The Non-Volatile One

The Data Center One

The Cloudy One

The Buggy One

Thursday, July 16

The Machine Learning One

The OS and Virtualization One

The WAN One

The One about Big Data

Friday, July 17

The One about Acceleration

The One about Storage

The Memorable One

The One on the Edge

Message from the USENIX ATC ’20 Program Co-Chairs

1. Preamble

Every year, conference chairs share their thoughts about the conference. This is often chock-full of statistics about acceptance rates, etc. We’ll include stats for sure. We felt, however, that we’d like to share with all of you some of the “inside scoop” of how a conference is organized and run from the Co-Chairs’ perspective. Many authors don’t know what happens behind the scenes; and even most PC members don’t get to chair a conference of this magnitude. We are honored to have been selected to co-chair USENIX ATC ’20. Running a conference like ATC is substantially more work than some other, even well established conferences, for the reasons outlined below (and that effort skyrocketed when the pandemic hit). There is a lot to know and we hope that this information will be valuable to all of you in the future.

2. Early Decisions

ATC is a large and complex conference to run for several reasons.

First, while it is a systems conference, ATC is fairly broad. Whereas conferences such as OSDI, FAST, NSDI, etc. see more focused papers, ATC has a much broader set of papers that span many systems conferences: networking, storage, operating systems, security, etc. This breadth meant that the PC’s makeup had to be carefully balanced to ensure appropriate representation for all likely topics.

Second, ATC is also the place where new systems papers are often submitted for topics that may not have a home of their own. FAST, NSDI, USENIX Security, and others—all started in part because ATC was getting too many papers in those areas, suggesting it was time to form a new, more focused conference. In recent years ATC started getting papers on edge computing and applied machine learning; and this year we expected we might get for the first time ever papers in quantum computing (and we were right). This meant that the PC’s makeup also had to include people who could review papers in newer and emerging topics such as machine learning and quantum computing.

Third, ATC receives submissions from many first time or relatively junior authors. Everyone has to start somewhere. But this meant that the PC had to do more work in reviewing and shepherding papers.

It would be nearly impossible to find ATC PC Chairs who are experts in all areas of systems research, including emerging ones. Recognizing this, we decided, for the first time, to recruit a few “PC Leaders” early on. We recruited five excellent PC leaders who, in addition to reviewing papers, would also help us form the PC itself. These five Leaders are experts in areas that us Co-Chairs were not as knowledgeable in, and they were instrumental in recommending and helping us pick members for this large PC.

Another important decision we made followed previous ATCs: we selected two “Submission Co-Chairs,” one each at our respective institutions: Ketan Bhardwaj (Georgia Institute of Technology) and Dongyoon Lee (Stony Brook University). They were instrumental in assisting us run the conference submissions site (HotCRP) and overall, during the review process. They helped us analyze data, collect various statistics, write scripts, monitor online discussions, helped us run the (virtual) PC, and more. We cannot imagine running this conference without them, especially when the pandemic demanded a lot more effort on everyone’s part.

2.1. Decisions we made early on: R1 rejections, topics/themes

Every chair gets a chance to redefine the process of running the conference somewhat. We looked at past conferences as well as past ATCs and decided to try a few changes.

2.1.1. Two review rounds and early rejections

ATC and other conferences have two rounds of reviewing. In the first round (R1), every paper gets a few reviews, and we decided to keep it at 3 reviews. There would then be online discussion and filtering. Those papers deemed worthy would advance to the second round of reviewing (R2) and receive about 2 more reviews. We aimed for 3 reviews in R1 and 5 in R2. There’s an “art” of sorts to deciding how many reviews to have in each round: if you have too few, less informed decisions are made. But ironically, if you have too many reviews, in many cases that does not lead to better decisions. We have seen it before:

when you assign a paper more reviews, there's sometimes less convergence to an accept/reject decision; often the result is more variance, so converging on a decision is harder. No, more reviews aren't necessarily better. Rather, PC members have to be given time to discuss their reviews and try to convince each other of the merits of one's opinions.

Traditionally, papers that don't make it to R2 are slated for rejection. But as there's a second round of reviewing and a PC meeting, there's often a month or more between when R2 reviewing begins and all rejection notices are sent.

So we decided to send rejection notices for papers in R1 who didn't make it to R2, as quickly as we could. That was almost a month before final paper decisions were released. We did this to help authors, who now have even more time to consider their papers and the reviews they received, and decide how to revise the work for an eventual resubmission.

While sending R1 rejections helped authors, it meant more work for the PC and Co-Chairs, and a tighter schedule. Before any reviews are sent out, we decided to follow past models and perform a "Review Sufficiency Check" (RSC). In this stage, a paper reviewer is assigned to read all of the reviews and to ensure that they are complete, detailed, fair, respectful, proofread, and not missing useful information. An example of what an RSC check catches is when a reviewer might say "this work was done before," during this RSC phase, we would catch this and ask the reviewer to provide more details such as an actual citation to the "done before" work.

2.1.2. Paper topics

When authors submit papers, they check several boxes to indicate what topics their paper fits into (e.g., networking, storage, operating systems). Similarly, before PC members begin to review any paper, they log in to the conference reviewing system, HotCRP (yes, pronounced hot-crap :-), and configure their expertise level in each of the topics. PC members mark their expertise on a five-point scale from "no expertise," to "neutral," to "expert." This indicates the PC member's preference in reviewing or not reviewing papers on certain topics.

Assigning hundreds of papers to over 100 PC members is a daunting task. Thankfully, HotCRP has a built-in "auto-assignment" feature. HotCRP can match papers to PC members by mutual interest in a given topic. HotCRP's initial assignment is very helpful but is not perfect, so it still needs a lot of review and tweaking by the Co-Chairs.

One trend in recent years has been to increase the number of topics and even add "cross-cutting" themes (sometimes called "aspects"). For example, instead of just saying "networking," you break it down into local-area, wide-area, mobile, protocols, data-center, etc., networking. And instead of saying "storage" you break it down to file systems, NVMs, Flash storage, network storage, KV stores, etc. And then you add orthogonal themes that can be applied to any of the finer-grained topics, for example: performance, scalability, security, availability, reliability, scheduling, etc.

There was a good reason to add more and more fine-grained topics and themes: HotCRP could do a better matching of papers to reviewers, ensuring that the best-qualified experts would get to review a paper. But there was a growing problem with the proliferation of topics and themes.

First, asking PC members and authors to mark 60+ topics and themes was a growing burden.

Second, authors don't always mark their papers correctly, often missing important topics/themes.

Third, some PC members don't want to mark their topic preference on purpose: they would like to get a "random assignment" of papers from the pool of submissions. There is a valid reason for this. A good paper should not just appeal to experts in the paper's field, but to a wider audience from the same community. So by reviewing some papers by highly technical PC members, but not necessarily experts, you ensure the selection of papers with greater appeal to the systems community.

Fourth, and most important. We found that the "cross-cutting themes" were not helping much; in fact, they were likely hurting HotCRP's initial assignment of papers to reviews. Suppose an author marks their paper with one or more topics and the theme of "performance." A person who can review a "storage performance" paper well probably won't be able to review a "network performance" paper as well. Similarly, "scheduling" in data centers is very different from I/O scheduling or network-packet scheduling. Analyzing these themes, we decided that they were not helpful and even counter-productive, and so we decided to eliminate all cross-cutting themes from the USENIX ATC '20 CFP.

Next, we tackled proliferation in the number of themes. After much discussion that involved our PC Leaders and Submission Co-Chairs, we decided to narrow the list of topics from several dozen to just 14. The reason to reduce the number of topics was to lower the burden on authors and PC members when marking their expertise; but at the same time, we wanted to ensure that we would still be able to assign papers to expert reviewers. So we chose multi-topic themes such that expertise in one topic is likely to translate to another. For example, one topic was “Distributed Systems, Clouds, Clusters, Data Centers.” The idea was that if a PC member can review a paper in “Distributed systems,” then they should also be able to review a paper on “data centers” reasonably well. No paper-to-reviewers assignment is ever perfect, but we felt that the way we chose themes and fewer of them helped reduce overall burden and still keep the reviewing quality high.

3. PC Selection Process

PC selection is a multi-dimensional optimization problem. Co-Chairs have to ensure that the PC is well balanced as much as possible across multiple dimensions (in no particular order):

1. **Junior vs. senior people:** it’s good to have some “fresh blood” and first time PC members, but also to have senior people who provide the necessary “institutional memory” and the wisdom that comes with... gray hair.
2. **Industry vs. academia:** it’s not enough to have just academics on a PC. We have to have representation from industry, who work on many real-world cutting-edge problems.
3. **Domestic vs. international:** the systems community is spread around the world. We want representation not just from U.S. researchers, but from Europe, Far and Middle East, and more.
4. **Male vs. female:** notwithstanding that genders are not binary, computer science and systems research are sorely lacking in female representation. This is true in academia (faculty and students), as well as industry. Inclusivity and diversity has proven to improve outcomes of many decision-making processes. Alas, our community has far fewer female researchers than we’d like to have. Many female researchers get asked repeatedly to serve on PCs, creating perhaps an unfair load. We tried to invite as many female PC members to join as we could: 24% of invited were female; and in the end our PC had 23% female representation.
5. **Topic diversity:** it’s important for the PC to have just the right number of people to review papers in various topics. We reviewed stats from previous years, such as how many papers were received in traditional topics (e.g., storage, clouds) as well as emerging topics (e.g., edge, ML). We estimated how many papers we might get overall and how many papers in each topic. We planned for getting anywhere from 300 to 500 (worst case) submissions. In the end, we had just under 350 reviewed submissions. For each PC member we considered inviting, we had a spreadsheet to mark their expertise in various areas.

Next, we chose to follow previous year’s models and invite PC members in multiple rounds and for multiple effort levels. During the fall of 2019 we sent out eight different rounds of invitations. After waiting to hear back, we reviewed the current makeup of the PC along the five aforementioned dimensions. We used google sheets and docs extensively. We then adjusted our strategy and sent out the next round of invitations, consulting with our PC Leaders as necessary. Adjustment was necessary to ensure that, if we were short in one dimension above, that we doubled our efforts to catch up along that dimension without hurting other dimensions.

We offered three tiers of reviewing load. Heavy PC members were expected to review 16–20 papers; Light PC members were expected to review 8–10 papers; and External Review Committee (ERC) members were expected to review 1–3 papers at most. Heavy PC members were required to attend the physical PC meeting (which was converted to a virtual PC—more on that later). ERC members were selected for specialized expertise in narrow areas where we felt we would need a couple more reviews. All PC members were expected to review papers in two rounds and participate in both rounds’ online discussions. We first invited Heavy, then Light, then ERC. In some cases, those who declined our invitation to be Heavy PC members were offered to be a Light PC member (several agreed).

We made a total of 214 PC invitations. 42% of all invited declined (many are understandably busy). Of the 125 that accepted, we had 67 Heavy PC members, 48 Light, and 10 ERC.

CFP updated and posted, PC formed, HotCRP configured, we were ready...

... or so we thought.

> *Con permiso, Capitán. The hall is rented, the orchestra engaged. It’s now time to see if you can dance.*
>
> –Q to Captain Picard, “Q Who,” Star Trek: The Next Generation

4. Before Paper Submission Due Date

Anonymizing papers helps ensure the integrity of the conference. When neither authors nor PC members know each other's identity, this is called a double-blind review process.

We received dozens of emails from authors who asked for clarifications on how to anonymize their papers. This is always a difficult subject. If you anonymize your paper too much, you may be hiding information about useful prior work you did, which could help the current paper under submission. Ironically, if you anonymize your past work too well, you could be incorrectly accused of reproducing or even plagiarizing "someone else's work" where it's really your own work.

If you don't anonymize, or poorly anonymize, you expose your identity, even indirectly to PC members. There's no consensus whether it helps or hurts a paper's chances, but there is consensus that it biases the process one way or another.

Many ATC authors are first-timers or relatively junior, which explains why we received many such queries about the anonymization process. Our advice to authors was as follows. PC members are encouraged not to search the Internet for information that might reveal the authors' identities. So authors had to ensure that their papers were anonymized and self-contained. Citations to one's own paper should be stated in the third person: you can refer to your own past work as "John Doe et al. [1] did this or that" and then state how you improved on those "other" people's work.

There are times when anonymization can get very difficult. Suppose the authors are from a very large cloud operator and are reporting on their experiences running a million computers across dozens of data centers worldwide. This kind of experience is invaluable to report to the systems community, as most researches can only dream of having access to such a large set of computers and its associated data sets. Therefore it doesn't make sense in such a paper, to "hide" details as to the size and scope of the environment being studied: hiding such details would likely hurt such a paper considerably. However, anyone reviewing such an anonymized paper would have a pretty good guess which company the authors work for. After all, we can all count on one hand the number of cloud operators with such a large operation.

The above was just one example. We generally told authors that anonymizing is a "best-effort" process: try your best to hide your identity but avoid going too far that it genuinely hurts your paper.

5. After Submissions Were Received

HotCRP had 408 records of submissions, but many were just from novice authors experimenting with HotCRP to see how it works; some authors re-uploaded their paper multiple times, creating duplicate submissions; and some authors registered the paper days earlier, but withdrew or never completed their submission.

There were just over 350 complete submissions. We inspected each one of them! Not surprisingly, we found over a dozen submissions that did not follow the rules: many did not anonymize and even had the authors' full names on the title page; some had bad fonts or bad PDFs; some had odd background colors or a watermark; some violated the formatting guidelines (fonts, sizes, margins, or the number of pages). We contacted each of those papers' authors and gave them 24 hours to fix their submission or we might have been forced to withdraw their papers. Most authors complied quickly. A couple of papers were withdrawn. We were left with 348 submissions that were ready to be reviewed.

6. Conflict Management and Integrity

A conference's reputation and prestige depend heavily on at least two important factors. First, the number, length, and quality of the reviews received. This is especially important for rejected papers. Getting a paper rejected is always disappointing; a good conference will provide reviews that would show authors that reviewers understood their paper, read it carefully, and provided constructive criticism to help the authors improve the work for a future resubmission.

Second, the perceived fairness of the process. In a conference like ATC, where over 80% of all papers are rejected, it is vital that the authors of all those rejected papers would feel that the process was fair and unbiased: that the decision on papers which got accepted or rejected was based on merit alone, and not on who reviewed, who was on the PC, or who are the conference organizers.

In 2019, there were stories circulating about possible poor practices in certain systems conferences. In one case this led to a tragedy. Organizations such as ACM and IEEE are still investigating various reports. And we have also heard from other senior members of our community, directly and indirectly, about possible conflicts and violations of anonymity rules.

We expected and followed three common conflict and anonymity rules:

1. PC chairs are prohibited from submitting papers to their conference. When recruiting our Submission Co-Chairs, we told them they would also not be allowed to submit papers to ATC'20. That is because all four of us had "superuser" privileges on HotCRP, allowing us to see any review.
2. Authors had to mark every PC conflict (and select a reason) for their paper. HotCRP is excellent at ensuring that conflicted PC members had no direct or indirect knowledge about papers those PC members are conflicted with: they can't see reviews, who reviewed, or scores; and they would be excluded from all online and PC discussions regarding conflicted papers.
3. Both of us Co-Chairs had papers marked as conflicts (often from our collaborators or ex-students). That's unavoidable. Thankfully there were no papers in which we were both conflicted. Therefore, we decided that each one of us PC Co-Chairs would alone handle all matters (e.g., PC discussions and decisions) relating to papers we were conflicted on; this included getting us PC Co-Chairs (or Submission Co-Chairs) excluded from parts of the live PC meeting discussions, as well as the selection of paper awards.

Nevertheless, we decided to "take it up a notch":

First, we added a new statement to the CFP that read as follows:

> Authors and others are prohibited from directly or indirectly communicating with any ATC '20 PC/ERC member about any potentially submitted paper. All requests should be made exclusively to atc20chairs@usenix.org. Violations of these guidelines may seek remedies as stipulated in the USENIX Conference Submissions Policy.

This was to ensure that PC members and authors should never communicate directly, regardless of whether a paper was accepted or rejected, even after the conference is long passed.

