Abstract. A high-resolution extraterrestrial solar spectrum has been determined from ground-based measurements of direct solar spectral irradiance (SSI) over the wavelength range from 300 to 500 nm using the Langley-plot technique. The measurements were obtained at the Izaña Atmospheric Research Centre from the Agencia Estatal de Meteorología, Tenerife, Spain, during the period 12 to 24 September 2016. This solar spectrum (QASUMEFTS) was combined from medium-resolution (bandpass of 0.86 nm) measurements of the QASUME (Quality Assurance of Spectral Ultraviolet Measurements in Europe) spectroradiometer in the wavelength range from 300 to 500 nm and high-resolution measurements (0.025 nm) from a Fourier transform spectroradiometer (FTS) over the wavelength range from 305 to 380 nm. The Kitt Peak solar flux atlas was used to extend this high-resolution solar spectrum to 500 nm. The expanded uncertainties of this solar spectrum are 2% between 310 and 500 nm and 4% at 300 nm. The comparison of this solar spectrum with solar spectra measured in space (top of the atmosphere) gave very good agreements in some cases, while in some other cases discrepancies of up to 5% were observed. The QASUMEFTS solar spectrum represents a benchmark dataset with uncertainties lower than anything previously published. The metrological traceability of the measurements to the International System of Units (SI) is assured by an unbroken chain of calibrations leading to the primary spectral irradiance standard of the Physikalisch-Technische Bundesanstalt in Germany.

1 Introduction

Quantifying the spectral solar radiation penetrating the atmosphere is crucial to understand and quantify its interaction with the atmosphere, oceans and the surface. In particular, the ultraviolet part of the solar spectrum drives the photochemistry of a number of important atmospheric trace gases such as ozone, nitrogen dioxide and hydroxyl and has significant effects on the terrestrial and aquatic ecosystems. While airborne or surface-based measurements of solar radiation can be used to quantify these processes, often these measurements are not available and radiative transfer calculations are used instead. In the latter case, the solar extraterrestrial spectrum is a necessary parameter which is needed to perform these calculations. Similarly, the determination of atmospheric constituents from remote sensing applications requires a very precise knowledge of the solar spectrum penetrating the atmosphere. In all cases, the uncertainty of the solar extraterrestrial spectrum is one of the main components in the corresponding uncertainty budgets. Therefore, reducing the uncertainty of the solar extraterrestrial spectrum has direct and significant implications on a large number of atmospheric and environmental activities.

In the past 25 years, a number of satellite experiments have measured the solar extraterrestrial spectrum from space to avoid atmospheric absorption and scattering effects, especially at wavelengths shorter than 300 nm where ozone and oxygen in the atmosphere absorb all incident radiation (e.g. Cebula et al., 1996; Thuillier et al., 1997; Harder et al., 2009). While prelaunch calibration and characterisation procedures reach very low uncertainties, once in space the

possibilities of verifying or recalibrating such instruments become very challenging. As recent studies have demonstrated (e.g. Schöll et al., 2016), the solar spectra measured from satellite platforms can differ significantly between each other, due in part to instrument degradation issues arising from the harsh space environment and the difficulties in accounting for possible instrument changes between the preflight calibration and its operation in space. In a strict metrological sense, such measurements cannot be considered traceable to SI (International System of Units) since metrological traceability inherently requires the repeated demonstration of the uninterrupted traceability to primary standards, which is currently not available to instruments located in space (https://www.nist.gov/traceability/supplementary-materials-nist-policy-review#internal_map).

Prior to the space age, solar irradiance measurements were performed from the surface, applying zero air mass extrapolation techniques to derive the solar irradiance at the top of the atmosphere (Ångström, 1970; Shaw, 1983). In more recent years, spectral solar irradiance measurements using spectroradiometers (e.g. Bais, 1997; Gröbner and Kerr, 2001; Bolsée et al., 2014) or sun photometers (Schmid and Wehrli, 1995) were used to determine the spectral solar spectrum in wavelength regions unaffected by strong atmospheric absorption features. These measurements were either used for atmospheric research or for the validation of existing solar extraterrestrial spectra obtained from space measurements or from models of the sun (Fontenla et al., 2006; Shapiro et al., 2010). While ground-based measurements of the solar irradiance have the disadvantage of needing to account for changing atmospheric conditions, the considerable advantage over space-based instruments is the possibility of recalibrating ground-based instruments and thereby validating and confirming their traceability to SI.

