the highest detection rate and lowest false positives because it separately follows and learns the behaviors of each cardholder.

0252) Smart-agents have a further advantage in data size reduction. Once, say twenty-seventerabytes of historical data is transformed into Smart-agents, only 200-gigabytes is needed to represent twenty-seven million distinct smartagents corresponding to all the distinct cardholders.

[0253] Incremental learning technologies are embedded in the machine algorithms and Smart-agent technology to con tinually re-train from any false positives and negatives that occur along the way. Each corrects itself to avoid repeating the same classification errors. Data mining logic incremen tally changes the decision trees by creating a new link or updating the existing links and weights. Neural networks update the weight matrix, and case based reasoning logic updates generic cases or creates new ones. Smart-agents update their profiles by adjusting the normal/abnormal thresholds, or by creating exceptions.

(0254 FIG. 30 represents a flowchart of an algorithm 3000 executed by an apparatus needed to implement a method embodiment of the present invention for improving predictive model training and performance by data enrichment of trans action records.

[0255] The data enrichment of transaction records is done first with supervised and unsupervised training data 124 (FIG. 1) and training sets 420+422+424, 421+423+425, and 440+ 442+444 (FIG. 4) during training to build predictive models 127, 131, 135,139,143, and 147 (FIG. 1), and 601-606 (FIG. 6). These are ultimately deployed as predictive models  $611-616$  (FIG. 6) for use in real time with a raw feed of new event. non-training data records 906 (FIG. 9).

(0256 FIG. 30 shows on the left that method 500 (FIG. 5) includes a step 3001 to delete some data fields not particularly useful, a step 3002 to add some data fields are helpful, a step 3003 to test that the data fields added in step 3002 do improve the final predictions, and a step 3004 to loop until all the original data fields are scrutinized.

[0257] In summary, embodiments of the present invention include a method 3000 of operating an artificial intelligence machine 100 to produce predictive model language documents 128, 132, 136, 140, 144, and 148 describing improved predictive models that generate better business decisions 660, 661 from raw data record inputs 618. A first phase includes deleting 3001 with at least one processor a selected data field and any data values contained in the selected data field from each of a first series of data records (e.g., training sets 420+ 422+424, 421+423+425, and 440+442+444 FIG. 4) stored in a memory of the artificial intelligence machine to exclude each data field in the first series of data records that has more than a threshold number of random data values, or that has only one repeating data value, or has too small a Shannon entropy, and then transforming a surviving number of data fields in all the first series of data records into a corresponding reduced-field series of data records stored in the memory of the artificial intelligence machine.

[0258] A next phase includes adding 3002 with the at least one processor a new derivative data field to all the reduced field series of data records stored in the memory of the arti ficial intelligence machine and initializing each added new derivative data field with a new data value, and including an apparatus for executing an algorithm to either change real scaler numeric data values into fuzzy values, or if symbolic, to change a behavior group data value, and testing that a mini mum number of data fields survive, and if not, then to generate a new derivative data field and fix within each an aggregation type, a time range, a filter, a set of aggregation constraints, a set of data fields to aggregate, and a recursive level, and then assessing the quality of a newly derived data field by testing it with a test set of data, and then transforming the results into an enriched-field series of data records stored in the memory of the artificial intelligence machine.

[0259] And a next phase includes verifying 3003 with the at least one processor that a predictive model trained with the enriched-field series of data records stored in the memory of the artificial intelligence machine produces more accurate predictions from the artificial intelligence machine having fewer errors than the same predictive model trained only with the first series of data records.

0260 Another phase of the method includes verifying with the at least one processor that a predictive model 611 616 fed a non-training set of the enriched-field series of data records 906 stored in the memory of the artificial intelligence machine produces more accurate predictions 660, 661 with fewer errors than the same predictive model fed with data records with unmodified data fields.

0261) A still further phase of the method includes record ing as a data-enrichment descriptor 3006 and 3008 into the memory of the artificial intelligence machine including the at least one processor an identity of any data fields in a data record format of the first series of data records that were subsequently deleted and can be ignored, and which newly derived data fields were subsequently added, and how each newly derived data field was derived and from which infor mation sources.

[0262] Another phase includes passing along the data-enrichment descriptor with the at least one processor informa-<br>tion stored in the memory of the artificial intelligence machine to an artificial intelligence machine including processors for predictive model algorithms to produce and output better business decisions from its own feed of new events as raw data record inputs stored in the memory of the artificial intelligence machine.