Second, our Submission Co-Chairs leveraged past scripts and data-sets that scour the Web, DLBP paper databases, and other resources. Those scripts attempt to identify additional or incorrectly marked conflicts for every paper. The scripts, for example, attempt to find if person A collaborated with person B on a recently published paper, person A submitted to USENIX ATC '20, person B was a PC member, but person B was not marked as a conflict for person A's submission. The scripts also looked at possible institutional conflicts, and more.

These scripts were far from perfect. They produced many false positives due to very similar names as well as their inability to perfectly match people's names with abbreviated initials. Our Submission Co-Chairs manually poured over thousands(!) of flagged potential conflicts from these scripts and together we narrowed them down to about 242 possible conflicts across 92 papers. We wrote separate scripts that emailed all authors and asked them to verify whether these possible conflicts were valid or not. Over 50% of all responses indicated that indeed these were valid conflicts for those papers, and so we marked additional conflicts.

We were now ready in earnest to assign papers to reviewers and begin the first round of reviews.

Phew.

7. Next Stages of Running a Conference

At this stage of any conference, about half of the Co-Chairs' work is done: forming a PC, posting a CFP, getting and sanitizing papers, and assigning reviews. We could now sit back and relax for a while...

... or so we thought.

COVID-19 happened. In other words, the Borg was unleashed on us before anyone was ready.

For many of us, the amount of work in our day-jobs increased considerably. Food and supply shortages. Dire predictions every day. No one knows what happens next. Many of us who are parents were having to juggle twice the workload and now having to provide full-time childcare, with schools and childcare facilities closed. People losing their jobs in droves. The economy tanking. The stress levels everyone was going through were through the roof.

We began to receive reports from PC members who were unable to meet the already tight review deadlines. Some reviewers reported stress, work and family problems, and even health problems related to COVID-19. Not prying, we tried our best to work with everyone's abilities and schedules. In some cases, we had to reassign papers and reviews to ensure we kept the expected review quality of ATC. This was a non-stop daily effort from mid-February to mid-April of 2020.

8. The PC Meeting

An in-person PC meeting is important. No amount of written reviews and numeric scores can replace the human experience. When people discuss a paper face to face, everyone can better gauge exactly how every reviewer feels about a paper. Seeing people's faces, hearing the inflection in their voices, and noting their body language are all vital cues that help us communicate better with one another. This is especially important because the PC meeting is often reserved for the most challenging borderline papers whose fate depends on informed discussions.

We had grand plans to hold a day-long physical PC meeting at Georgia Tech. The plan was to review no more than 70 papers during the PC meeting.

We started to get many emails from PC members who were concerned about traveling due to their own health, or their employer restricted or prohibited all travel. It was clear that holding a physical conference was not possible. So we canceled it and informed all PC members that it would be a virtual PC.

We had no idea how we would run a virtual PC yet. But we realized that we would not be able to hold a day-long virtual PC, nor would we have time to review ~70 papers virtually.

Based on past experience, we had already decided to pre-accept and pre-reject some papers during the R2 discussion period (and recall we also sent out early rejections for papers that were rejected in R1). The thinking was that if the PC can reach accept/reject decisions on some papers during the R2 online discussion period, and ahead of the PC meeting, then there would be fewer papers that had to be discussed at the actual PC. Past experience suggested that such papers' decisions rarely change during a PC meeting, so it was just going to waste time if we discussed them. Therefore, we assigned a discussion leader to each paper and asked them to see if a consensus could be reached during the R2 discussion period: pre-accept, pre-reject, or "need to be discussed at the PC." We gave PC members wide latitude to opine on those pre-accepted and pre-rejected papers. If any reviewer felt the decision was incorrect, then that paper would be discussed at the PC instead.

In normal times, it's just too easy to "punt" on making difficult decisions and merely push the paper to be discussed at the PC meeting. But now, having been forced to run a shorter, virtual PC, we could not afford to leave too many papers for the PC meeting itself. So we pushed our PC to make the difficult decisions early on, try to reach consensus, and pre-accept or pre-reject as many papers as possible. In order to provide for some cross-paper "calibration," we configured HotCRP so as to make all reviews and discussions visible to all non-conflicted PC members. This was difficult for everyone, especially during a worldwide pandemic. But our PC did admirably well. We were left with 38 papers to discuss at the PC meeting.

8.1. The Virtual PC (vPC)

Running a virtual PC (vPC) was a new thing. Few have ever attempted it. We could write ten more pages of "Chair Notes" about our experience. Wait, we did! You can find our full-length report on how we planned and ran our vPC here: https://www3.cs.stonybrook.edu/~ezk/vPC.html. So we'll only give you the highlights below:

1. We (two Co-Chairs and two Submission Chairs) evaluated multiple solutions and in the end, we chose Zoom as the most suitable one.
2. We shortened the PC meeting to just five hours. But we underestimated how long it would take. Indeed, we ran about 2 hours longer.
3. We polled our PC members for their schedules and current time-zones. And we clustered the papers to discuss into groups that best optimize for PC members' availability.
4. In a physical PC meeting, PC members who are conflicted are asked to leave the room, then they're called back in. With a vPC, we used Zoom's "Waiting Room" feature: it neatly allowed us to virtually move conflicted PC members from the actual PC to the waiting room, where their video and audio are disabled, they cannot hear or see any of the discussions, until they are let back in.

Given the unprecedented circumstances we faced, we believe the vPC went very well. And we strongly believe that USENIX ATC '20 maintains the high standards of quality despite all that everyone had to go through.

8.2. The Stats

And now, for the customary statistics from the paper review process.

Finalizing the program decisions for USENIX ATC '20 took 1,379 reviews, 4,193 discussion comments posted during the two online discussion rounds (post R1 and post rebuttals). The PC wrote a total of over 1.15 million words. Out of the initial 348 submissions, 150 papers (43%) were advanced to the second round, the remaining 198 papers received an early (R1) rejection notification. During the post-rebuttal online discussion period, the PC decided to pre-accept 42 highly-ranked papers and to pre-reject 70 more papers. The remaining 38 papers were further discussed during the vPC meeting. 23 of these papers were accepted and 15 were rejected. The final acceptance rate for ATC '20 is 18.7% (65 out of 348).

Among the accepted papers, 61 are regular full-length papers, 3 are short papers which were submitted as short, one paper will appear at the conference as a short paper but was originally submitted as a full-length 11-page paper, and another paper submitted as long was accepted as a short paper but given 9 pages. All accepted papers were initially conditionally accepted and assigned 1 or 2 shepherds, who ensured that the final version of the paper addressed the reviewers' feedback.

9. The Conference

With the paper selection process complete, we were almost done—just to organize the papers in sessions that fit the more-or-less standard schedule template that USENIX was going to provide…

… or so we thought.

Shortly after the vPC concluded and all decisions were communicated, unsurprisingly, it was determined that the actual conference will also have to be held as a virtual event. So, we were back in uncharted territory, trying to make the best decisions on how to organize and run a multi-day, multi-track USENIX ATC '20 conference—and for the first time fully online.

We spoke with Co-Chairs of other major systems conferences that switched to virtual mode—ASPLOS '20, Eurosys '20, and ISCA '20. We polled some of our PC members for their feedback from virtual conferences they had attended. We read blogs and recommendations on different virtual conference tools and experiences. We consulted on a weekly basis with the USENIX staff and the Co-Chairs of the workshops affiliated with ATC (HotStorage and HotCloud). And we mapped out the time zones of the authors of the accepted papers, and much more.

In the end, we arrived at a program that retained the original conference dates, organized in 12 technical papers sessions presented in two parallel tracks, and two plenary keynote addresses. With a goal of creating a balance among giving to authors an opportunity to present their work in front of a live audience, providing conference attendees with high-quality technical content, and shielding everyone from "Zoom fatigue," we opted for a schedule that combines longer, asynchronously-delivered, pre-recorded presentations, and live sessions with shorter video presentations and Q&A.

The two keynotes are scheduled at the end of the first two days of the conference, with ample time for discussions and Q&A. The first keynote is by Professor Ethan Miller from UC Santa Cruz on "The Future of the Past: Challenges in Archival Storage" and discusses, for example, future storage technologies such as DNA and Glass. The second keynote is by Professor Margo Seltzer from the University of British Columbia, titled "The Fine Line between Bold and Fringe Lunatic." Margo's talk hopefully sets a new tradition at USENIX ATC where the previous year's Lifetime Achievement Award Winner delivers one of the keynote addresses in the following year.

We look forward to three days of technical papers, keynote presentations, and discussions.

10. In Closing

Despite the tremendous amount of (unanticipated) work, we are thrilled to have had the honor of chairing USENIX ATC. We are thankful to everyone who helped and contributed along the way: to the authors who submitted their high-quality work to ATC, to the dedicated program committee and external reviewers who evaluated hundreds of submissions and provided constructive feedback to the authors, to the PC Leaders, Submission Co-Chairs and to the USENIX staff who provided invaluable advice and support.

We are excited to welcome everyone at the first-ever virtual USENIX Annual Technical Conference, and we hope you will enjoy it.

Abstract

Fast non-volatile memory (NVM) technology changes the landscape of file systems. A series of research efforts to overcome the traditional file system designs that limit NVM performance. This research has proposed NVM-optimized file systems to leverage the favorable features of byte-addressability, low-latency, and high scalability. The work tailors the file system stack to reduce the software overhead in using fast NVM. As a further step, NVM IO systems use the memory-mapped interface to fully capture the performance of NVM. However, the memory-mapped interface makes it difficult to manage the consistency semantics of NVM, as application developers need to consider the low-level details. In this work, we propose Libnvmmio, an extended user-level memory-mapped IO, which provides failure-atomicity and frees developers from the crash-consistency headaches. Libnvmmio reconstructs a common data IO path with memory-mapped IO, providing better performance and scalability than the state-of-the-art NVM file systems. On a number of microbenchmarks, Libnvmmio gains up to 2.2× better throughput and 13× better scalability than file accesses via system calls to underlying file systems. For SQLite, Libnvmmio improves the performance of Mobibench and TPC-C by up to 93% and 27%, respectively. For MongoDB, it gains up to 42% throughput increase on write-intensive YCSB workloads.

1 Introduction

The recent surge of non-volatile main memory (NVM) technology such as PCM [32, 55], STT-MRAM [4, 30], NVDIMMs [45], and 3D Xpoint memory [21] allows applications to access persistent data via CPU `load`/`store` instructions directly. With the benefits of competitive performance, low power consumption, and high scalability, they are expected to complement or even replace DRAM in future systems [30, 33].

To leverage the performance and persistent features, researchers have proposed NVM-optimized file systems [8, 12, 13, 24, 28, 46, 65, 67, 68]. The most important challenge addressed in the series of work is to revise the inefficient behavior of the software IO stack, which presents a dominating overhead in fast NVM [2, 3, 9, 22, 26, 48, 69]. To reduce the overhead, state-of-the-art NVM-aware file systems discard the traditional block layer and the page cache layer in the IO path. Despite these optimizations, file accesses through the OS kernel's file system still incur significant overhead. For example, `read` and `write` system calls are still expensive ways to leverage the low latency of NVM, due to frequent user/kernel mode switches, data copies, and complicated VFS layers [7, 9, 24, 25, 27, 57, 62].

A promising approach to further reduces IO overhead of NVM file systems is to use memory-mapped IO [9, 35, 58, 60, 67, 68]. The memory-mapped IO naturally fits the characteristics of NVM. Applications can map files to their virtual address space and access files directly with `load`/`store` instructions without kernel interventions. Memory-mapped IO also minimizes the CPU overhead of file system operations by eliminating file operations such as indexing to locate data blocks and checking permissions [65]. With these benefits, the `mmap` would be a critical interface for file IO in future NVM systems.

While memory-mapped IO exposes the raw performance of NVM to applications, a lot of responsibility is laid on applications as well. One thing to keep in mind for application programmers is that memory-mapped IO does not guarantee atomic-durability. If a system failure occurs during memory-mapped IO, the file contents may be corrupted and inconsistent in the application context. In return for fast performance, developers should build application-specific crash-safe mechanisms. Cache lines should be flushed to ensure durability and memory barriers should be enforced to provide a correct persistent ordering for NVM updates. This mechanism often induces a serious software overhead, and makes it notoriously difficult to write accurate and efficient crash-proof code for NVM systems [38, 50–52, 71]. For an instance, applying cache flush and memory barrier instructions correctly in the right locations is challenging; excessive use causes performance degradation, but omitting them in required locations leads to data corruption [39, 70]. This is the major obstacle blocking the adoption of memory-mapped IO to fully exploit the advantages of NVM.

We propose *Libnvmmio*, a user library that provides failure-atomic memory-mapped IO with `msync`. We add atomicity and ordering features to the existing `msync` at user-level. By separating failure-atomicity concerns from memory-mapped IO applications, Libnvmmio allows developers to focus on the main logic of programs. To make the `msync` failure-atomic, Libnvmmio uses user-level logging techniques. Our library stages written data to per-block, persistent logs and applies the updates to memory-mapped files in a failure-atomic manner on `msync`.

Implementing `msync` at user-level has many advantages. First, the user-level `msync` minimizes system call overhead. Existing `msync` imposes system call overhead, which takes locks and excessively serializes threads in a multi-threaded application. Second, it reduces write amplification. Kernel-level `msync` flushes rather large ranges whose size are multiples of the system page size (4KB, 2MB, or 1GB). Whereas, user-level `msync` can track dirty data at a cacheline granularity and flush them at cacheline level. Third, it avoids TLB-shootdown overhead. When applications invoke `msync` on NVM file systems, operating systems track down updated pages by searching for dirty bits in the page table and flush corresponding cache lines of those dirty pages to NVM. After the flush, they clear the dirty bits in the page table to enable tracking new updates. This incurs TLB invalidations in other cores, as dirty bit state is just kind of information in TLB along with the virtual to physical page mapping. As Libnvmmio's `msync` maintains user-level logs for update tracking, we can totally avoid TLB-shootdown overhead. Fourth, it takes advantage of non-temporal `store` instructions which bypass CPU caches with no need of cache flushing. Kernel-level `msync` flushes the entire range, even if updates are performed with non-terminal `store` instructions. In general, there is no other way to communicate with `msync` that the non-temporal stores are used. For all of these reasons, a user-level `msync` in Libnvmmio can perform better than a kernel-level `msync`.

Existing applications that use conventional file IO interface (*e.g.*, `read`/`write`, `fsync`, *etc.*) can also benefit from memory-mapped IO using Libnvmmio. Like FLEX [66] and SplitFS [24], Libnvmmio transparently intercepts the traditional file IO requests and then perform memory-mapped IO. When applications call `fsync`, Libnvmmio carries out its failure-atomic `msync`. Libnvmmio rebuilds the common IO path with efficient mechanisms for read and write performance, but the uncommon, complex file operations such as directory namespace and protection are passed to the slow path of the existing file systems.

Libnvmmio runs on any file systems that supports memory-mapped interface on NVM such as Ext4-DAX, XFS-DAX, PMFS [13], and NOVA [68]. Libnvmmio running on NOVA performs better than NOVA by 2.5× and Ext4-DAX by 1.18× in Mobibench and TPC-C.

Libnvmmio makes the following contributions:

- Libnvmmio extends the semantics of `msync`, providing failure-atomicity.
- With experimental evidences, Libnvmmio demonstrates lower-latency and higher-throughput with scalability than the state-of-the-art NVM file systems
- Design and implementation of Libnvmmio, running on Ext4-DAX, XFS-DAX, PMFS, NOVA. Libnvmmio is publicly available at: https://github.com/chjs/libnvmmio.

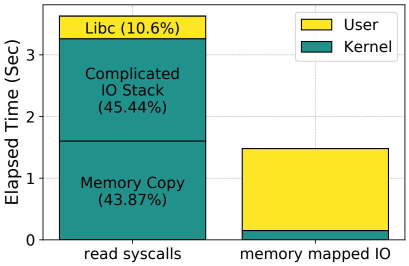

Figure 1: Read syscalls vs. memory mapped IO. Sequential read on a 16GB file. Both cases use `read` or `memcpy` to copy file data into the user buffer by 4KB.