In this study we present ground-based direct spectral solar irradiance measurements obtained with the transportable reference double monochromator spectroradiometer QASUME (Quality Assurance of Spectral Ultraviolet Measurements in Europe) and a high-resolution Fourier transform spectroradiometer (FTS) over the wavelength range from 300 to 500 nm and from 300 to 390 nm respectively. A high-resolution absolute extraterrestrial solar spectrum is then derived by applying the Langley-plot technique to the measurements of each instrument before combining them to a single high-resolution solar extraterrestrial spectrum.

2 Instruments and methods

The measurements were performed at the Izaña Atmospheric Observatory (IZO) located on the island of Tenerife (Canary Islands, Spain, 28.309° N, 16.499° W) from 12 to 24 September 2016. IZO is a high mountain station at an elevation of 2373 m a.s.l. (above sea level) above a strong subtropical temperature inversion layer, which acts as a natural barrier

for local pollution and low-level clouds. QASUME was installed on the roof of the measurement building at about 20 m above ground, while the FTS was operated on the ground.

2.1 QASUME

The transportable reference spectroradiometer QASUME consists of a double monochromator with a focal length of 150 mm and two 2400 lines mm⁻¹ gratings resulting in a full width at half maximum (FWHM) of 0.86 nm. The whole system resides in a temperature-controlled enclosure to allow outdoor operation under constant ambient conditions. The solar radiation is collected with a temperature-stabilised diffuser connected via an optical fibre to the entrance slit of the monochromator. A portable lamp monitoring system allows the calibration of the whole system while being deployed in the field. A detailed description of the system can be found in Gröbner et al. (2005) and Hülsen et al. (2016). A collimator tube with a full opening angle of 2.5° is mounted on an optical tracker to which the diffuser head can be fitted, allowing the measurement of direct solar spectral irradiance (SSI). A comprehensive uncertainty budget for global solar spectral irradiance measurements was discussed in Hülsen et al. (2016). Due to the fact that direct solar irradiance measurements are not affected by the directional response of the diffuser nor by the diffuse sky radiation distribution, the resulting expanded uncertainty is reduced from 3.1 % for global solar irradiance measurements to 1.83 % for direct solar spectral irradiance measurements in the spectral range 300 to 500 nm. The increase in measurement noise at short wavelengths below 305 nm becomes only relevant at large zenith angles above 75°, which are not used in this analysis. Solar spectra were measured every 15 min from sunrise to sunset. QASUME was calibrated every day using a portable lamp monitoring system with a set of three 250 W tungsten-halogen lamps in order to verify its stability and demonstrate its traceability to SI. The calibrations were taken into account daily and varied by less than ±0.5 % over the course of the campaign, which has been taken into account in the uncertainty budget (see Hülsen et al., 2016).

2.2 Fourier transform spectroradiometer

The transportable Fourier transform spectroradiometer (FTS) consists of a Bruker Vertex 80 Fourier transform spectroradiometer with a customised fibre-based entrance optic for direct spectral irradiance measurements, i.e. a collimator tube with a field of view of approximately ±3.5°. The instrument is installed in a temperature-controlled transportable housing. The internal detector is a UG11 filtered GaP photodiode covering the spectral range from 300 to 390 nm. The wavenumber resolution of the FTS was set to 2 cm⁻¹ resulting in a wavelength resolution of less than 0.025 nm for this wavelength range. Solar spectra were obtained approximately every 50 s. The wavelength scale of the FTS is

Figure 1. Langley plot using direct solar irradiance measurements of QASUME on the morning of 14 September 2016. The green, blue and red dots represent measurements at 310, 320 and 350 nm respectively. The lines represent a linear fit to the data points to retrieve the intercept at air mass 0.

inherently traceable to SI using a stabilised internal HeNe laser. The wavelength uncertainty is estimated to be equal to or less than 0.01 nm. The radiometric calibration of the FTS was performed by a comparison with a calibrated spectroradiometer under natural sunlight conditions. The entrance optic was mounted on an optical tracker together with a monitor filter radiometer. The monitor filter radiometer is a temperature-controlled UG11 filtered GaP photodiode mounted within a collimator tube. The monitor correction turned out to be necessary to correct for the instability of the absolute scale of the FTS spectrum. The filter radiometer correction factor f_{FR} is a scaling factor derived from the ratio of the measured filter radiometer current and the product of the measured radiometric corrected FTS spectrum and the spectral responsivity of the filter radiometer determined previously at the Physikalisch-Technische Bundesanstalt,