[0263] A method  $622$  (FIG. 6) of operating an artificial intelligence machine including processors for predictive model algorithms that produces and that outputs better busi ness decisions 660, 661 from a new series of data records of new events as raw data record inputs 618 and 906, includes a phase to recover with at least one processor a recording of a data-enrichment descriptor stored in a memory of an artificial intelligence machine including an identity 3006 of any data fields in a data record format of a series of data records that were subsequently deleted by an artificial intelligence machine including processors for predictive model building, and which of any newly derived data fields 3008 were subse quently added, and how each newly derived data field was derived and from which information sources. A next phase includes accepting a new series of data records 906 of new events with the artificial intelligence machine including at least one processor to receive and store records in the memory of the artificial intelligence machine. A next phase of the method 3000 includes ignoring or deleting 3010 with the at least one processor all data fields and all data values contained in the data fields from each of a new series of data records of new events, stored in the memory of the artificial intelligence machine, according to the data-enrichment descriptor 3006. And in a next phase that includes adding 3011 with the at least one processor a new derivative data field to each record of the new series of data records stored in the memory of the artifi cial intelligence machine according to the data-enrichment descriptor 3008, and initializing each added new derivative data field with a new data value stored in the memory of the artificial intelligence machine.

0264. The method further includes producing and output ting a series of predictive decisions 660, 661 with the at least one processor that operates at least one predictive model algorithm 611-616 derived from one originally built and trained with records (e.g., training sets 420+422+424, 421+ 423+425, and 440+442+444 FIG. 4) having a same record format described by the data-enrichment descriptor and stored in the memory of the artificial intelligence machine.

[0265] The method excludes each data field stored in the memory of the artificial intelligence machine that has more than a threshold number of random data values, or that has only one repeating data value, or that has too small a Shannon entropy, and then transforming a surviving number of data fields into a corresponding reduced-field series of data records stored in the memory of the artificial intelligence machine.

[0266] The method adds a new derivative data field to a reduced-field series of data records stored in the memory of the artificial intelligence machine and initialize each added new derivative data field with a new data value, and to either change real scaler numeric data values into fuzzy values, or if symbolic, to change a behavior group data value stored in the memory of the artificial intelligence machine, and testing that a minimum number of data fields survive in that stored in the memory of the artificial intelligence machine, and if not, then to generate a new derivative data field and fix within each an aggregation type, a time range, a filter, a set of aggregation constraints, a set of data fields to aggregate, and a recursive level, and which the quality of each newly derived data field was test, and then transforming the results into an enriched field series of data records stored in the memory of the arti ficial intelligence machine.

[0267] Although particular embodiments of the present invention have been described and illustrated, such is not will no doubt become apparent to those skilled in the art, and it is intended that the invention only be limited by the scope of the appended claims.

1. A method of operating an artificial intelligence machine to improve their decisions from included predictive models, comprising:

- deleting with at least one processor a selected data field and any data values contained in the selected data field from each of a first series of data training records stored in a memory of the artificial intelligence machine to exclude each data field in the first series of data training records that has more than a threshold number of random data values, or that has only one repeating data value, or that has too small a Shannon entropy, and using any infor mation gained to select the most useful data fields, and then transforming a Surviving number of data fields in all the first series of data training records into a correspond ing reduced-field series of data training records stored in the memory of the artificial intelligence machine;
- adding with the at least one processor a new derivative data field to all the reduced-field series of data training records stored in the memory and initializing each added new derivative data field with a new data value, and including an apparatus for executing an algorithm to values, or if symbolic, to change a behavior group data value, and testing that a minimum number of data fields survive, and if not, then to generate a new derivative data field and fix within each an aggregation type, a time range, a filter, a set of aggregation constraints, a set of data fields to aggregate, and a recursive level, and then assessing the quality of a newly derived data field by

testing it with a test set of data, and then transforming the results into an enriched-field series of data training records stored in the memory of the artificial intelligence machine;

- Verifying with the at least one processor that each predic tive model if trained with the enriched-field series of data training records stored in the memory produces decisions having fewer errors than the same predictive model trained only with the first series of data training records;
- recording a data-enrichment descriptor into the memory to include an identity of selected data fields in a data train ing record format of the first series of data training records that were subsequently deleted, and which newly derived data fields were subsequently added, and how each newly derived data field was derived and from which information sources:
- causing the at least one processor of the artificial intelli gence machine to start extracting decisions from a new series of data records of new events by receiving and storing the new series of data records in the memory of the artificial intelligence machine;
- causing the at least one processor to fetch the data-enrich ment descriptor and use it to select which data fields to delete and then deleting all the data values included in the selected data fields from each of a new series of data records of new events;
- wherein, each data field deleted matches a data field in the first series of data training records had more than a threshold number of random data values, or that had only one repeating data value, or that had too small a Shannon entropy;
- adding with the at least one processor a new derivative data field to each record of the new series of data records stored in the memory according to the data-enrichment descriptor, and initializing each added new derivative data field with a new data value stored in the memory;<br>wherein, each new derivative data field added matches a
- new derivative data field added to the enriched-field series of data training records in which real scaler numeric data values were changed into fuzzy values, or if symbolic, were changed into a behavior group data value stored in the memory, and were tested that a minimum number of data fields survive, and if not, then that generated a new derivative data field and fixed within each an aggregation type, a time range, a filter, a set of aggregation constraints, a set of data fields to aggregate, and a recursive level; and
- producing and outputting a series of predictive decisions with the at least one processor that operates at least one predictive model algorithm derived from one originally built and trained with records having a same record format described by the data-enrichment descriptor and stored in the memory of the artificial intelligence machine.