2 Background

2.1 Need for Memory-Mapped IO

The fundamental difference between memory-mapped IO and read-write IO is the data path. The read-write interface copies the user buffer into a kernel buffer[1], searches the file system index to locate physical block address, and performs metadata operations if necessary. Whereas, the memory-mapped interface allows direct accesses to storage, skipping the index searching and copying to the kernel buffer. The simplified data path in memory-mapped IO drastically reduces the software overhead compared to the read-write interface, which significantly improves IO performance in fast non-volatile memory. To compare the performance, we run a micro-benchmark performing sequential reads on a 16 GB file. Figure 1 shows the performance difference. Memory-mapped IO shows 2.3× better performance than the `read` system call. The `read` system calls spends 43.9% out of the IO entire latency on copying user buffers to kernel buffers and 45.4% for the rest of kernel IO stack. Memory-mapped IO eliminates most of the software overhead. We observed that the total number of instructions to execute a single read

[1] Some NVM file systems such as NOVA avoid it.

is 69× less in the memory-mapped IO than the `read` system call.

2.2 Need for Atomic Updates

Modern processors guarantee only cache-sized, aligned stores (64 bit) to be atomic. The atomicity guarantee is not sufficient for general file IO which requires more complex and larger atomic updates. On writing a 4 KB or larger block, a crash may cause partially updated states, which needs significant costs to detect and recover the block. To avoid the hassle, researchers put an effort to make large updates *failure-atomic* in non-volatile memory file systems [24, 28, 67]. Existing file systems deploy a variety of techniques to implement the failure-atomicity guarantee: copy-on-write and journaling. These techniques work in different ways, and the advantages and disadvantages in terms of performance vary.

2.2.1 Copy-on-Write

When updating a block, the Copy-on-Write (CoW) (or shadow-paging) [12, 17, 42, 56, 67, 68] mechanism creates a copy of the original page and writes the new data to the copied page rather than updating the new data in place. Not only for data update but the CoW mechanism performs the out-of-place update for index. For a tree-based indexing structure, the CoW mechanism causes a change of a child node to update its parent node in an out-of-place manner, propagating all the changes of internal nodes up to the top of the tree (called *wandering tree problem*).

The CoW mechanism induce significant software overhead when used in the NVMM system. First, CoW dramatically increases write amplification. CoW usually performs writes at the page granularity, which is a typical node size of file systems indexing. Even if only a few bytes are updated, the entire page must be written. Besides, as the capacity of main memory has increased, the utilization of hugepages (*e.g.*, 2MB or 1GB) is increasing [6, 13, 14, 29, 47, 54]. This trend makes the use of the CoW technique more costly [9]. Second, the CoW technique causes TLB-shootdown overhead in memory-mapped IO. If the CoW technique is applied to memory-mapped files, the mapping of the virtual address must be changed from the original page to the copied page, necessitating TLB-shootdown whenever an update occurs. When a CoW occurs, the kernel flushes the local TLB and send flush requests to remote cores through inter-processor interrupt (IPI). The remote cores flush their TLB entries according to the information received by the IPI and report back when completed. If the remote core has interrupts disabled, the IPI may be kept pending. The initiator core expects to receive all acknowledge the process of flushing the TLBs. This process could take microseconds, causing a notable overhead [3, 61].

2.2.2 Journaling

Journaling (or logging) is a technique that is widely used in databases [43] and journaling file systems [13, 16, 22, 34, 49, 53] to ensure data-atomicity and consistency between data and metadata. It persists a copy of new or original data before updating the original file. If a system failure occurs during writing, the valid log can be used for recovery. Two logging policies are possible: undo logging and redo logging. Redo logging first writes new data to the redo log. When the new data becomes durable in the log, the data are overwritten to the original file. If a system failure occurs while updating the file, the new data in the log can be written again to the file. For read requests, applications need to check the log first because only the log may have the up-to-date data. Undo logging first copies the original data to the log. After the original data becomes persistent, undo logging updates the new data to the file in place. If a system failure occurs during the write, undo logging allows to roll back the original data using the undo log. Because the latest data are always in the file, applications can read the data directly from the file without checking the log. Therefore, undo logging is appropriate for the applications that perform read frequently (§3.4).

Logging techniques require writing data twice: once to the log and once to the original file, which may cause software overhead. However, redo logging allows updating the original file out of the critical path of execution. Because the log has the persistent data, redo logging can postpone updating the file in the background (§3.3). Besides, logging technique is convenient to implement the *differential logging* [1,15,23,36]. Unlike page-based logging, which logs an entire page, the differential logging only logs differential data at the byte-granularity. Differential logging can significantly reduce write amplification especially when it is used for byte-granularity storage devices such as NVM [27].

2.3 Atomic Update for Memory-Mapped IO

While the direct access of memory-mapped IO is essential for reducing the software overhead in NVM file system, it pushes the burden of data atomicity to the application. The POSIX `msync` primitives provides durability and consistency between data and metadata but not atomicity. To support atomicity of large updates, application developers must implement their own reliability mechanism. However, implementing the in-house mechanism is tedious and notoriously buggy [50].

Researchers have proposed adding the atomicity guarantee to the `msync` interface in traditional storage [50] and NVM [67]. To provide atomicity to memory-mapped files, they take journaling-like approaches; dirty pages are staged first and copied to the original file. Providing atomicity at the kernel-level has a fundamental limit which impacts good performance. For example, NOVA [67] creates a replica page on a page fault and maps the replica page on the faulting virtual address. On msync, kernel copies the replica page to the original page atomically. The minimum unit of copying is a page size (4 KB or 2 MB), which causes write amplification for small IO requests.

3 Libnvmmio

The purpose of Libnvmmio is eliminating software overhead, while providing low-latency, scalable file IO with ensured data-atomicity. Libnvmmio is linked with applications as a library, providing the efficient IO path by using the mmap interface. In particular, Libnvmmio has following design goals and implementation strategies.

Low-latency IO. Reducing software overhead is crucial to take advantage of low latency NVM. Since Libnvmmio aims to make the common IO path efficient for low-latency IO, it avoids using the complicated kernel IO path including the slow journaling for common cases.

Efficient logging for data atomicity. Libnvmmio transparently intercepts file APIs and provides atomicity for data operations by using logging. As sustaining low-latency file IO is essential, Libnvmmio endeavors to minimize write amplification and software overhead for data logging.

High-throughput, scalable IO with high concurrency. To sustain high throughput across different IO sizes, Libnvmmio uses varying sizes of log entries depending on IO sizes. To this end, Libnvmmio deploys a flexible data structure for indexing the log entries and handles various *log entry* sizes. Additionally, Libnvmmio aims to achieve high concurrency through fine-grained logging and scalable indexing structure.

Data-centric, per-block based organization. Libnvmmio constructs most of its data structures and metadata as data-centric. For example, Libnvmmio builds per-block logs and metadata rather than per-thread or per-transaction based logs. Data-centric design allows a single instance of a data structure and metadata for a corresponding data block. The singleton design makes it easy to coordinate shared accesses with locks. As multiple threads access the same large file concurrently in recent applications, they require more fine-grained locks than entire file locks [40]. With fine-grained locks at block level, Libnvmmio achieves scalability for data-centric logging. Per-inode logging improves scalability, when multiple accesses are performed on different files [67,68]. However, it provides a limited degree of scalability for multiple accesses to the same file.

Transparent to underlying file systems. On top of existing NVM file systems, Libnvmmio improves the performance for common data IO, keeping POSIX interfaces unchanged. For complex, uncommon IO operations, Libnvmmio leverages rich, well-tested features of existing file systems. Without breaking POSIX semantics, Libnvmmio offers extended POSIX APIs to applications for additional features. For example, POSIX semantics does not guarantee atomicity of mmap. While atomicity is useful, not all files need atomic update guarantees — it is unnecessary for temporal files. Libnvmmio extends open API to let applications indicate atomicity guarantee in a per-file basis. To communicate with the kernel, Libnvmmio translates the extended APIs to the conventional APIs with additional flags. With such a user-level extension design, Libnvmmio runs on any NVM file systems that support DAX-mmap, while enjoying file-system specific features such as fast snapshot and efficient block allocation.

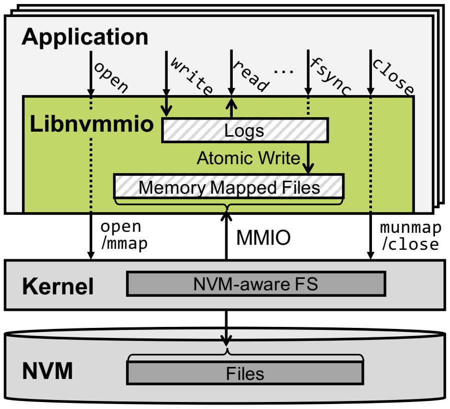

Figure 2: Libnvmmio Overview

3.1 Overall Architecture

Libnvmmio runs in the address space of a target application as a library and interacts with underlying file systems. Libnvmmio intercepts IO requests and turns them into internal operations. For each IO request, Libnvmmio distinguishes data and metadata operations. For all data requests, Libnvmmio services them in the user-level library, bypassing the slow kernel code. Whereas, for complex metadata and directory operations, Libnvmmio lets the operations be processed by the kernel. This design is based on the observation that data updates are the common, performance-critical operations. On the other hand, the metadata and directory operations are relatively uncommon and include complex implementation to support POSIX semantics. Handling them differently, the architecture of Libnvmmio follows the design principle of making the normal case fast [31] with a simple, fast user-level implementation.

Figure 2 shows the overall architecture of Libnvmmio. When an application opens a file, Libnvmmio interposes the open call with a user-level open API. Within the open API, it maps the whole content of the file onto the user memory space and initializes *per-file metadata* (§3.5). The metadata Libnvmmio initializes includes inode number, logging policy, epoch number, *etc*. After the initialization, it returns the file descriptor to the application.

Memory-mapped IO. To directly access the NVM, Libnvmmio maps the file via `mmap` system call. Libnvmmio intercepts and replaces `read` calls with `memcpy`, and `write` calls with a non-temporal version of `memcpy` that uses the `movnt` instruction. There are two reasons why the memory-mapped IO allows faster NVM access than the traditional kernel-served read and write method. First, when persisting and obtaining data, the simple, the fast code path in Libnvmmio replaces the complex, slow kernel IO path [24, 28]. Second, `read` and `write` system calls involve indexing operations to locate physical blocks, which causes a non-trivial software overhead for fast NVM accesses. Whereas, in memory-mapped IO, the kernel searches the complex index when it maps the file blocks to the user address space on page faults. After the mapping is established, Libnvmmio can access the file data simply with offset in the memory-mapped address, eliminating the indexing operations in the steady state. Besides, finding file blocks through virtual addresses is offloaded to the MMU (*e.g.*, page table walkers, TLBs). Therefore, it reduces a sizable amount of the CPU overhead caused by file indexing [65].

Atomicity and durability with user-level logging. On `SYNC`[2] calls, Libnvmmio flushes the cache data and stores the data to NVM atomically via the logging mechanism. All write data are firstly persisted to the user-level log and later they are copied (called *checkpoint*) to the memory-mapped file. Data from both `write` and `memcpy` interfaces goes down the same path.

Providing atomicity via the user-level logging has several advantages over the kernel-level design. Using the user-level IO information, Libnvmmio can leverage the byte-addressability of NVM to log data in the fine-grained unit. On the other hand, in the kernel-level approach, the logging unit should be a page size, as `msync` relies on the page dirty bit to log the memory-mapped data, causing write amplification in case of small writes (*i.e.*, less than a page size). After `msync` is done, kernel must clear the dirty bit in the page table followed by TLB shootdown. However, user-level design uses own data structure to track dirty data without relying on the page dirty mechanism, saving unnecessary TLB shootdowns.

Application transparency. For applications using `read` and `write`, Libnvmmio can transparently replace them with the memory mapped IO operations. For applications using `mmap`, Libnvmmio can redirect the memory operations to NVM memory-mapped IO operations without effort.

Providing atomic-durability on top of the `mmap` interface makes the case challenging, as Libnvmmio cannot distinguish the `memcpy` operations that requires atomic-durability from the ones that do not require.

Guaranteeing atomicity to all IO operations is prohibitively expensive. Some IO requests do not need atomicity such as logging internal traces or errors. To address the problem, Libnvmmio exposes two version of `memcpy`: POSIX version and Libnvmmio version. Libnvmmio versions are prefixed with `nv` (*e.g.*, `nvmmap`, `nvmemcpy`, `nvmunmap`, *etc.*) and provide atomic-durability. Libnvmmio avoids intrusive modifications of existing applications in order to use the Libnvmmio APIs. Instead, we instrument the application binary with an in-house tool, which lists the files the application accesses and asks developers which files need atomic-updates. With the list of files requiring atomic-durability, we patches the binary to use Libnvmmio APIs. In most cases, applications use `read`, `write`, or `memcpy` APIs, which are easy to patch for the application binary. However, in case of manipulating files with pointers, we need source-level modifications (*e.g.*, 182 lines in the MongoDB MMAPv1 engine).

3.2 Scalable Logging

Applications such as in-memory database and key-value stores, that benefit from Libnvmmio, require high concurrency level to sustain high throughput. Libnvmmio responds to the high concurrency requirement with scalable logging that is based on per-block data logging and indexing.

3.2.1 Scalable per-block logging

Finding proper logging granularity is necessary to achieve high concurrency. Application-centric techniques such as per-thread and per-transaction logging are widely adopted in databases, providing high concurrency. However, these techniques rely on the strong assumption that data is only visible and applicable to the current thread or transaction; *e.g.*, data in logs need not to be shared among threads or transactions, which is guaranteed by isolation property. Logging without needing to consider shared data allows for high scalability. However, the assumptions do not hold in general IO cases; sharing IO data among threads is a common use case. Moreover, the transaction boundary is not visible to the current design of Libnvmmio.

Instead, Libnvmmio performs data-centric logging. It divides the file space into multiple file blocks (4 KB∼2 MB) and creates a log entry for each file block. Log entries in Libnvmmio are visible to all threads. The fine-grained, per-block logging allows a flexible way to share data among threads. When an update is made to a mapped file, Libnvmmio creates a log entry indexed by the offset, where the update occurred in the memory-mapped file. If other threads read the updated offset, it serves data from the log entry instead of the original

[2] This term means both `fsync` and `msync`.

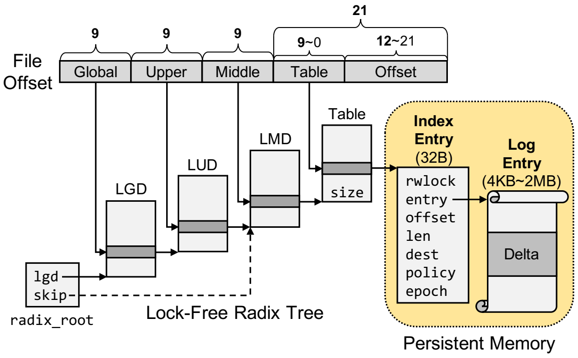

Figure 3: Indexing structure of Libnvmmio.

mapped file. When another update comes to the same file offset, it overwrites the update in the existing log entry. For shared data reads, per-block logging provides better performance than per-thread logging, as per-thread logging needs to search all the logs of all threads to gather all the updates made to the same file blocks. In addition to per-block logging, Libnvmmio takes advantage of the byte-addressable characteristics of NVM and reduces write amplification by performing differential logging for a partial update, where the update size is smaller than log block size.

3.2.2 Scalable log indexing

Along with data logging, indexing design is also critical to achieve high concurrency. Libnvmmio uses a file offset as an index key to a log block. To index many log blocks, Libnvmmio uses multi-level indexing to reduce space overhead. Similar to the page table, it uses radix trees for indexing. Fixed-depth trees allow lock-free mechanisms, which provide better concurrency than balanced trees such as red-black trees. As balanced trees require coarse-grained locks to protect the entire trees for tree re-balancing, their algorithms severely hurt concurrency [10, 11].