$$f_{FR} = \frac{U_{FR}/R_{shunt}}{\int s_{FR}(\lambda) \cdot E_{rel, FTS_{corr}}(\lambda) d\lambda}, \quad (1)$$

where U_{FR} represents the measured voltage corresponding to the photocurrent of the filter radiometer, R_{shunt} the shunt resistance, $s_{FR}(\lambda)$ the spectral responsivity of the filter radiometer and $E_{rel, FTS_{corr}}$ the radiometric corrected normalised relative spectral irradiance measured by the FTS. The instability of the FTS over time is then corrected by multiplying the raw FTS signal with this correction factor. The expanded uncertainty for measurements of the relative direct solar spectral irradiance was determined to be between 2 and 4 % in the spectral range 310 to 380 nm. Below 310 nm the uncertainty of the FTS rises rapidly due to the low signal to noise ratio of the instrument.

2.3 Solar extraterrestrial spectrum retrieval

The method used to retrieve the solar extraterrestrial spectrum from ground-based measurements of direct solar irradi-

ance uses the Beer–Lambert law,

$$I_\lambda = I_\lambda^0 R_{SE} e^{-\tau_\lambda m}, \quad (2)$$

where I_λ represents the solar irradiance measurement at wavelength λ , I_λ^0 the solar irradiance at the top of the atmosphere, R_{SE} the sun–earth distance normalised to 1 AU, τ_λ the total optical depth and m the air mass. Taking the logarithm and expanding the optical depth τ and the air mass m for the main atmospheric constituents gives

$$\log I_\lambda = \log(I_\lambda^0 R_{SE}) - \tau_\lambda^{O_3} m_{O_3} - \tau_\lambda^R m_R - \tau_\lambda^{aod} m_{aod}, \quad (3)$$

where the superscripts O_3 , R and aod represent the atmospheric ozone, Rayleigh and aerosol optical depth (AOD) respectively. The representative air mass m_{O_3} for the atmospheric ozone is calculated assuming that all the ozone is concentrated in a layer at 22 km height, while m_R and m_{aod} are calculated for a layer at 5 km.

The Langley-plot technique consists of linearly regressing Eq. (3) vs. air mass (in this study the air mass range from 1.1 to 3.5 was used) to retrieve the intersect I^0 for every wavelength separately, assuming that τ remains constant during this period. For this assumption to be valid, measurements are usually performed at high-altitude sites where the aerosol optical depth is very small and variations in AOD will have no significant effect on the regression.

Due to the strong absorption of ozone below 340 nm, the regression in that wavelength region is done against m_{O_3} , while at longer wavelengths the regression is done against m_R . Since the Rayleigh optical depth τ_R has a similar magnitude to the ozone optical depth at wavelengths below 340 nm, Eq. (3) is slightly rearranged to take into account the Rayleigh optical depth, which can be calculated easily from the known atmospheric pressure at the measurement site,

$$\log I_\lambda + \tau_\lambda^R m_R = \log(I_\lambda^0 R_{SE}) - \tau_\lambda^{O_3} m_{O_3} - \tau_\lambda^{aod} m_{aod}. \quad (4)$$

Figure 1 shows the log of the QASUME direct irradiance measurements at 310, 320 and 350 nm for the morning of 14 September 2016 vs. air mass, from which the zero air mass solar irradiances are retrieved by a linear extrapolation. In this particular example 18 measurements are used for this Langley plot, while for the FTS up to 450 points are used due to the higher sampling rate. The slopes of the linear curves represent the optical depth $\tau_\lambda^{O_3} + \tau_\lambda^{aod}$, which is larger at short wavelengths due to the increase in ozone absorption with decreasing wavelengths.

At IZO, the aerosol optical depth at 500 nm is often smaller than 0.02; correspondingly, the aerosols provide a negligible contribution to the total optical depth in the wavelength range of strong ozone absorption, justifying the regression of Eq. (4) vs. m_{O_3} at wavelengths shorter than 340 nm. The Langley-plot procedure is quite robust for the atmospheric conditions found in September at IZO during the measurement campaign, since most days have AOD variations of less than 0.005 at 500 nm and the total column ozone

Table 1. Summary of the atmospheric conditions during the measurement campaign. For each half-day (indicated by M, morning, and A, afternoon) the aerosol optical depth at 500 nm, the total column ozone (TCO) in DU, and the change of AOD and TCO during the period is shown. The * indicates that this half-day satisfied the criteria for inclusion in the average set.