2. A method of operating an artificial intelligence machine to produce predictive model language documents describing improved predictive models that generate better business decisions from raw data record inputs, comprising:

deleting with at least one processor a selected data field and any data values contained in the selected data field from each of a first series of data records stored in a memory of the artificial intelligence machine to exclude each data field in the first series of data records that has more than a threshold number of random data values, or that has only one repeating data value, or has too small a Shannon entropy, and then transforming a Surviving number of data fields in all the first series of data records into a corresponding reduced-field series of data records stored in the memory of the artificial intelligence machine;

- adding with the at least one processor a new derivative data field to all the reduced-field series of data records stored in the memory of the artificial intelligence machine and initializing each added new derivative data field with a new data value, and including an apparatus for executing an algorithm to either change real scaler numeric data values into fuzzy values, or if symbolic, to change a behavior group data value, and testing that a minimum number of data fields survive, and if not, then to generate<br>a new derivative data field and fix within each an aggregation type, a time range, a filter, a set of aggregation constraints, a set of data fields to aggregate, and a recur sive level, and then assessing the quality of a newly derived data field by testing it with a test set of data, and then transforming the results into an enriched-field series of data records stored in the memory of the arti ficial intelligence machine; and
- verifying with the at least one processor that a predictive model trained with the enriched-field series of data records stored in the memory of the artificial intelligence machine produces more accurate predictions from the artificial intelligence machine having fewer errors than the same predictive model trained only with the first series of data records.<br>3. The method of claim 2, further comprising:
- 
- verifying with the at least one processor that a predictive model supplied with a non-training set of the enrichedfield series of data records stored in the memory of the artificial intelligence machine produces more accurate predictions with fewer errors than the same predictive model fed with data records with unmodified data fields.
- 
- 4. The method of claim 2, further comprising: recording as a data-enrichment descriptor into the memory of the artificial intelligence machine including the at least one processor an identity of any data fields in a data record format of the first series of data records that were subsequently deleted, and which newly derived data fields were subsequently added, and how each newly derived data field was derived and from which informa tion sources; and
- passing along the data-enrichment descriptor with the at least one processor information stored in the memory of the artificial intelligence machine to an artificial intelli gence machine including processors for predictive model algorithms to produce and output better business decisions from its own feed of new events as raw data record inputs stored in the memory of the artificial intel ligence machine.

5. A method of operating an artificial intelligence machine including processors for predictive model algorithms that new series of data records of new events as raw data record inputs, comprising:

recovering with at least one processor a recording of a data-enrichment descriptor stored in a memory of the artificial intelligence machine including an identity of any data fields in a data record format of a series of data

records that were subsequently deleted by an artificial intelligence machine including processors for predictive model building, and which of any newly derived data fields were subsequently added, and how each newly derived data field was derived and from which informa tion sources;

- accepting a new series of data records of new events with the artificial intelligence machine including at least one processor to receive and store records in the memory of the artificial intelligence machine;
- deleting with the at least one processor all data fields and all data values contained in the data fields from each of a new series of data records of new events, stored in the memory of the artificial intelligence machine, according to the data-enrichment descriptor;
- adding with the at least one processor a new derivative data field to each record of the new series of data records stored in the memory of the artificial intelligence machine according to the data-enrichment descriptor, and initializing each added new derivative data field with a new data value stored in the memory of the artificial intelligence machine; and
- producing and outputting a series of predictive decisions with the at least one processor that operates at least one predictive model algorithm derived from one originally built and trained with records having a same record format described by the data-enrichment descriptor and stored in the memory of the artificial intelligence machine.

6. The method of claim 5 which includes causing the at least one processor in the step of deleting to:

exclude each data field stored in the memory of the artifi cial intelligence machine that has more than a threshold number of random data values, or that has only one repeating data value, or that has too small a Shannon entropy, and then transforming a surviving number of data fields into a corresponding reduced-field series of data records stored in the memory of the artificial intel ligence machine.

7. The method of claim 6 which includes causing the at least one processor in the step of adding to:

add a new derivative data field to a reduced-field series of data records stored in the memory of the artificial intel ligence machine and initialize each added new deriva tive data field with a new data value, and to either change real scaler numeric data values into fuzzy values, or if symbolic, to change a behavior group data value stored in the memory of the artificial intelligence machine, and testing that a minimum number of data fields survive in that stored in the memory of the artificial intelligence machine, and if not, then to generate a new derivative data field and fix within each an aggregation type, a time range, a filter, a set of aggregation constraints, a set of data fields to aggregate, and a recursive level, and which the quality of each newly derived data field was test, and then transforming the results into an enriched-field series of data records stored in the memory of the arti ficial intelligence machine.