Figure 3 shows the index design of Libnvmmio. Each internal node is an array of buckets pointing to the next level internal nodes. Each set of 9 bits from file offset is used to locate a bucket in a corresponding internal node. Each leaf node points to an *index entry*, where entry field points to *log entry*. The index entry also contains other metadata for the given file offset. Libnvmmio supports variable-size log entries for large IO requests. Log entries range from 4KB to 2MB, doubling the size. To index 4KB log entries, it uses 9 bits for Table and 12 bits for Offset. For 2 MB log entry, it uses 21 bits for Offset without using Table.

In an index entry, offset and len are used for updated data offset within a log entry and update size, respectively. If update size in len is smaller than the log entry size, it means the log entry contains partial updates (Delta). The log entry can hold a single delta chunk indicated by offset and len. If another delta chunk needs to be added in the same log entry, the two chunks are merged. The virtual address of the memory mapped file specified in dest is the location where the log will be checkpointed. The logging policy for the corresponding data is specified in policy, which decides whether Libnvmmio uses undo log or redo log (§3.4). To determine if the log entry should be checkpointed, the number in epoch is used (§3.3).

The radix tree has a fixed depth to implement a lock-free mechanism. The four-level radix tree can support 256 TiB file size, but it can cause unnecessary search overhead for small files. Libnvmmio uses a skip pointer to implement a lock-free radix tree while also reducing the search overhead. As shown in Figure 3, the radix_root has a skip field. If the file size is small, Libnvmmio uses the field to skip unnecessary parent nodes. When the file size changes, Libnvmmio can adjust the skip pointer.

To achieve fast indexing, Libnvmmio manages the internal nodes of the radix tree in DRAM and does not persist them to NVM. It persists only the index entries and the log entries. Libnvmmio does not need to build the entire radix tree for recovery. On a crash, it simply scans the persisted index and log entries, which are committed but not checkpointed yet. It can copy the log entries to the original file by referring the dest attribute in the corresponding index entries and the per-file metadata. To achieve high concurrency, Libnvmmio does not use any coarse-grained locks to update internal nodes of the radix tree. Instead, it updates each bucket of internal nodes with an atomic operation. Only when it needs to update index entry, it holds the per-entry, reader-writer lock.

3.3 Epoch-based Background Checkpointing

Log entries are committed on SYNC[3]. The committed log entries must be checkpointed to the corresponding memory-mapped file and cleaned. To make the checkpoint operations out of the performance critical path, Libnvmmio checkpoints the log entries in the background. It periodically wakes up checkpointing threads for copying and cleaning log entries[4]. While checkpointing, the background threads do not need to obtain a coarse-grained tree lock. This minimizes disruption on on-going read/write operations. The background threads holds a per-entry writer lock to serialize checkpoint operations and read/write requests on the log entry.

Libnvmmio uses per-block logging. When an application calls SYNC, it must convert many of the corresponding per-block logs to committed status. This increases the commit overhead significantly. To avoid such overhead, Libnvmmio performs committing and checkpointing based on the epoch, which increases monotonically. Libnvmmio maintains two

[3] This term means both fsync and msync.

[4] Through sensitivity studies, we configured Libnvmmio wakes up the threads every 100 microsecond.

types of epoch numbers; each index entry has an epoch number for its update log and per-file metadata carries the current global epoch number. When allocating an index entry, it assigns the current global epoch number for file to the epoch number for the index entry. Libnvmmio increases the current global epoch number, when applications issue SYNC calls to the file. The epoch numbers are used to distinguish committed (but yet to be checkpointed) log entries from the uncommitted ones. If a log entry has a smaller epoch number than the current global epoch number, it indicates that the log entry is committed. If the epoch number of a log entry is the same as the global epoch number, the log entry is not yet committed. Libnvmmio checkpoints only committed log entries in the background threads. After being checkpointed, log entries are cleaned and reused later.

The epoch-based approach allows fast commit of log entries, as Libnvmmio does not need to traverse the radix tree and mark log entries as committed. Instead, it simply increases the current global epoch number in the per-file metadata, which reduces SYNC latency greatly. Commit operations are performed synchronously and atomically, when the application calls SYNC. Meanwhile, checkpoint operations are done asynchronously by background threads. Consequently, there are committed logs and uncommitted logs mixed in the radix tree. When applications request writes, the corresponding log entries are overwritten for uncommitted ones. Meanwhile, Libnvmmio synchronously checkpoints the committed logs first for committed ones. After completing the checkpointing, it allocates a new uncommitted log and processes write requests.

3.4 Hybrid Logging

Libnvmmio uses a hybrid logging technique to optimize IO latency and throughput. As pointed out in §2.2.2, undo logging performs better when accesses are mostly reads, whereas redo logging is better when accesses are mostly writes. To achieve the best performance of both logging policies, Libnvmmio transparently monitors the access patterns of each file and applies different logging policies depending on current read and write intensity.

Libnvmmio maintains counters to record read and write operations for a file (§3.5). When SYNC is called, Libnvmmio checks the counters to determine whether which type of logging would be better for the next epoch. If the logging policy changes, Libnvmmio carries out both committing and checkpointing synchronously. SYNC is a clean transition point for changing the logging policy, as current log data are checkpointed and cleaned. This allows Libnvmmio to avoid complex cases where it otherwise has to maintain two log policies at the same time. The per-file, hybrid logging enables the fine-grained logging policy, allowing Libnvmmio to adopt the individually best logging mechanism for each file. By default, Libnvmmio uses undo logging. It switches to redo logging, when the ratio of write operations becomes higher than or equal to 40%. The policy for the new epoch is determined by the write ratio in the previous epoch. The threshold ratio is obtained from the sensitivity analysis in §4.2.1.

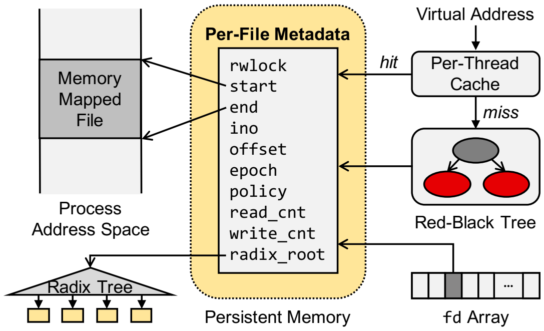

Figure 4: Per-File Metadata

3.5 Per-File Metadata

Libnvmmio maintains two types of metadata in persistent memory; the index entry is the metadata for each log entry, and the per-file metadata shown in Figure 4 is the metadata for each file. Libnvmmio stores both metadata as well as log entries in NVM, which enables Libnvmmio to recover its data in case of system failures.

When Libnvmmio accesses a file, it first gets the per-file metadata of the file and the index entry corresponding to the file offset. If applications access a file with nvmemcpy interface, it needs to find the per-file metadata by using access address of the nvmemcpy. The approach Libnvmmio takes for this purpose is to employ a red-black tree and perform range searches with virtual addresses. To speed up the search process, Libnvmmio caches recently used per-file metadata in the per-thread cache. Meanwhile, Libnvmmio can quickly obtain the per-file metadata through the file descriptor, if applications access files with read/write interface.

The per-file metadata consists of ten fields. The rwlock is a reader-writer lock. During SYNC process, this lock prevents other threads from accessing the file. The start and end fields store the location of the virtual address to which the file is mapped. The ino and offset fields record which part of a file is mapped. The epoch field stores the current global epoch number for the file. The policy field stores the current logging policy for the file. The read_cnt and write_cnt are counters of read and write operations during the current epoch, respectively. The radix_root field stores the root node of the radix tree indexing for index entries and log entries.

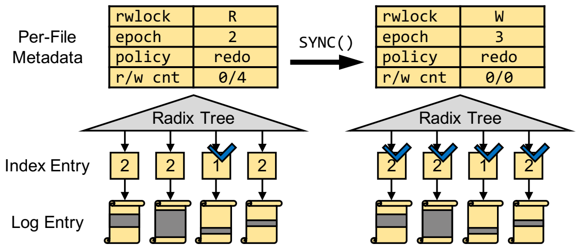

Figure 5: Epoch-based committing

3.6 Putting all together: `write` and `SYNC`

Figure 5 shows the steps of the epoch-based checkpointing in Libnvmmio. The numbers in the index entries indicate per-entry epoch numbers, and the check marks indicate their log entries are committed. A simplified version of per-file metadata is shown in tables.

Write. ① The thread holds the reader lock in the per-file metadata of the file and increases the write counter with atomic operations. Holding the reader lock in per-file metadata allows multiple threads to access the file concurrently. ② The thread traverses the in-memory radix tree to locate the corresponding index entry and holds the writer lock for the index entry. ③ Depending on the current logging policy in the per-file metadata, Libnvmmio creates an undo or redo log entry. ④ The thread writes data to the log entry with the non-temporal `store` instruction, and Libnvmmio updates the index entry of the log entry. ⑤ Libnvmmio calls `sfence` indicating logging is done and unlocks the index entry and per-file metadata, and returns to the application.

SYNC. ① Libnvmmio holds the writer lock in the per-file metadata and increases the global epoch counter by one. Holding the writer lock of the per-file metadata prevents other threads from accessing the file. ② Libnvmmio calculates the write ratio from the write and read counters. In the example in Figure 5, Libnvmmio continues to use redo logging for the next epoch, as the access pattern is write-intensive (4 writes out of 4 accesses). After determining the logging policy, Libnvmmio initializes the counters. When logging policy is unchanged, Libnvmmio lets checkpointing threads commit log entries in the background. If Libnvmmio decides to change logging policy, it synchronously checkpoints all committed log entries before the new epoch begins. ③ Finally, Libnvmmio unlocks the per-file metadata and returns to the application.

3.7 Crash Consistency and Recovery

Libnvmmio preserves write ordering of a sequence of write requests. For each write, Libnvmmio writes data to the log and flushes the CPU cache. The order-preserving write provides the prefix semantics [63], guaranteeing every thread to see a consistent version of data updates. Along with the consistency of data, Libnvmmio guarantees consistency between metadata and data. Libnvmmio maintains two persistent metadata: per-file metadata and index entries. Libnvmmio strictly orders between the sequence of [data update, index entry update] and `SYNC` call.

In the recovery phase, Libnvmmio checks whether the index entries are committed, while scanning the index entries. If Libnvmmio finds a committed log, whose epoch number is smaller than the global epoch number, it finds the per-file metadata from the index entry's `dest` attribute. Then, it redoes or undoes according to the logging policy. Libnvmmio can efficiently parallelize this recovery task by using multithreading.

NVMM	Rand Read	Rand Write	Seq Read	Seq Write
NVDIMM-N	35.84	20.61	92.42	20.65
Optane DC	3.588	1.026	13.64	4.30

Table 1: NVMM Characteristics (GB/s)

4 Evaluation

We implemented Libnvmmio from scratch. Our prototype of Libnvmmio has a total 3,452 LOC[5] in C code. To persist data to NVM, Libnvmmio employs the PMDK library [20].

4.1 Experimental setup

To evaluate Libnvmmio on different types of NVM, we used NVDIMM-N [45] and Intel Optane DC Persistent Memory Module [19]. The system with 32GB NVDIMM-N has 20 cores and 32GB DRAM. Another system with 256GB Optane has 16 cores and 64GB DRAM. In the Optane server, we used two 128GB Optanes configured in *interleaved App Direct* mode. Table 1 shows the results of measuring the performance of each memory using Intel Memory Latency Checker (MLC) [18].

In our experiment, Libnvmmio used NOVA [68] running on Linux kernel 5.1 as its underlying file system. To compare Libnvmmio with various file systems, we experimented with four file systems: Two of these, Ext4-DAX and PMFS [13], journal only metadata and perform in-place writes for data. The two others, NOVA and SplitFS [24], guarantee data-atomicity for each operation. We configured NOVA to use CoW updates, but without enabling checksums. For SplitFS, we configured it to use *strict* mode. We ran PMFS and SplitFS on Linux kernel 4.13, and Ext4-DAX and NOVA on Linux kernel 5.1. Kernel versions are the latest versions that support the underlying file systems.

[5] we measure LOC with sloccount [64]

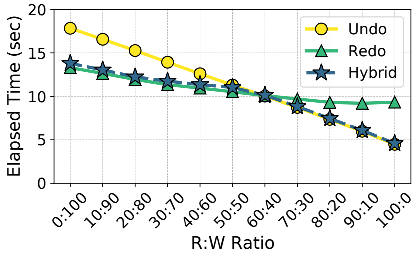

Figure 6: Performance on different logging policies

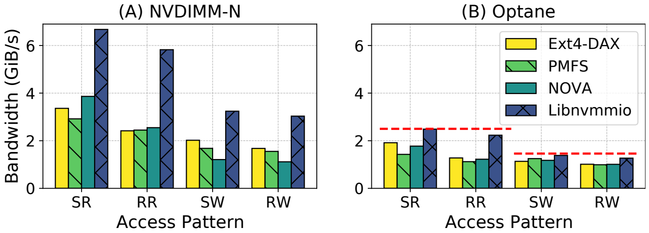

Figure 7: Performance on different access patterns

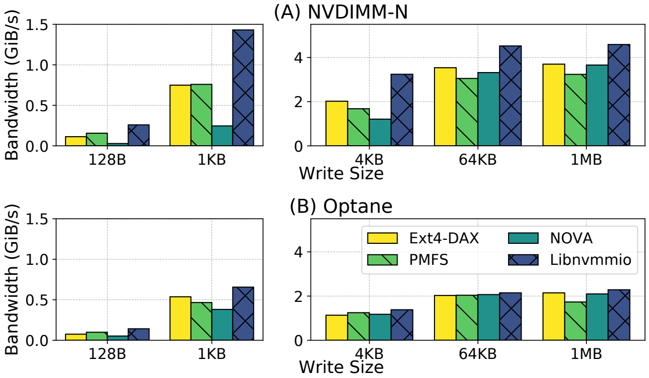

Figure 8: Performance on different write sizes

4.2 Microbenchmark

4.2.1 Hybrid logging

Most logging systems adopt only one logging policy (redo or undo). Each logging policy has different strengths and weaknesses, depending on the type of file accesses. While redo logging is better for write-intensive workloads, undo logging is better for read-intensive workloads.

Figure 6 shows how logging policies (redo, undo, and hybrid logging) affect the performance of Libnvmmio. Undo logging shows better performance than redo, when the workload has high read ratio. Redo logging shows better performance than undo, when the workload has high write ratio. When the *R:W ratio* is 60:40, the two logging policies show the same level of the performance. Based on this observation, Libnvmmio uses the ratio as a change point for its hybrid logging policy. As shown in Figure 6, hybrid logging in Libnvmmio achieves the best case performance of the two logging policies.

4.2.2 Throughput

We measured the bandwidth performance by using FIO [5]. It repeatedly accesses a 4GB file in units of 4KB for 60 seconds in a single thread. Two graphs in Figure 7 show the experiment results on NVDIMM-N (A) and Optane (B), respectively. Four file access patterns are used for our experiment: sequential read (SR), random read (RR), sequential write (SW), and random write (RW). All the other file systems except Libnvmmio perform the file IO at kernel level. Libnvmmio avoids the kernel IO stack overhead and performs file IO mostly at user level.

As shown in Figure 7, Libnvmmio provides the highest throughput on all access patterns, outperforming the other file systems by 1.66$\sim$2.20× on NVDIMM-N and 1.14$\sim$1.74× on Optane. The performance improvements are more noticeable in NVDIMM-N than in Optane. The maximum achievable bandwidths on Optane are 2.5GB/s and 1.46GB/s for FIO mmap based read and write without atomicity support. These are indicated as red dotted lines in Figure 7 (B). The performance results on Optane are almost near the maximum achievable bandwidths for Libnvmmio, which suggests the performance on Optane is limited by the hardware limit, not by the mechanisms in Libnvmmio.

The performance in Libnvmmio is also improved over the other file systems by maximizing logging efficiency in hybrid logging. For read access patterns (SR and RR), Libnvmmio performs only user-level `memcpy` from the memory-mapped file to the user buffer under the undo logging. For write access patterns (SW and RW), Libnvmmio updates only the log, not the memory-mapped file, under the redo logging and asynchronously writes the data from the redo log on `SYNC` call at the file close.