Day	AOD at 500 nm	dAOD	TCO	dTCO
*14M	0.009	−0.002	286.9	1.0
*14A	0.008	0.003	284.1	1.9

Figure 2. Ratio between solar spectra obtained from direct irradiance measurements with the QASUME spectroradiometer to their average during 7 half-days for the period 14 to 24 September 2016.

(TCO) variations determined with co-located Brewer spectrophotometers are less than 2 DU during each Langley-plot period (half-day). Table 1 shows a summary of the atmospheric conditions encountered during the campaign which were used to select the most appropriate periods for the subsequent analysis.

The criteria used for an objective selection of measurements to include in the analysis were total AOD less than 0.02, AOD variation equal to or less than 0.005 and TCO variations less than 2 DU. For the measurement period, 7 out of a total of 13 half-days satisfy these criteria, from which zero air mass solar spectra I_0 were retrieved. The ratio between these seven spectra to their average is shown in Fig. 2 for QASUME. The variability observed at wave-

lengths shorter than 320 nm can be clearly correlated to the ozone variability during each Langley-plot period. Indeed, the regression of the residuals shown in Fig. 2 at wavelengths shorter than 320 nm vs. the observed ozone variation (not shown) gives a zero crossing of the residuals for zero ozone variation, which coincides with the I_0 retrieved from the seven individual spectra, supporting the assumption that the ozone variations do not introduce a significant systematic bias in the Langley-plot procedure. Furthermore, for wavelengths longer than 305 nm the solar extraterrestrial spectrum (ETS) retrieved from averaging the spectra from all 13 half-days as shown in Table 1 is only 0.2 % higher than the solar ETS from the seven best half-days, demonstrating that the selection introduces no systematic bias to the retrieved I_0 , but only decreases its standard deviation.

Due to the finite resolution of 0.86 nm of QASUME, a small spectral correction needs to be applied to the retrieved I_0 as described in Gröbner and Kerr (2001). This bandwidth correction is estimated by determining I_0 from synthetic (modelled) direct solar irradiance spectra using a total column ozone value of 280 DU representative for the campaign and for an air mass range between 3.5 and 1. The high-resolution solar ETS COKITHQA solar spectra (Egli et al., 2012), I_0^{ref} based on the Kitt Peak solar flux atlas (Kurucz et al., 1984), is used as reference for these model calculations. The synthetic solar spectra are then convolved with the slit function of QASUME before determining I_0^{mod} using Eq. (4), thereby simulating the measurements of QASUME during the campaign. The bandwidth correction which needs to be applied to the solar extraterrestrial spectra determined with QASUME is then simply the ratio between I_0^{ref} convolved with the QASUME slit function and I_0^{mod} . The correction is negligible at wavelengths longer than 330 nm and gradually increases to 4 % at 300 nm, which is slightly larger than the correction shown in Gröbner and Kerr (2001) for a Brewer spectroradiometer with a resolution of 0.57 nm.

The same Langley-plot regression was applied to the direct irradiance measurements of the FTS. The measurements which were used for the analysis were obtained on 24 September for a resolution setting of 2 cm^{-1} , which is equivalent to a resolution of close to 0.025 nm in the measured wavelength range from 300 to 390 nm. Figure 3 shows the solar extraterrestrial spectra derived by QASUME and the FTS as well as the solar spectrum of the FTS convolved with the QASUME slit function.

The two solar spectra agree remarkably well, as can be seen in Fig. 3. The largest differences arise at short wavelengths below 310 nm due to the low sensitivity of the FTS at larger air masses which affect the retrieval of I_0 using the Langley-plot procedure. Below 305 nm, the spectrum decreases significantly and does not give consistent results anymore.

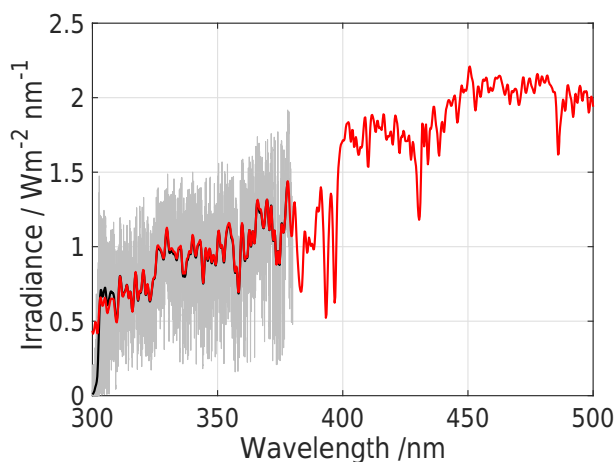

Figure 3. Solar spectra obtained from direct irradiance measurements with QASUME (red curve) and the FTS (grey curve). The black curve is calculated from convolving the high-resolution spectrum of the FTS with the QASUME slit function.

We have compared the spectral features of the high-resolution FTS spectrum shown in Fig. 3 with the COKITHQA solar spectrum, whose high-resolution component is based on the Kitt Peak solar flux atlas. Due to the extremely high resolution of this solar spectrum, we have convolved it first with a 0.025 nm bandpass to bring it to the same resolution as the measurements of the FTS. We have furthermore selected three spectral regions of about 1 nm each to show the two solar spectra. Figure 4 shows the solar spectra of the FTS and Kitt Peak centred at 314.5, 344.5 and 365.5 nm. As can be seen in the figure, both spectra agree remarkably well with each other, both spectrally and in absolute levels. Specifically, we would like to emphasise the nearly perfect wavelength agreement between the two spectra, which was assessed by shifting one spectrum by a small wavelength increment and calculating the residuals of the spectral ratio between the two solar spectra. The lowest residuals were obtained for no shift, and a relative wavelength shift of ± 1 pm has already led to significantly larger residuals, confirming the perfect wavelength scale agreement between the FTS and Kitt Peak solar spectra.

2.4 Uncertainty estimation

The main contribution to the uncertainties of the solar extraterrestrial spectra shown in Fig. 3 is the absolute calibration of the QASUME and FTS spectroradiometers. Additional uncertainty components are the variability of the Langley-plot retrievals (see Fig. 2 for QASUME), the uncertainty in the finite bandwidth correction, and the uncertainty of the ozone and aerosol air masses used in the Langley-plot retrievals. The uncertainty in the finite bandwidth correction is mainly a function of the total column ozone, which varied by ± 5 DU during the campaign, and the effective height of

the ozone layer above Izaña, 22 ± 0.5 km, which was measured several times during the campaign by ozone sondes.

The scattered circumsolar radiation from Rayleigh scattering as well as from the forward scattering of aerosols can introduce a bias in the measurement of direct solar irradiance which is not accounted for by the simple Beer–Lambert law presented in Eq. (3). To estimate the magnitude of this effect for the conditions encountered in Izaña during the campaign, we estimated this contribution using the radiative transfer model libRadtran (Mayer and Kylling, 2005), using as basis for the radiative transfer calculations the atmospheric conditions found at Izaña, namely atmospheric pressure of 772 mbar and aerosol optical depth of 0.02 with an assumed aerosol asymmetry factor of 0.76. The model calculations were carried out for several air masses between 1 and 3.5 and for the wavelength range between 290 and 500 nm in order to simulate the effect of the scattered radiation on the Langley-plot retrieval. The contribution of scattered radiation in the field of view of QASUME with respect to the direct irradiance is largest at short wavelengths and large air masses: at an air mass of 3.5 the relative contribution is 0.55 and 0.14 % at 300 and 310 nm respectively. At smaller air masses and longer wavelengths, this contribution decreases to less than 0.1 %. The significant dependence on wavelength suggests that the dominant contribution comes from Rayleigh scattering, while the forward-scattered radiation from the aerosols is negligible. This relative contribution is very small and clearly within the measurement uncertainties. When the zero air mass extrapolation is performed on the measurement data including the modelled relative contribution from circumsolar radiation, the resulting zero air mass spectrum differs by less than 0.1 % from the original, demonstrating that scattered radiation in the field of view of QASUME has a negligible effect on the resulting extraterrestrial solar spectrum and can therefore be neglected. While this effect is expected to be approximately a factor of 3 larger for the FTS due to its larger field of view with respect to QASUME, we have not taken it explicitly into account since any resulting bias in the retrieved solar spectrum of the FTS will be taken into account when the QASUME and FTS spectra are combined, as explained in the following section.

The individual uncertainty components are shown in Fig. 5 for QASUME, as well as the combined uncertainties of QASUME and the FTS.