Figure 8 shows the performance of the FIO sequential write on various IO sizes. Libnvmmio performs per-block logging, but provides various log block sizes. With this feature, Libnvmmio can keep the high performance across different IO sizes. The performance generally improves on the increased IO sizes for all file systems and Libnvmmio, as the number of write system calls decreases within the 60 second duration of FIO experiment. Libnvmmio shows significantly higher performance than the other file systems when the IO size is smaller than the page size (128B, 1KB). This is mainly due to the differential logging feature in Libnvmmio. For file systems that use CoW for atomicity, such as NOVA, write amplification becomes a large overhead on sub-page size data writes.

Figure 9 shows the performance of the FIO sequential write on different `fsync` intervals. The horizontal axis represents the fsync frequency. For example, the interval *10* means FIO performed fsync after every ten writes issued. The performance of Ext4-DAX and PMFS slightly increased as the fsync interval increased. Since Ext4-DAX and PMFS perform

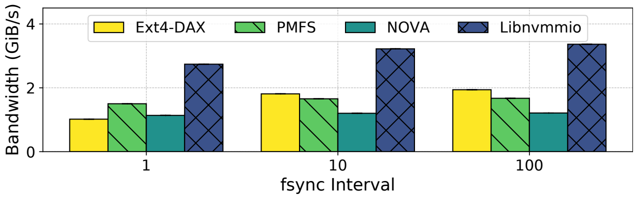

Figure 9: Performance on different `fsync` intervals

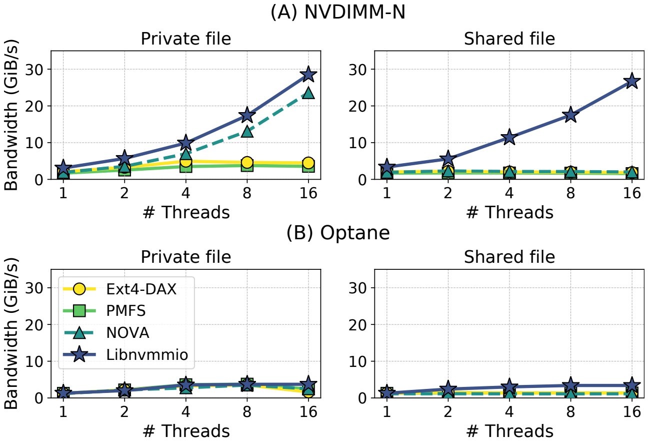

Figure 10: Scalability: FIO random write with multithreads

Latency (us)	Ext4-DAX read	 write	PMFS read	 write	NOVA read	 write	Libnvmmio read	 write
Avg.	1.73	50.43	2.21	6.16	1.73	4.43	1.12	4.14
99th	3	61	3	9	3	9	2	10
99.9th	6	552	4	12	3	10	3	12
99.99th	8	605	8	239	6	15	5	15
99.999th	12	648	17	258	8	5216	7	76

Table 2: 4KB read and write latencies on Optane

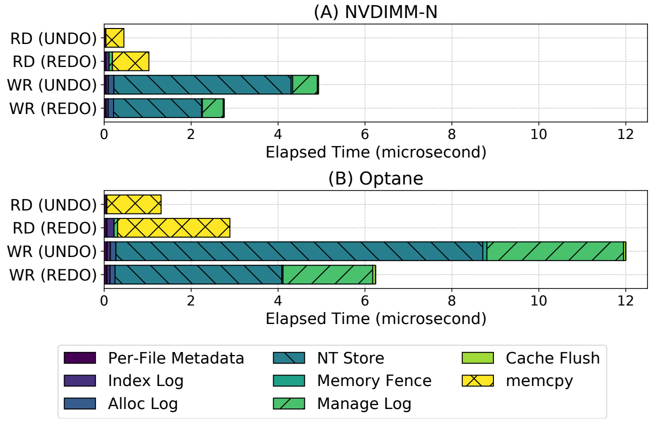

Figure 11: Latency breakdown

only metadata journaling, there is no dramatic performance improvement. NOVA shows the same performance regardless of the fsync interval. Since NOVA performs all the writes atomically and fsync actually does nothing, its performance is not sensitive to the fsync intervals. Libnvmmio implements fsync efficiently with almost little overhead by increasing the current global epoch number at user level. A heavy-lifting work for checkpointing data log is processed in the background. As the fsync interval increases, checkpointing can be done in a batch even in the background. Thus, Libnvmmio can slightly increase the performance on long intervals.

4.2.3 Scalability

Figure 10 shows the performance of multithreaded file IO with FIO random write. In *private file* configuration, each thread writes data to its private file. Whereas, all threads write data to one shared file in *shared file* configuration. In private file configuration on NVDIMM-N, Libnvmmio and NOVA show highly scalable performance. Libnvmmio still shows 29% better performance than NOVA. In contrast, only Libnvmmio sustains scalable performance in shared file configuration on NVDIMM-N. Libnvmmio achieves 13× better performance on 16 threads run than NOVA. It is common for modern applications to access shared files simultaneously from multithreads [40]. While NOVA uses per-inode logging with entire file locks, Libnvmmio uses per-block logging with fine-grained per-block locks. This makes Libnvmmio achieve scalable performance, even when multithreads access the shared file simultaneously. The scalability on Optane is limited mainly due to the memory bandwidth limitation, but Libnvmmio on Optane still shows a little promising results than the others. The other two file systems, Ext4-DAX and PMFS rarely scale on multi-threaded experiments.

4.2.4 Latency

We measured write and read latencies of various NVM-aware file systems and Libnvmmio. To make a fair comparison, all operations are synchronous (`fsync` on every write operation). Table 2 shows the latency of 4KB IO by a single thread. The results were measured on Optane. Libnvmmio outperforms all the other file systems. The advantage of Libnvmmio comes from writing logs in user space and background checkpointing. Ext4-DAX requires copying data between user and kernel buffers, PMFS involves modification of complex data structures, and NOVA requires CoW. Low tail latencies on 99.999th show that Libnvmmio has a high chance to meet the demand for target applications. Since Libnvmmio hooks read/write calls and does not involve any kernel mode switches, Libnvmmio on any file systems can remove the complex techniques the kernel level file systems use. The Libnvmmio latencies on other file systems exhibit almost the same as the ones in Table 2. Our results indicate that applications sensitive to tail latency can adopt Libnvmmio on top of their file systems and drop tail latency dramatically.

Figure 11 shows the latency breakdown of `read` and `write` for two logging policies (undo and redo). As for write, the

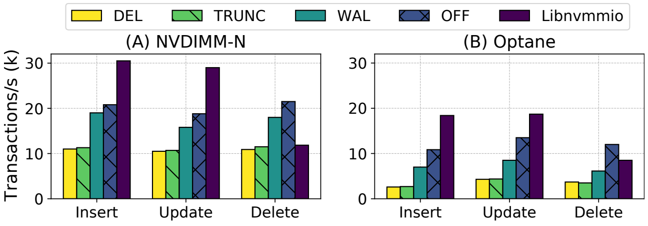

Figure 12: Mobibench on SQLite

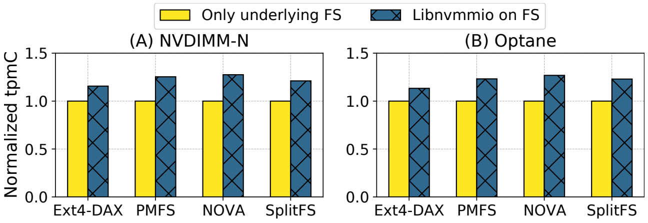

Figure 13: TPC-C on SQLite

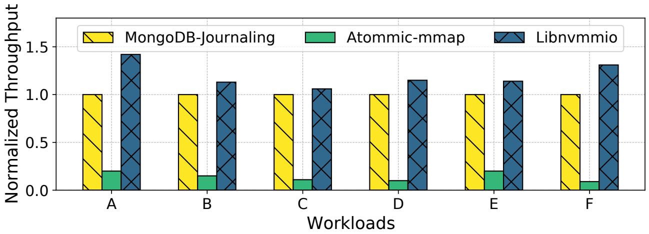

Figure 14: YCSB performance on MongoDB

portion of non-temporal store (NT Store) is dominating. However, the overheads of the memory fence and cache flush is low due to NT store. In this experiment, we confirmed that it is crucial to select an appropriate logging policy according to access types, as the time spent on memory copy (memcpy, NT Store) varies greatly depending on logging policy. The actual seconds for read and write latencies in Figure 11 are bigger than the latency in Table 2, as time measurement routines for breakdown have been injected.

4.3 Real applications

4.3.1 SQLite

We experimented with SQLite [59] to see how Libnvmmio performs in real applications. To guarantee data-atomicity, SQLite uses its own journaling by default. SQLite calls `fsync` on commit to ensure that all data updated in a transaction is persistent. Libnvmmio keeps updated data in its logs and atomically writes to the original file when `fsync` called. This is how data-atomicity can be guaranteed on SQLite on Libnvmmio without the journaling provided by SQLite. However, the file systems we experimented with cannot turn off the journaling. Even file systems that provide data-atomicity for each operation cannot guarantee the atomicity at transaction level without the journaling.

We used Mobibench [41] to evaluate the basic performance of SQLite. In this experiment, we ran SQLite on NOVA with various journal modes: delete (*DEL*), truncate (*TRUNC*), write-ahead logging (*WAL*), no-journaling (*OFF*). Figure 12 shows that Libnvmmio outperforms all journaling modes on insert and update queries. Even when no journaling is provided from SQLite, Libnvmmio outperforms as all file accesses are handled at user level. Compared to WAL mode on NVDIMM-N, insert and update queries have 60% and 93% performance gains in Libnvmmio, respectively. On Optane, the performance gains become 162% and 120%. Mobibench queries request about 100B data IOs. Libnvmmio excels on such small size IOs. On delete transactions, Libnvmmio performs not quite well. According to our call trace, files are truncated frequently on delete workload. When a file is truncated, Libnvmmio needs to adjust the mapping size along with the file size as in FLEX [66] and SplitFS [24]. This incurs relatively high overhead on Libnvmmio. To mend this problem, Libnvmmio needs to optimize file size changes by reflecting file size changes on file close.

We evaluate Libnvmmio on four different file systems by running TPC-C with SQLite. Figure 13 shows that running on Libnvmmio exhibits better performance than running only on underlying file systems. The performance gains range from 16% to 27% on NVDIMM-N and from 13% to 27% on Optane. Since Libnvmmio processes file IO at user level, most of file IO operations can be handled efficiently. As for SplitFS [24], which is built as user-level file system, Libnvmmio uses only mmap interface from SplitFS and performs all other functionalities with its own mechanism. This is why the performance on SplitFS is better for Libnvmmio than only SplitFS. Data updates are kept in its staging files in SplitFS. When applications call `fsync`, SplitFS relinks the updated blocks in staging files into the original file without additional data copying. To make the relink mechanism work, a complete content of the block is required. If applications update only part of a block, SplitFS must copy the rest of the partial data for that block on fsync. The relink mechanism also needs splitting and remapping the existing mapping. Since mapping changes require expensive TLB-shootdown, remapping can cause a higher cost than copying [37]. Additionally, frequent relinks can cause extent fragmentation, as SplitFS uses Ext4-DAX as its underlying file system.

4.3.2 MongoDB MMAPv1

To evaluate Libnvmmio for applications that use memory-mapped IO, we experimented with MongoDB [44] MMAPv1 engine. MongoDB MMAPv1 maps DB files onto its address space, and read/write data with `memcpy`. We have modified 182 lines of source code to make MongoDB MMAPv1 engine use interfaces in Libnvmmio. Figure 14 shows the performance of YCSB workloads on MongoDB. *MongoDB-Journaling* represents the performance when MongoDB uses its own journaling. In order to ensure that all modifications to a MongoDB data set are durably written to DB files, MongoDB, by default, records all modifications to a journal file. After persisting the data in journal, MongoDB writes the data to a memory-mapped file. Then, it calls `msync` periodically to flush the data in the memory to its file image on the persistent storage. If a system failure occurs during the synchronization, MongoDB can redo the updates by using the journal. *Atomic-mmap* represents the performance when MongoDB uses atomic-mmap provided by NOVA [67]. NOVA maps the replica pages of files onto the user memory, and later when `msync` is called, it copies the replica pages atomically to the original file. In this case, MongoDB can guarantee data-atomicity without using its own journaling. Libnvmmio also ensures the same level of data-atomicity as the atomic-mmap in NOVA. *Libnvmmio* represents the performance when Libnvmmio is used without MongoDB journaling. Compared to MongoDB journaling, Libnvmmio shows 31∼42% performance gains on write intensive workloads (A and F). On read intensive workloads (B, C, D, and E), it shows 6∼15% gains.

Libnvmmio shows the highest performance for all workloads. In YCSB workloads, the default record size is 1KB. Since MongoDB-Journaling uses msync provided by the OS kernel, the synchronization is performed at page granularity. This increases the write amplification but also incurs TLB-shootdown overhead. Whereas, Libnvmmio uses differential logging and user-level msync to minimize write amplification and eliminate unnecessary TLB-shootdown. Atomic-mmap also performs synchronization at page granularity. Besides, as all the replica pages of the file are synchronized regardless of their states (clean or dirty), huge write amplification occurs. Due to such inefficiency, the atomic-mmap feature has been removed from the latest NOVA [68].

5 Related Work

In NVMM systems, file operations travel through memory bus led significantly improved latency. In traditional systems, storage latency was dominant in the total file IO overhead, but in NVMM systems, inefficient behavior of software stacks becomes a dominating overhead. State-of-the-art NVMM-aware file systems bypass the block layer and the page cache layer to avoid the software overhead. Many optimizations take the characteristics of NVMM into account in the file system design. Some suggest to fundamentally change the way file operations work from kernel space to user space.

BPFS and PMFS are early versions of NVMM-aware file systems. BPFS [12] manages the CPU cache based on epoch to provide an accurate ordering and provides atomic data persistence with short-circuit shadow paging. PMFS [13] came up with eXecute In Place (XIP) which nowadays call Direct Access (DAX). PMFS pointed out that NVMM systems should bypass the block layer and page cache to remove unnecessary management schemes from past days.

NOVA [67, 68] suggested more efficient software layer to manage NVMM. NOVA extends the log-structuring technique optimized for block devices to NVMM. NOVA gives each inode a separate log. This technique is suited well in NVMM utilizing fast random access characteristics of NVMM. NOVA provides protection against media errors as well as software errors.

Aerie [62] is a user-level file system that provides flexible file system interfaces. Aerie maximizes the benefits of low-latency NVMM by implementing file system functionality at the user-level. However, Aerie does not guarantee data-atomicity and does not support POSIX semantics.

Strata [28] is a cross-media file system that suggested separation of kernel and user responsibilities. While providing fast performance for read and write, Strata does not support atomic memory-mapped IO. Strata brought data into user space and processes metadata in kernel space.

FLEX [66] replaces read/write system calls with memory-mapped IO to avoid entering the OS kernel. FLEX provides transparent user-level file IO, allowing existing applications to utilize the characteristics of NVMM efficiently. However, FLEX does not guarantee data-atomicity.

SplitFS [24] supports user-level IO while providing flexible crash-consistency guarantees. The relink mechanism proposed by SplitFS allows atomic file updates with minimal data copying. SplitFS handles common data operations at the user level and offloads complex and uncommon metadata operations to kernel file systems. SplitFS proposed the proper role of user libraries and kernel file systems for efficient file IO.

6 Conclusion

Libnvmmio is a simple and practical solution, which provides low-latency and scalable IO while guaranteeing data atomicity. Libnvmmio rebuilds performance-critical software IO path for NVM. It leverages the memory-mapped IO for fast data access and makes applications free from the crash-consistency concerns by providing failure-atomicity. Source code is publicly available at: https://github.com/chjs/libnvmmio.

Abstract

Popular LSM-tree based key-value stores suffer from suboptimal and unpredictable performance due to write amplification and write stalls that cause application performance to periodically drop to nearly zero. Our preliminary experimental studies reveal that (1) write stalls mainly stem from the significantly large amount of data involved in each compaction between L_0-L_1 (i.e., the first two levels of LSM-tree), and (2) write amplification increases with the depth of LSM-trees. Existing works mainly focus on reducing write amplification, while only a couple of them target mitigating write stalls.

In this paper, we exploit non-volatile memory (NVM) to address these two limitations and propose MatrixKV, a new LSM-tree based KV store for systems with multi-tier DRAM-NVM-SSD storage. MatrixKV's design principles include performing smaller and cheaper L_0-L_1 compaction to reduce write stalls while reducing the depth of LSM-trees to mitigate write amplification. To this end, four novel techniques are proposed. First, we relocate and manage the L_0 level in NVM with our proposed *matrix container*. Second, the new *column compaction* is devised to compact L_0 to L_1 at fine-grained key ranges, thus substantially reducing the amount of compaction data. Third, MatrixKV increases the width of each level to decrease the depth of LSM-trees thus mitigating write amplification. Finally, the *cross-row hint search* is introduced for the matrix container to keep adequate read performance. We implement MatrixKV based on RocksDB and evaluate it on a hybrid DRAM/NVM/SSD system using Intel's latest 3D Xpoint NVM device Optane DC PMM. Evaluation results show that, with the same amount of NVM, MatrixKV achieves 5× and 1.9× lower 99^{th} percentile latencies, and 3.6× and 2.6× higher random write throughput than RocksDB and the state-of-art LSM-based KVS NoveLSM respectively.

1 Introduction

Persistent key-value stores are increasingly critical in supporting a large variety of applications in modern data centers. In write-intensive scenarios, log-structured merge trees (LSM-trees) [49] are the backbone index structures for persistent key-value (KV) stores, such as RocksDB [24], LevelDB [25], HBase [26], and Cassandra [35]. Considering that random writes are common in popular OLTP workloads, the performance of random writes, especially sustained and/or bursty random writes, is a serious concern for users [2,41,51]. This paper takes random write performance of KV stores as a major concern. Popular KV stores are deployed on systems with DRAM-SSD storage, which intends to utilize fast DRAM and persistent SSDs to provide high-performance database accesses. However, limitations such as cell sizes, power consumption, cost, and DIMM slot availability prevent the system performance from being further improved via increasing DRAM size [4,23]. Therefore, exploiting non-volatile memories (NVMs) in hybrid systems is widely considered as a promising mechanism to deliver higher system throughput and lower latencies.

LSM-trees [49] store KV items with multiple exponentially increased levels, e.g., from L_0 to L_6. To better understand LSM-tree based KV stores, we experimentally evaluated the popular RocksDB [24] with a conventional system of DRAM-SSD storage, and made observations that point to two challenging issues and their root causes. First, **write stalls** lead to application throughput periodically dropping to nearly zero, resulting in dramatic fluctuations of performance and long-tail latencies, as shown in Figures 2 and 3. The troughs of system throughput indicate write stalls. Write stalls induce highly unpredictable performance and degrade the quality of user experiences, which goes against NoSQL systems' design goal of predictable and stable performance [53,57]. Moreover, write stalls substantially lengthen the latency of request processing, exerting high tail latencies [6]. Our experimental studies demonstrate that the main cause of write stalls is the large amount of data processed in each L_0-L_1 compaction. The L_0-

[*] Corresponding author. Email: jgwan@hust.edu.cn

L_1 compaction involves almost all data in both levels due to the unsorted L_0 (files in L_0 are overlapped with key ranges). The all-to-all compaction takes up CPU cycles and SSD bandwidth, which slows down the foreground requests and results in write stalls and long-tail latency. Second, **write amplification** (WA) degrades system performance and storage devices' endurance. WA is directly related to the depth of the LSM-tree as a deeper tree resulting from a larger dataset increases the number of compactions. Although a large body of research aims at reducing LSM-trees' WA [20,36,41,44,45,51], only a couple of published studies concern mitigating write stalls [6,31,53]. Our study aims to address both challenges simultaneously.

Targeting these two challenges and their root causes, this paper proposes MatrixKV, an LSM-tree based KV store for systems with DRAM-NVM-SSD storage. The design principle behind MatrixKV is leveraging NVM to (1) construct cheaper and finer granularity compaction for L_0 and L_1, and (2) reduce LSM-trees' depth to mitigate WA. The key enabling technologies of MatrixKV are summarized as follows:

Matrix container. The matrix container manages the unsorted L_0 of LSM-trees in NVM with a receiver and a compactor. The receiver adopts and retains the MemTable flushed from DRAM, one MemTable per row. The compactor selects and merges a subset of data from L_0 (with the same key range) to L_1, one column per compaction.

Column compaction. A column compaction is the fine-grained compaction between L_0 and L_1, which compacts a small key range a time. Column compaction reduces write stalls because it processes a limited amount of data and promptly frees up the column in NVM for the receiver to accept data flushed from DRAM.

Reducing LSM-tree depth. MatrixKV increases the size of each LSM-tree level to reduce the number of levels. As a result, MatrixKV reduces write amplification and delivers higher throughput.

Cross-row hint search. MatrixKV gives each key a pointer to logically sort all keys in the matrix container thus accelerating search processes.

2 Background and Motivation

In this section, we present the necessary background on NVM, LSM-trees, LSM-based KV stores, and the challenges and motivations in optimizing LSM-based KV stores with NVMs.

2.1 Non-volatile Memory

Service providers have constantly pursued faster database accesses. They aim at providing users with a better quality of service and experience without a significant increase in the total cost of ownership (TCO). With the emergence and development of new storage media such as phase-change memory [8,33,48,52], memristors [55], 3D XPoint [28], and STT-MRAM [21], enhancing storage systems with NVMs becomes a cost-efficient choice. NVM is byte-addressable, persistent, and fast. It is expected to provide DRAM-like performance, disk-like persistency, and higher capacity than DRAM at a much lower cost [9,16,61]. Compared to SSDs, NVM is expected to provide 100× lower read and write latencies and up to ten times higher bandwidth [3,10,14,22].

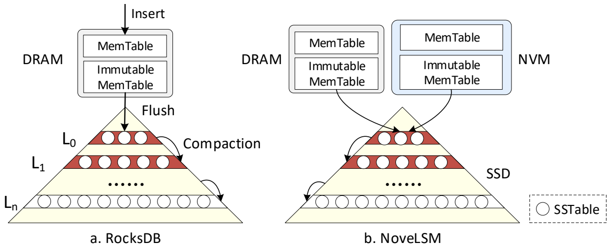

Figure 1: The structure of RocksDB and NoveLSM.

NVM works either as a persistent block storage device accessed through PCIe interfaces or as main memory accessed via memory bus [1,38]. Existing research [31] shows that the former only achieve marginal performance improvements, wasting NVM's high media performance. For the latter, NVM can supplant or complement DRAM as a single-level memory system [27,58,61,65], a system of NVM-SSD [30], or a hybrid system of DRAM-NVM-SSD [31]. In particular, systems with DRAM-NVM-SSD storage are recognized as a promising way to utilize NVMs due to the following three reasons. First, NVM is expected to co-exist with large-capacity SSDs for the next few years [32]. Second, compared to DRAM, NVM still has 5 times lower bandwidth and 3 times higher read latency [28]. Third, a hybrid system balances the TCO and system performance. As a result, MatrixKV focuses on efficiently using NVMs as persistent memory in a hybrid system of DRAM, NVMs, and SSDs.

2.2 Log-structured Merge Trees

LSM-trees [29,49] defer and batch write requests in memory to exploit the high sequential write bandwidth of storage devices. Here we explain a popular implementation of LSM-trees, the widely deployed SSD-based RocksDB [24]. As shown in Figure 1 (a), RocksDB is composed of a DRAM component and an SSD component. It also has a write-ahead log in SSDs protecting data in DRAM from system failures.

To serve write requests, writes are first batched in DRAM by two skip-lists (MemTable and Immutable MemTable). Then, the immutable MemTable is flushed to L_0 on SSDs generating Sorted String Tables (SSTables). To deliver a fast flush, L_0 is unsorted where key ranges overlap among different SSTables. SSTables are compacted from L_0 to deeper levels (L_1, L_2...L_n) during the lifespan of LSM-trees. Compaction makes each level sorted (except L_0) thus bounding the overhead of reads and scans [53].

To conduct a compaction, (1) an SSTable in L_i (called a victim SSTable) and multiple SSTables in L_{i+1} who has overlapping key ranges (called overlapped SSTables) are picked as the compaction data. (2) Other SSTables in L_i that fall in this compaction key ranges are selected reversely. (3) Those SSTables identified in steps (1) and (2) are fetched into memory, to be merged and sorted. (4) The regenerated SSTables are written back to L_{i+1}. Since L_0 is unsorted and each SSTable in L_0 spans a wide key range, the L_0-L_1 compaction performs step (1) and (2) back and forth involving almost all SSTables in both levels, leading to a large all-to-all compaction.

To serve read requests, RocksDB searches the MemTable first, immutable MemTable next, and then SSTables in L_0 through L_n in order. Since SSTables in L_0 contain overlapping keys, a lookup may search multiple files at L_0 [36].

2.3 LSM-tree based KV stores

Existing improvements on LSM-trees includes: reducing write amplification [19, 36, 44, 46, 51, 62–64], improving memory management [7, 39, 56], supporting automatic tuning [17, 18, 40], and using LSM-trees to target hybrid storage hierarchies [5, 47, 50]. Among them, random write performance is a common concern since it is severely hampered by compactions. In the following, we discuss the most related studies of our work in three categories: those reducing write amplification, addressing write stalls, and utilizing NVMs.

Reducing WA: PebblesDB [51] mitigates WA by using guards to maintain partially sorted levels. Lwc-tree [62] provides lightweight compaction by appending data to SSTables and only merging the metadata. WiscKey [36] separates keys from values, which only merges keys during compactions thus reducing WA. The key-value separation solution brings the complexities of garbage collection and range scans and only benefits large values. LSM-trie [59] de-amortizes compaction overhead with hash-range based compaction. VTtree [54] uses an extra layer of indirection to avoid reprocessing sorted data at the cost of fragmentation. TRIAD [44] reduces WA by creating synergy between memory, disk, and log. However, almost all these efforts overlook performance variances and write stalls.

Reducing write stalls: SILK [6] introduces an I/O scheduler which mitigates the impact of write stalls to clients' writes by postponing flushes and compactions to low-load periods, prioritizing flushes and lower level compactions, and preempting compactions. These design choices make SILK exhibits ordinary write stalls on sustained write-intensive and long peak workloads. Blsm [53] proposes a new merge scheduler, called "spring and gear", to coordinate compactions of multiple levels. However, it only bounds the maximum write processing latency while ignoring the large queuing latency [43]. KVell [37] makes KV items unsorted on disks to reduce CPU computation cost thus mitigating write stalls for NVMe SSD based KV stores, which is inapplicable to systems with general SSDs.

Improving LSM-trees with NVMs: SLM-DB [30] proposes a single level LSM-tree for systems with NVM-SSD storage. It uses a B^+-tree in NVM to provide fast read for the single level LSM-tree on SSDs. This solution comes with the overhead of maintaining the consistency between B^+-trees and LSM-trees. MyNVM [23] leverages NVM as a block device to reduce the DRAM usage in SSD based KV stores. NoveLSM [31] is the state-of-art LSM-based KV store for systems with hybrid storage of DRAM, NVMs, and SSDs. NVMRocks [38] aims for an NVM-aware RocksDB, similar to NoveLSM, which adopts persistent mutable MemTables on NVMs. However, as we verified in § 2.4.3, mutable NVM MemTables only reduce access latencies to some extent while generating a negative effect of more severe write stalls.

Since we build MatrixKV for systems with multi-tier DRAM-NVM-SSD storage and redesign LSM-trees to exploit the high performance NVM, NoveLSM [31] is considered the most relevant to our work. We use NoveLSM as our main comparison in evaluations. In addition, we also evaluate PebblesDB and SILK on NVM-based systems since they are state-of-art solutions for reducing WA or write stalls but their original designs are not for the hybrid systems.

2.4 Challenges and Motivations

To explore the challenges in LSM-tree based KV stores, we conduct a preliminary study on the SSD-based RocksDB. In this experiment, an 80 GB dataset of 16bytes-4KB key-value items is written/loaded to RocksDB in uniformly random order. The evaluation environments and other parameters are described in § 5. We record random write throughput every ten seconds as shown in Figure 2. The experimental results expose two challenging issues. **Challenge 1, Write stalls**. System performance experiences peaks and troughs, and the troughs of throughput manifest as write stalls. The significant fluctuations indicate unpredictable and unstable performance. **Challenge 2, Write amplification**. WA causes performance degradation. System performance (i.e., the average throughput) shows a downward trend with the growth of the dataset size since the number of compactions increases with the depth of LSM-trees, bringing more WA.

2.4.1 Write Stalls

In an LSM-based KV store, there are three types of possible stalls as depicted in Figure 1(a). (1) Insert stalls: if MemTable fills up before the completion of background flushes, all insert operations to LSM-trees are stalled [31]. (2) Flush stalls: if L_0 has too many SSTables and reaches a size limit, flushes to

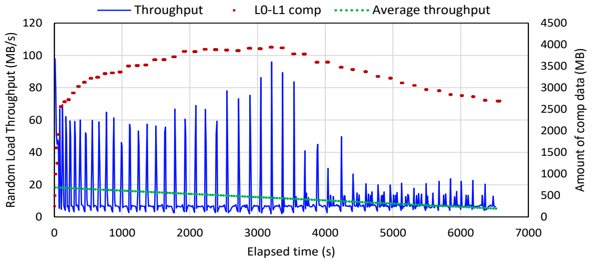

Figure 2: RocksDB's random write performance and L_0-L_1 compactions. *The blue line shows the random write throughput measured in every 10 seconds. The green line shows the average throughput. Each red line represents the duration and amount of data processed in a L_0-L_1 compaction.*

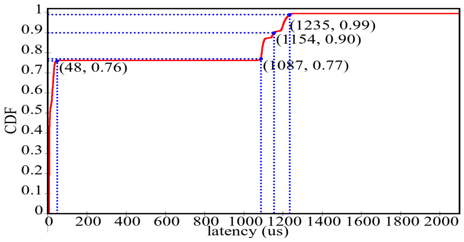

Figure 3: The CDF of latencies of the 80 GB write requests.

storage are blocked. (3) Compaction stalls: too many pending compaction bytes block foreground operations. All these stalls have a cascading impact on write performance and result in write stalls.

Evaluating these three types of stalls individually by recording the period of flushes and compactions at different levels, we find that the period of L_0-L_1 compaction approximately matches write stalls observed, as shown in Figure 2. Each red line represents a L_0-L_1 compaction, where the length along the x-axis represents the latency of the compaction and the right y-axis shows the amount of data processed in the compaction. The average amount of compaction data is 3.10 GB. As we elaborate in § 2.2, since L_0 allows overlapping key ranges between SSTables, almost all SSTables in both levels join the L_0-L_1 compaction. A large amount of compaction data leads to heavy read-merge-writes, which takes up CPU cycles and the SSD bandwidth, thus blocking foreground requests and making L_0-L_1 compaction the primary cause of write stalls.

Write stalls not only are responsible for the low system throughput, but also induce high write latency leading to the long-tail latency problem. Figure 3 shows the cumulative distribution function (CDF) of the latency for each write request during the 80 GB random load process. Although the latency of 76% of the write requests is less than 48 us, the write latency of the 90^{th}, 99^{th}, and 99.9^{th} percentile reaches 1.15, 1.24, and 2.32 ms respectively, a two-order magnitude increase. The high latency significantly degrades the quality of user experiences, especially for latency-critical applications.