In order to produce a consistent high-resolution solar extraterrestrial spectrum from QASUME and the FTS, and taking into account the smaller uncertainties of QASUME with respect to the FTS, the spectral ratio between QASUME and the convolved FTS spectrum in the wavelength range from 304.8 to 378 nm was applied to the high-resolution FTS solar spectrum to normalise it to the QASUME absolute irradiance. This effectively transfers the absolute irradiance scale of QASUME to the high-resolution solar spectrum measured with the FTS. Furthermore, the high-resolution Kitt Peak solar flux atlas was used in conjunction with the QASUME so-

Figure 4. FTS (red curve) and COKITHQA (Kitt Peak; dashed blue curve) solar spectra for three spectral intervals. Panel (a) shows the two solar spectra from 313.9 to 315.1 nm, panel (b) from 343.9 to 345.1 nm and panel (c) from 364.9 to 366.1 nm.

Figure 5. Relative uncertainty of the solar extraterrestrial spectra derived from the direct solar irradiance measurements using the Langley-plot method. The red and black curves represent the total relative uncertainties of the FTS and QASUME respectively. The remaining curves represent the uncertainty contributions calculated for QASUME for the direct solar irradiance measurements (blue), the Langley-plot variability (green), the effective ozone height (magenta) and the bandwidth correction (cyan).

lar spectrum for the wavelength range 300 to 304.8 nm and from 378 to 500 nm in order to extend the high-resolution solar spectrum over the whole wavelength range of QASUME. The resulting high-resolution solar spectrum QASUMEFTS combines the high-resolution solar spectrum obtained with the FTS with the absolute irradiance scale of QASUME. The resulting expanded uncertainty (at a 95 % coverage probability) shown in Fig. 5 for the combined QASUMEFTS solar spectrum is 2.0 % between 310 and 500 nm, gradually increasing to 4 % at 300 nm.

3 Comparison to literature solar extraterrestrial spectra

This high-resolution solar spectrum QASUMEFTS was compared to seven solar spectra determined either in space or through the combination of the Kitt Peak solar flux atlas with lower-resolution space-based solar spectra.

From top to bottom, Fig. 6 shows the comparison to the solar ET spectra measured with SOLSPEC onboard the International Space Station (the version SOLSPEC_A by Bolsée et al., 2017, and SOLAR_ISS by Meftah et al., 2016), SIM v17 onboard SORCE (Harder et al., 2010), SCIAMACHY (Hilbig et al., 2017), the ATLAS-3 solar spectrum (Thuillier et al., 2003), the Chance–Kurucz solar spectrum (SAO, Smithsonian Astrophysical Observatory; Chance and Kurucz, 2010), a composite solar spectrum made up from a variety of spectra (Gueymard, 2003) and finally another composite solar spectrum corrected by a comparison to ground-based measurements (Egli et al., 2012). The wavelength scales of the five space-based solar spectra were adjusted to air wavelengths to provide a consistent wavelength scale for this comparison. The relative uncertainties of the space-based solar spectra are described in the respective references, while the two composite solar spectra only provide uncertainty estimates based on the spectra used to produce the composites. Unfortunately, not every spectrum has a documented uncertainty budget analysis, and often the coverage probability that is used when quoting an uncertainty is not clearly defined. Therefore, only the expanded relative uncertainty of QASUME is shown in Fig. 6.

With the exception of the SIM and SOLSPEC_A solar spectra where the instrument slit functions were available, the comparison was performed by convolving the spectra with a 1 nm FWHM triangular slit function before calculating the ratio to QASUMEFTS, which was also convolved the same way. For SIM and SOLSPEC_A, the high-resolution QASUMEFTS spectrum was convolved with the