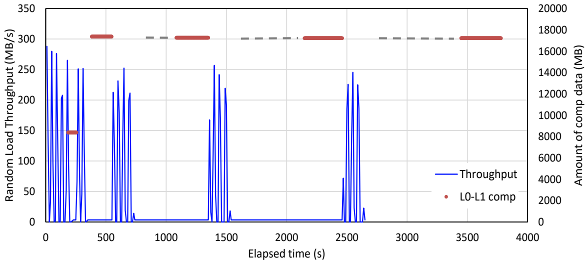

Figure 4: NoveLSM's random write performance and L_0-L_1 compactions. *Comparing to RocksDB in Figure 2, the average period of write stalls is increased.*

2.4.2 Write Amplification

Next, we analyze the second observation, i.e., system throughput degrades with the increase in dataset size. Write amplification (WA) is defined as the ratio between the amount of data written to storage devices and the amount of data written by users. LSM-tree based KV stores have long been criticized for their high WA due to frequent compactions. Since the sizes of adjacent levels from low to high increase exponentially by an amplification factor ($AF = 10$), compacting an SSTable from L_i to L_{i+1} results in a WA factor of AF on average. The growing size of the dataset increases the depth of an LSM-tree as well as the overall WA. For example, the WA factor of compacting from L_1 to L_2 is AF, while the WA factor of compacting from L_1 to L_6 is over $5 \times AF$. The increased WA consumes more storage bandwidth, competes with flush operations, and ultimately slows down application throughput. Hence, system throughput decreases with higher write amplification caused by the increased depth of LSM-trees.

2.4.3 NoveLSM

NoveLSM [31] exploits NVMs to deliver high throughput for systems with DRAM-NVM-SSD storage, as shown in Figure 1(b). The design choices of NoveLSM include: (1) adopting NVMs as an alternative DRAM to increase the size of MemTable and immutable MemTable; (2) making the NVM MemTable mutable to allow direct updates thus reducing compactions. However, these design choices merely postpone the write stalls. When the dataset size exceeds the capacity of NVM MemTables, flush stalls still happen, blocking foreground requests. Furthermore, the enlarged MemTables in NVM are flushed to L_0 and dramatically increase the amount of data in L_0-L_1 compactions, resulting in even more severe write stalls. The worse write stalls magnify performance variances and hurt user experiences further.

We evaluate NoveLSM (with 8 GB NVM) by randomly writing the same 80 GB dataset. Test results in Figure 4 show that NoveLSM reduces the overall loading time by 1.7× compared to RocksDB (Figure 2). However, the period of write stalls is significantly longer. This is because the amount

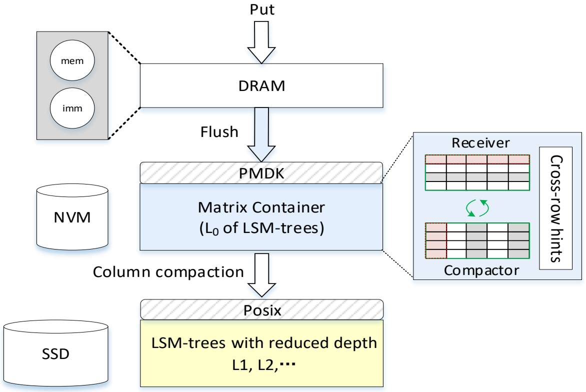

Figure 5: MatrixKV's architectural overview. *MatrixKV is a KV store for systems consisting of DRAM, NVMs, and SSDs.*

of data involved in each L_0-L_1 compaction is over 15 GB, which is 4.86× larger than that of RocksDB. A write stall starts when compaction threads call for the L_0-L_1 compaction. Then, the compaction waits and starts until other pending compactions with higher priorities complete (i.e., the grey dashed lines). Finally, performance rises again as the compaction completes. In general, NoveLSM exacerbates write stalls.

From the above analysis, we conclude that the main cause of write stalls is the large amount of data involved in L_0-L_1 compactions, and the main cause of increased WA is the deepened depth of LSM-trees. The compounded impact of write stalls and WA deteriorates system throughput and lengthens tail latency. While NoveLSM attempts to alleviate these issues, it actually exacerbates the problem of write stalls. Motivated by these observed challenging issues, we propose MatrixKV that aims at providing a stable low-latency KV store via intelligent use of NVMs, as elaborated in the next section.

3 MatrixKV Design

In this section, we present MatrixKV, an LSM-tree based key-value store for systems with multi-tier DRAM-NVM-SSD storage. MatrixKV aims to provide predictable high performance through the efficient use of NVMs with the following four key techniques, i.e., the matrix container in NVMs to manage the L_0 of LSM-trees (§ 3.1), column compactions for L_0 and L_1 (§ 3.2), reducing LSM-tree levels (§ 3.3), and the cross-row hint search (§ 3.4). Figure 5 shows the overall architecture of MatrixKV. From top to bottom, (1) DRAM batches writes with MemTables, (2) MemTables are flushed to L_0 that is stored and managed by the matrix container in NVMs, (3) data in L_0 are compacted to L_1 in SSDs through column compactions, and (4) SSDs store the remaining levels of a flattened LSM-tree.

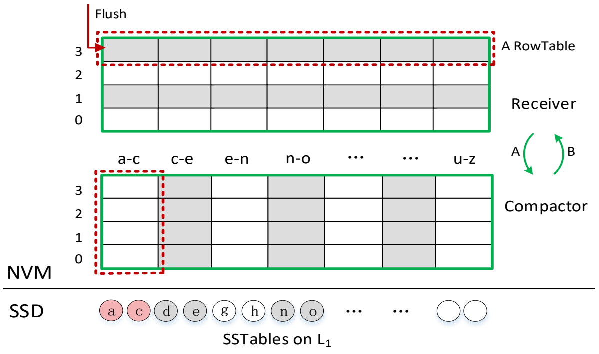

Figure 6: Structure of matrix container. *The receiver absorbs flushed MemTables, one per row. Each row is reorganized as a RowTable. The compactor merges L_0 with L_1 in fine-grained key ranges, one range at a time, referred to as* column compaction. *In Process A, the receiver becomes the compactor once RowTables fill its capacity. In Process B, each column compaction frees a column.*

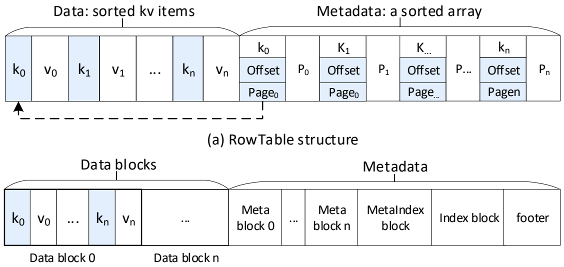
3.1 Matrix Container

LSM-tree renders all-to-all compactions for L_0 and L_1 because L_0 has overlapping key ranges among SSTables. The heavy L_0-L_1 compactions are identified as the root cause of write stalls as demonstrated in § 2.4. NoveLSM [31] exploits NVM to increase the number and size of MemTables. However, it actually exacerbates write stalls by having a larger L_0 and keeping the system bottleneck, L_0-L_1 compactions, on lower-speed SSDs. Hence, the principle of building an LSM-tree based KV store without write stalls is to reduce the granularity of L_0-L_1 compaction via high-speed NVMs.

Based on this design principle, MatrixKV elevates L_0 from SSDs to NVMs and reorganizes L_0 into a matrix container to exploit the byte-addressability and fast random accesses of NVMs. Matrix container is a data management structure for the L_0 of LSM-trees. Figure 6 shows the organization of a matrix container, which comprises one receiver and one compactor.

Receiver: In the matrix container, the receiver accepts and retains MemTables flushed from DRAM. Each such MemTable is serialized as a single row of the receiver and organized as a *RowTable*. RowTables are appended to the matrix container row by row with an increasing sequence number, i.e., from 0 to n. The size of the receiver starts with one RowTable. When the receiver size reaches its size limit (e.g., 60% of the matrix container) and the compactor is empty, the receiver stops receiving flushed MemTables and dynamically turns into the compactor. In the meantime, a new receiver is created for receiving flushed MemTables. There is no data migration for the logical role change of the receiver to the compactor.

RowTable: Figure 7(a) shows the RowTable structure consisting of data and metadata. To construct a RowTable, we first serialize KV items from the immutable MemTable in the



(a) RowTable structure

(b) Conventional SSTable structure

Figure 7: RowTable and conventional SSTable.

order of keys (the same as SSTables) and store them to the data region. Then, we build the metadata for all KV items with a sorted array. Each array element maintains the key, the page number, the offset in the page, and a forward pointer (i.e., p_n). To locate a KV item in a RowTable, we binary search the sorted array to get the target key and find its value with the page number and the offset. The forward pointer in each array element is used for cross-row hint searches that contribute to improving the read efficiency within the matrix container. The cross-row hint search will be discussed in § 3.4. Figure 7(b) shows the structure of conventional SSTable in LSM-trees. SSTables are organized with the basic unit of blocks in accordance with the storage unit of devices such as SSDs and HDDs. Instead, RowTable takes an NVM page as its basic unit. Other than that, RowTables are only different from SSTables in the organization of metadata. As a result, the construction overhead of SSTables and RowTables is similar.

Compactor: The compactor is used for selecting and merging data from L_0 to L_1 in SSDs at a fine granularity. Leveraging the byte addressability of NVMs and our proposed RowTables, MatrixKV allows cheaper compactions that merge a specific key range from L_0 with a subset of SSTables at L_1 without needing to merge all of L_0 and all of L_1. This new L_0-L_1 compaction is referred to as column compaction (detailed in § 3.2). In the compactor, KV items are managed by logical columns. A column is a subset of key spaces with a limited amount of data, which is the basic unit of the compactor in column compactions. Specifically, KV items from different RowTables that fall in the key range of a column compaction logically constitute a column. The amount of these KV items is the size of a column, which is not strictly fixed but at a threshold determined by the size of column compactions.

Space management: After compacting a column, the NVM space occupied by the column is freed. To manage those freed spaces, we simply apply the paging algorithm [3]. Since column compactions rotate the key ranges, at most one page per RowTable is partially fragmented. The NVM pages fully freed after column compactions are added to the free list as a group of page-sized units. To store incoming RowTables in the receiver, we apply free pages from the free list. The 8 GB matrix container contains 2^{11} pages of 4 KB each. Each page is identified by the page number of an unsigned integer. Adding the 8 bytes pointer per list element, the metadata size for each page is 12 bytes. The metadata of the free list occupies a total space of 24 KB on NVMs at most.

It is worth noting that in the matrix container, while columns are being compacted in the compactor, the receiver can continue accepting flushed MemTables from DRAM simultaneously. By freeing the NVM space one column at a time, MatrixKV ends the write stalls forced by merging the entire L_0 with all of L_1.

3.2 Column Compaction

Column compaction is a fine-grained L_0-L_1 compaction that each time compacts only a column, i.e., a small subset of the data in a specific key range. Thus, column compaction can significantly reduce write stalls. The main workflow of column compaction can be described in the following seven steps. (1) MatrixKV separates the key space of L_1 into multiple contiguous key ranges. Since SSTables in L_1 are sorted and each SSTable is bounded by its smallest key and largest key, the smallest keys and largest keys of all the SSTables in L_1 form a sorted key list. Every two adjacent keys represent a key range, i.e., the key range of an SSTable or the gap between two adjacent SSTables. As a result, we have multiple contiguous key ranges in L_1. (2) Column compaction starts from the first key range in L_1. It selects a key range in L_1 as the compaction key range. (3) In the compactor, victim KV items within the compaction key range are picked concurrently in multiple rows. Specifically, assuming N RowTables in the compactor, k threads work in parallel to fetch keys within the compaction key range. Each thread in charge of N/k RowTables. We maintain an adequate degree of concurrent accesses on NVMs with $k = 8$. (4) If the amount of data within this key range is under the lower bound of compaction, the next key range in L_1 joins. The k threads keep forward in N sorted arrays (i.e., the metadata of the RowTables) fetching KV items within the new key range. This key range expansion process continues until the amount of compaction data reaches a size between the lower bound and the upper bound (i.e., $\frac{1}{2}AF \times S_{sst}$ and $AF \times S_{sst}$ respectively). The two bounds guarantee the adequate overhead of a column compaction. (5) Then a column in the compactor is logically formed, i.e., KV items in N RowTables that fall in the compaction key range make up a logical column. (6) Data in the column are merged and sorted with the overlapped SSTables of L_1 in memory. (7) Finally, the regenerated SSTables are written back to L_1 on SSDs. Column compaction continues between the next key range of L_1 and the next column in the compactor. The key ranges of column compaction rotate in the whole key space to keep LSM-trees balanced.

We show an example of column compaction in Figure 8. First, MatrixKV picks the SSTable with key range 0-3 in L_1 as the candidate compaction SSTable. Then, we search the metadata arrays of the four RowTables. If the amount

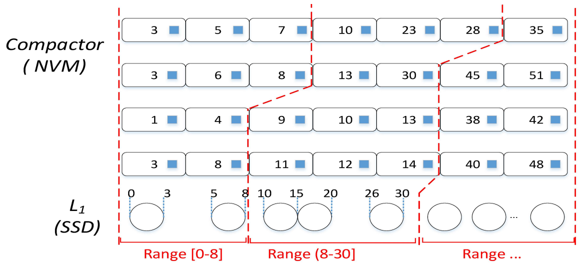


Figure 8: Column compaction: an example. *There are 4 RowTables in the compactor. Each circle represents an SSTable on L_1. Columns are logically divided (red dashed lines) according to the key range of compaction.*

of compaction data within key range 0-3 is under the lower bound, the next key range (i.e., key range 3-5) joins to form a larger key range 0-5. If the amount of compaction data is still beneath the lower bound, the next key range 5-8 joins. Once the compaction data is larger than the lower bound, a logical column is formed for the compaction. The first column compaction compacts the column at the key range of 0-8 with the first two SSTables in L_1.

In general, column compaction first selects a specific key range from L_1, and then compacts with the column in the compactor that shares the same key range. Comparing to the original all-to-all compaction between L_0 and L_1, column compaction compacts at a much smaller key range with a limited amount of data. Consequently, the fine-grained column compaction shortens the compaction duration, resulting in reduced write stalls.

3.3 Reducing LSM-tree Depth

In conventional LSM-trees, the size limit of each level grows by an amplification factor of $AF = 10$. The number of levels in an LSM-tree increase with the amount of data in the database. Since compacting an SSTable to a higher level results in a write amplification factor of AF, the overall WA increases with the number of levels (n) in the LSM-tree, i.e., WA=n*AF [36]. Hence, the other design principle of MatrixKV is to reduce the depth of LSM-trees to mitigate WA. MatrixKV reduces the number of LSM-tree levels by increasing the size limit of each level at a fixed ratio making the AF of adjacent levels unchanged. As a result, for compactions from L_1 and higher levels, the WA of compacting an SSTable to the next level remains the same AF but the overall WA is reduced with due to fewer levels.

Flattening conventional LSM-trees with wider levels brings two negative effects. First, since the enlarged L_0 has more SSTables that overlap with key ranges, the amount of data in each L_0-L_1 compaction increases significantly, which not only adds the compaction overhead but also lengthens the duration of write stalls. Second, traversing the larger unsorted L_0 decreases the search efficiency. MatrixKV addresses the first problem with the fine-grained column compaction. The amount of data involved in each column compaction is largely independent of the level width as a column contains a limited amount of data. For the second problem, MatrixKV proposes the cross-row hint search (§ 3.4) to compensate for the increased search overhead due to the enlarged L_0. It is worth noting that locating keys in fewer levels reduces the lookup time on SSDs, since SSTables from L_1 to L_n are well-sorted.

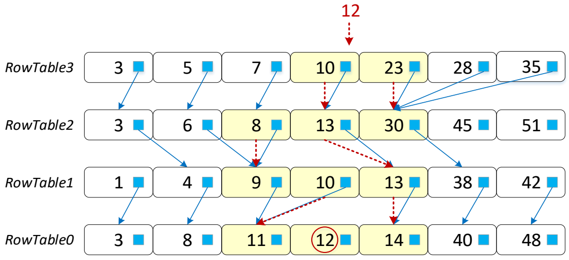

Figure 9: Cross-row hint search. *This figure shows an example of searching the target key ($k = 12$) with forward pointers of each array element.*

3.4 Cross-row Hint Search

In this section, we discuss solutions for improving the read efficiency in the matrix container. In the L_0 of MatrixKV, each RowTable is sorted and different RowTables are overlapped with key ranges. Building Bloom filters for each table is a possible solution for reducing search overheads. However, it brings costs on the building process and exhibits no benefit to range scans. To provide adequate read and scan performances for MatrixKV, we build cross-row hint searches.