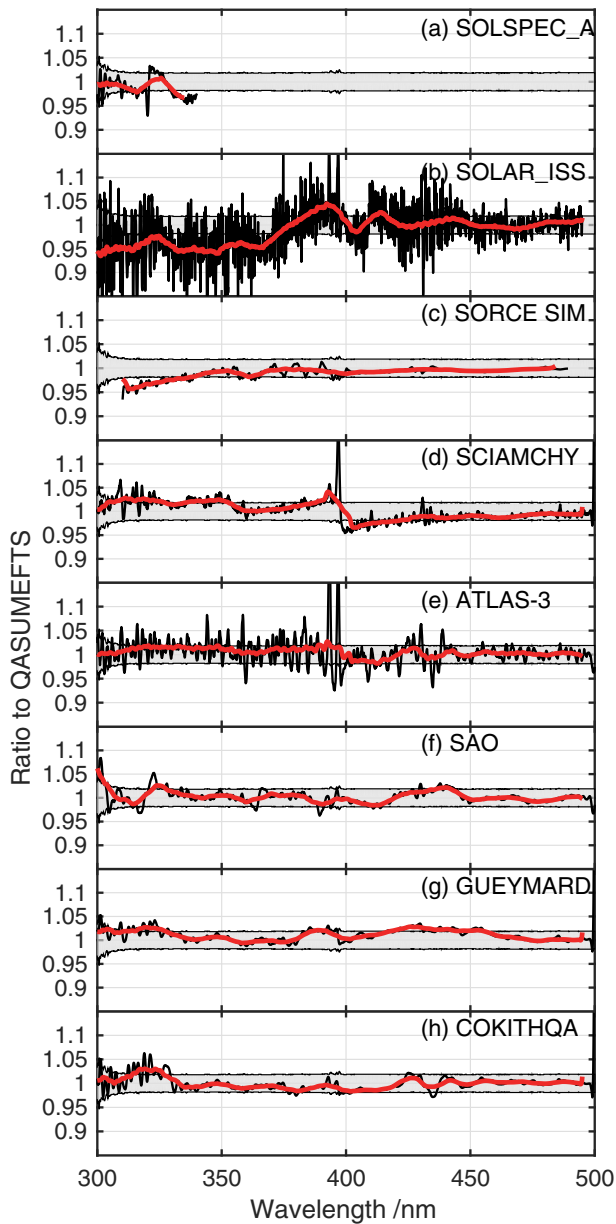

Figure 6. From (a) to (h): ratios between QASUMEFTS and the solar ET spectrum from SOLSPEC (SOLSPEC_A by Bolsée et al., 2017, and SOLAR_ISS by Meftah et al., 2016), SORCE SIM (Harder et al., 2010), SCIAMACHY (Hilbig et al., 2017), ATLAS-3 (Thuillier et al., 2003), SAO (Chance and Kurucz, 2010), the composite from Gueymard (2003) and the composite from Egli et al. (2012). The black lines are the ratios convolved with a 1 nm wide triangular slit function, while the red line is a 10 nm running average. The grey shaded area represents the expanded uncertainty of the QASUMEFTS spectrum.

spectrally varying instrument slit function before taking the ratio to the respective solar spectrum.

The SORCE spectrum used here was measured on 27 November 2004 and the SCIAMACHY spectrum on

27 February 2003. SOLSPEC-A represents the average over the period 6 June 2008 to 29 April 2009 while SOLSPEC-B represents the average for the period April to June 2008. Finally the ATLAS-3 spectrum was measured on several days in November 1994. Thus, all solar spectra shown here, including QASUME, were either measured during solar minimum or in the declining phase of the respective solar cycle.

Current studies provide only an upper limit of the solar spectral irradiance variability throughout a solar cycle of the order of 1 to 2 %. Based on the results from SORCE SIM discussed in Harder et al. (2009), the variability of SSI between 300 and 500 nm is at most 0.5 %. In that respect, the different measurement periods of the solar spectra discussed here should not have a significant impact on the comparisons.

As can be seen in Fig. 6, most of the solar spectra agree fairly well with QASUMEFTS. SOLSPEC_A shows an overall agreement with QASUMEFTS within the uncertainties. On the other hand, SOLAR_ISS underestimates QASUMEFTS by nearly 5 % in the range 300 to 370 nm, while agreeing with QASUMEFTS at longer wavelengths. This transition is consistent with a change between the UV and visible spectroradiometer of the SOLSPEC instrument. The large spectral variations are still under investigation (M. Meftah, personal communication, 2017).

The comparison with SORCE SIM shows good agreement to better than 2 % at wavelengths longer than 340 nm, while at shorter wavelengths SORCE SIM gradually underestimates QASUMEFTS by up to about 5 % at 310 nm.

The SCIAMACHY solar spectrum shows very good agreement over the whole wavelength range, with a small discontinuity at 395 nm, which comes from switching from one spectroradiometer channel to the next, which also includes a change of spectroradiometer resolution from about 0.2 to 0.4 nm (M. Weber, personal communication, 2017). The low spectral residuals (black curve in Fig. 6) show that the wavelength scale between SCIAMACHY and QASUMEFTS agrees very well and that the resolution of SCIAMACHY is sufficient to allow the convolution with a 1 nm bandpass.

The ATLAS-3 spectrum gives the overall best agreement with QASUMEFTS, being within the uncertainties of QASUMEFTS over the whole wavelength range for the 10 nm smoothed spectrum. The noisy residuals are an indication that the spectral resolution of the measurements is slightly too low for the 1 nm convolution and that some wavelength discrepancies between QASUMEFTS and ATLAS-3 might exist. The 10 nm running average smooths out the high-frequency spectral noise and shows that on an absolute scale both spectra agree to better than 2 % between 300 and 500 nm.

The comparisons to the three composite high-resolution spectra (SAO, GUEYMARD and COKITHQA) show much less noise because these are also based on a high-resolution spectrum, and thus the convolution works very well. It also shows that in the region 305 to 380 nm the Kitt Peak so-

lar flux atlas and the high-resolution spectrum obtained with the FTS agree very well. The larger spectral noise of COKITHQA than the one of GUEYMARD below 330 nm indicates that the procedure to create this composite needs to be improved in that wavelength region. While Gueymard (2003) uses ATLAS-3 for the wavelength region shorter than 400 nm, COKITHQA uses the ATLAS-3 solar spectrum as basis, together with minor modifications based on a comparison with ground-based measurements, as described in Egli et al. (2012).

Several spectral regions of the composite spectrum of GUEYMARD show deviations with respect to QASUMEFTS which are larger than the uncertainties. A general overestimation of 1.1 % between GUEYMARD and QASUMEFTS is observed, with differences of up to +3 % in the region between 300 and 330 nm and between 420 and 460 nm. The agreement of QASUMEFTS with COKITHQA is slightly better, with the largest deviations of +3 % between 310 and 320 nm. For the remaining wavelength range, COKITHQA is within the uncertainties of QASUMEFTS, which shows the improvements obtained using ground-based measurements to correct the COKITHQA composite.

4 Conclusions

A high-resolution extraterrestrial solar spectrum in the wavelength range from 300 to 500 nm has been determined using ground-based measurements of direct solar irradiance and applying the Langley-plot technique. This QASUMEFTS solar spectrum was constructed by combining the high-resolution direct solar irradiance measurements of a Fourier transform spectroradiometer with the moderate resolution of the QASUME spectroradiometer. The Kitt Peak solar flux atlas was used for the wavelength range not covered by the FTS.

A comprehensive uncertainty budget evaluation for the derived solar spectrum has been determined, with expanded uncertainties ($k = 2$, assuming a 95 % probability coverage) of 2 % between 310 and 500 nm. The uncertainties gradually increase to 4 % at 300 nm, reflecting the increased uncertainties due to atmospheric ozone variations affecting the Langley-plot retrieval of the zero air mass solar spectrum at these short wavelengths as well as the uncertainty of the finite bandwidth correction of the QASUME spectroradiometer.

The QASUMEFTS solar spectrum represents a benchmark dataset with uncertainties lower than anything previously published. The absolute irradiance scale of QASUME was monitored daily on-site using a portable field calibrator to monitor the sensitivity of the instrument. The metrological traceability of the measurements to SI is therefore assured by an unbroken chain of calibrations leading to the primary spectral irradiance standard of the Physikalisch-Technische Bundesanstalt in Germany.

The comparison of the QASUMEFTS solar spectrum with space-based solar spectra has shown good agreement within the uncertainties in some cases, while in some other cases differences as large as 5 % were observed.

This high-resolution solar spectrum will also be useful to radiative transfer modelling of the atmosphere for calculating the solar radiation in the atmosphere and at the surface. Furthermore, direct solar irradiance measurements in conjunction with QASUMEFTS will eventually allow fully traceable atmospheric trace gas retrievals with a comprehensive uncertainty budget integrating not only measurement uncertainties but also model uncertainties from the retrieval algorithm, which is a major objective of the European Metrology Research Programme (EMRP) Joint Research Project ATMOZ (<http://projects.pmodwrc.ch/atmoz/>).

Data availability. The high-resolution extraterrestrial solar spectrum QASUMEFTS can be obtained by anonymous FTP at <ftp://ftp.pmodwrc.ch/pub/people/julian.groebner/QASUMEFTS.dat>

Author contributions. JG, LE and GH operated the QASUME spectroradiometer, IK developed the FTS, and SR and PS operated the FTS during the campaign.

Acknowledgements. The NSO–Kitt Peak FTS data used here were produced by NSF–NOAO. The data are available from ftp://nispdata.nso.edu/pub/Kurucz_1984_atlas/. This work has been supported by the European Metrology Research Programme (EMRP) within the joint research project EMRP ENV59 ATMOZ “Traceability for atmospheric total column ozone”. The EMRP is jointly funded by the EMRP participating countries within EURAMET and the European Union. Jerry Harder provided the SORCE SIM v17 data and helped in the data comparison of the SIM spectrum. The authors would also like to thank the staff of the Izaña Atmospheric Observatory for their support during the campaign.