Constructing cross-row hints: When we build a RowTable for the receiver of the matrix container, we add a forward pointer for each element in the sorted array of metadata (Figure 7). Specifically, for a key x in RowTable i, the forward pointer indexes the key y in the preceding RowTable $i-1$, where the key y is the first key not less than x (i.e., $y \geq x$). These forward pointers provide hints to logically sort all keys in different rows, similar to the fractional cascading [11, 53]. Since each forward pointer only records the array index of the preceding RowTable, the size of a forward pointer is only 4 bytes. Thus, the storage overhead is very small.

Search process in the matrix container: A search process starts from the latest arrived RowTable i. If the key range of RowTable i does not overlap the target key, we skip to its preceding RowTable $i-1$. Else, we binary search RowTable i to find the key range (i.e., bounded by two adjacent keys) where the target key resides. With the forward pointers, we can narrow the search region in prior RowTables, $i-1, i-2, \ldots$ continually until the key is found. As a result, there is no need to traverse all tables entirely to get a key or scan a key range.

Cross-row hint search improves the read efficiency of L_0 by significantly reducing the number of tables and elements involved in a search process.

An example of cross-row hint search is shown in Figure 9. The blue arrows show the forward pointers providing cross-row hints. Suppose we want to fetch a target key $k = 12$ in the matrix container, we first binary search RowTable 3 to get a narrowed key range of key=10 to key=23. Then their hints lead us to the key 13 and 30 in RowTable 2 (the red arrows). The preceding key is added into the search region when the target key is not included in the key range of the two hint keys. Next, we binary search between key=8 and key=30. Failing to find the target key, we move to the prior RowTable 1, then RowTable 0, with the forward pointers. Finally, the target key 12 is obtained in RowTable 0.

4 Implementation

We implement MatrixKV based on the popular KV engine RocksDB [24] from Facebook. The LOC on top of RocksDB is 4117 lines [1]. As shown in Figure 5, MatrixKV accesses NVMs via the PMDK library and accesses SSDs via the POSIX API. The persistent memory development kit (PMDK) [1, 60] is a library based on the direct access feature (DAX). Next, we briefly introduce the write and read processes and the mechanism for consistency as follows.

Write: (1) Write requests from users are inserted into a write-ahead log on NVMs to prevent data loss from system failures. (2) Data are batched in DRAM, forming MemTable and immutable MemTable. (3) The immutable MemTable is flushed to NVM and stored as a RowTable in the receiver of the matrix container. (4) The receiver turns into the compactor logically if the number of RowTables reaches a size limit (e.g., 60% of the matrix container) and the compactor is empty. This role change has no real data migrations. (5) Data in the compactor is column compacted with SSTables in L_1 column by column. In the meantime, a new receiver receives flushed MemTables. (6) In SSDs, SSTables are merged to higher levels via conventional compactions as RocksDB does. Compared to RocksDB, MatrixKV is completely different from step 3 through step 5.

Read: MatrixKV processes read requests in the same way as RocksDB. The read thread searches with the priority of DRAM>NVMs>SSDs. In NVMs, the cross-row hint search contributes to faster searches among different RowTables of L_0. The read performance can be further improved by concurrently searching in different storage devices [31].

Consistency: Data structures in NVM must avoid inconsistency caused by system failures [12, 13, 34, 42, 58]. For MatrixKV, writes/updates for NVM only happen in two processes, flush and column compaction. For flush, immutable MemTables flushed from DRAM are organized as RowTables and written to NVM in rows. If a failure occurs in the middle of writing a RowTable, MatrixKV can re-process all the transactions that were recorded in the write-ahead log. For column compaction, MatrixKV needs to update the state of RowTables after each column compaction. To achieve consistency and reliability with low overhead, MatrixKV adopts the versioning mechanism of RocksDB. RocksDB records the database state with a manifest file. The operations of compaction are persisted in the manifest file as version changes. If the system crashes during compaction, the database goes back to its last consistent state with versioning. MatrixKV adds the state of RowTables into the manifest file, i.e., the offset of the first key, the number of keys, the file size, and the metadata size, etc. MatrixKV uses lazy deletion to guarantee that stale columns invalidated by column compactions are not deleted until a consistent new version is completed.

Table 1: FIO 4 KB read and write bandwidth

	SSDSC2BB800G7	Optane DC PMM
Rnd write	68 MB/s	1363 MB/s
Rnd read	250 MB/s	2346 MB/s
Seq write	354 MB/s	1444 MB/s
Seq read	445 MB/s	2567 MB/s

5 Evaluation

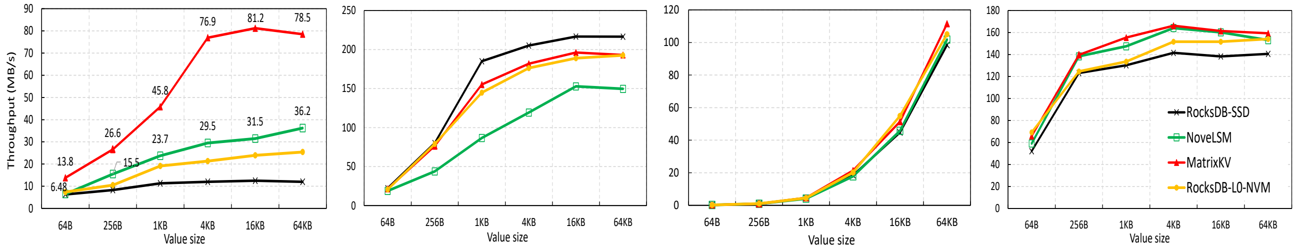
In this section, we run extensive experiments to demonstrate the key accomplishments of MatrixKV. (1) MatrixKV obtains better performance on various types of workloads and achieves lower tail latencies (§ 5.2). (2) The performance benefits of MatrixKV come from reducing write stalls and write amplification by its key enabling techniques (§ 5.3).

5.1 Experiment Setup

All experiments are run on a test machine with two Genuine Intel(R) 2.20GHz 24-core processors and 32 GB of memory. The kernel version is 64-bit Linux 4.13.9 and the operating system in use is Fedora 27. The experiments use two storage devices, an 800 GB Intel SSDSC2BB800G7 SSD and 256 GB NVMs of two 128 GB Intel Optane DC PMM [28]. Table 1 lists their maximum single-thread bandwidth, evaluated with the versatile storage benchmark tool FIO.

We mainly compare MatrixKV with NoveLSM and RocksDB (including RocksDB-SSD and RocksDB-L0-NVM). RocksDB-SSD represents the conventional RocksDB on a DRAM-SSD hierarchy. The other three KV stores are for systems with DRAM-NVM-SSD storage. They use 8 GB NVM to be consistent with the setup in NoveLSM's paper and force the majority of the 80 GB test data to be flushed to SSDs. RocksDB-L0-NVM simply enlarges L_0 into 8 GB and stores it in NVM. MatrixKV reorganizes the 8 GB L_0

[1] MatrixKV source code is publicly available at https://github.com/PDS-Lab/MatrixKV.



(a) Random write

(b) Sequential write

(c) Random read

(d) Sequential read

Figure 10: Performance on Micro-benchmarks with different value sizes.

in NVM and enlarges the L_1 in SSDs into the same 8 GB. NoveLSM employs NVM to store two MemTables (2*4 GB). Test results from this configuration can also demonstrate that MatrixKV achieves system performance improvement with the economical use of NVMs. Finally, we evaluate PebblesDB and SILK for systems with DRAM-NVM storage since they are the representative studies on LSM-tree improvement but are not originally designed for systems with multi-tier storage. Unless specified otherwise, the evaluated KV stores assume the default configuration of RocksDB, i.e., 64 MB MemTables/SSTables, 256 MB L_1 size, and AF of 10. The default key-value sizes are 16 bytes and 4 KB.

5.2 Overall performance evaluation

In this section, we first evaluate the overall performance of the four KV stores using db_bench, the micro-benchmark released with RocksDB. Then, we evaluate the performance of each KV store with the YCSB macro-benchmarks [15].

Write performance: We evaluate the random write performance by inserting KV items totaling 80 GB in a uniformly distributed random order. Figure 10(a) shows the random write throughput of four KV stores as a function of value size. The performance difference between RocksDB-SSD and RocksDB-L0-NVM suggests that simply placing L_0 in NVM brings about an average improvement of 65%. We use RocksDB-L0-NVM and NoveLSM as baselines of our evaluation. MatrixKV improves random write throughput over RocksDB-L0-NVM and NoveLSM in all value sizes. Specifically, MatrixKV's throughput improvement over RocksDB-L0-NVM ranges from 1.86× to 3.61×, and MatrixKV's throughput improvement over NoveLSM ranges from 1.72× to 2.61. Taking the commonly used value size of 4 KB as an example, MatrixKV outperforms RocksDB-L0-NVM and NoveLSM by 3.6× and 2.6× respectively. RocksDB-L0-NVM delivers relatively poor performance since putting L_0 in NVM only brings a marginal improvement. NoveLSM uses a large mutable MemTable in NVM to handle a portion of update requests thus slightly reducing WA. However, for both RocksDB and NoveLSM, the root causes of write stalls and WA remain unaddressed, i.e., the all-to-all L_0-L_1 compaction and the deepened depth of LSM-trees.

We evaluate sequential write performance by inserting a total of 80 GB KV items in sequential order. From the test results in Figure 10(b), we make three main observations. First, sequential write throughput is higher than random write throughput for the four KV stores as sequential writes incur no compaction. Second, RocksDB-SSD performs the best since the other three KV stores have an extra NVM tier, requiring data migration from NVMs to SSDs. Three, MatrixKV and RocksDB-L0-NVM have better sequential write throughput than NoveLSM since contracting RowTable/SSTables in NVMs is cheaper than updating the skip list of NoveLSM's large mutable MemTable.

Read performance: Random/sequential read performances are evaluated by reading one million KV items from the 80 GB randomly loaded database. To obtain the read performance free from the impact of compactions, we start the reading test after the tree becomes well-balanced. Figure 10(c) and (d) show the test results of random reads and sequential reads. Since NVM only accommodates 10% of the dataset, the read performance in SSDs dominates the overall read performance. Besides, since a balanced tree is well-sorted from L_1 to L_n on SSDs, the four KV stores exhibit similar read throughputs. MatrixKV does not degrade read performance and even has a slight advantage in sequential reads for two reasons. First, the cross-row hint search reduces the search overhead of the enlarged L_0. Second, MatrixKV has fewer LSM-tree levels, resulting in less search overhead on SSDs.

Macro-benchmarks: Now we evaluate four KV stores with YCSB [15], a widely used macro-benchmark suite delivered by Yahoo!. We first write an 80 GB dataset with 4KB values for loading, then evaluate workload A-F with one million KV items respectively. From the test results shown in Figure 11, we draw three main conclusions. First, MatrixKV gets the most advantage from write/load dominated workloads, i.e., load, and workload A and F. MatrixKV is 3.29× and 2.37× faster than RocksDB-L0-NVM and NoveLSM on the load workload (i.e., random write). Second, MatrixKV maintains adequate performance over read-dominated workloads, i.e., workloads B to E. Third, NoveLSM and MatrixKV behave better on workload D due to the latest distribution, where they both hit more in NVMs and thus MatrixKV can

	Load	A	B	C	D	E	F
Inserts	100%	0%	0%	0%	5%	5%	0%
Updates	0%	50%	5%	0%	0%	0%	0%
Reads	0%	50%	95%	100%	95%	0%	50%
Range query	0%	0%	0%	0%	0%	95%	0%
RMW	0%	0%	0%	0%	0%	0%	50%
Distribution	Uniform	Zipfian	Zipfian	Zipfian	Latest	Zipfian	Zipfian

Figure 11: Macro-benchmarks. *The y-axis shows the throughput of each KV store normalized to RocksDB-SSD. The number on each bar indicates the throughput in ops/s.*

Table 2: Tail Latency

Latency (us)	avg.	90%	99%	99.9%
RocksDB-SSD	974	566	11055	17983
NoveLSM	450	317	2080	2169
RocksDB-L0-NVM	477	528	786	1112
MatrixKV	**263**	**247**	**405**	**663**

benefit more from cross-row hints.

Tail latency: Tail latency is especially important for LSM-tree based KV stores, since they are widely deployed in production environments to provide services for write-heavy workloads and latency-critical applications. We evaluate the tail latency with the same methodology used in SILK [6], i.e., using the YCSB-A workload and setting request arrival rate at around 20K requests/s. Table 2 shows the average, 90^{th}, 99^{th}, and 99.9^{th} percentile latencies of four key-value stores. MatrixKV significantly reduces latencies in all cases. The 99^{th} percentile latency of MatrixKV is 27×, 5×, and 1.9× lower than RocksDB-SSD, NoveLSM, and RocksDB-L0-NVM respectively. The test results demonstrate that by reducing write stalls and WA, MatrixKV improves the quality of user experience with much lower tail latencies.

5.3 Performance Gain Analysis

To understand MatrixKV's performance improvement over random write workloads, we investigate the main challenges of LSM-trees (§ 5.3.1) and the key enabling techniques of MatrixKV (§ 5.3.2).

5.3.1 Main Challenges

In this section, we demonstrate that MatrixKV does address the main challenges of LSM-trees, i.e., write stalls and WA.

Write Stalls: We record the throughput of the four KV stores in every ten seconds during their 80 GB random write process (similar to Figures 2 and 4) to visualize write stalls. From the performance variances shown in Figure 12, we draw three observations. (1) MatrixKV takes a shorter time to process the same 80GB random write since it has higher random write throughput than other KV stores (as demonstrated in § 5.2). (2) Both RocksDB and NoveLSM suffer from write stalls due to the expensive L_0-L_1 compaction. NoveLSM takes longer to process a L_0-L_1 compaction because L_0 maintains large MemTables flushed from NVMs. Comparing to RocksDB-SSD, RocksDB-L0-NVM has lower throughput during write stalls, which means that it blocks foreground requests more severely because of the enlarged L_0. (3) MatrixKV achieves the most stable performance. The reason is that we reduce write stalls by the fine-grained column compaction which guarantees a small amount of data processed in each L_0-L_1 compaction.

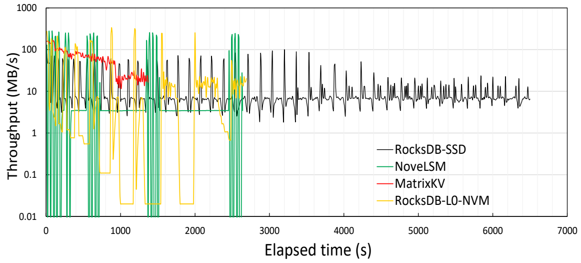


Figure 12: Throughput fluctuation as a function of time. *The random write performance fluctuates where the troughs on curves signify the occurrences of possible write stalls.*

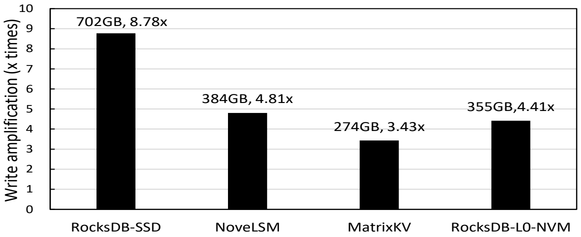

Figure 13: Write amplification of 80 GB random writes.*The numbers on each bar show the amount of data written to SSDs and the WA ratio respectively.*

Write Amplification: We measure the WA of four systems on the same experiment of randomly writing 80 GB dataset. Figure 13 shows the WA factor measured by the ratio of the amount of data written to SSDs and the amount of data coming from users. The WA of MatrixKV, NoveLSM, and RocksDB-L0-NVM are 2.56×, 1.83×, and 1.99× lower than RocksDB-SSD respectively. MatrixKV has the smallest WA since it reduces the number of compactions by lowering the depth of LSM-trees.

5.3.2 MatrixKV Enabling Techniques

Column compaction: To demonstrate the efficiency of column compaction, we record the amount of data involved, the duration of every L_0-L_1 compaction for four KV stores in the same 80 GB random write experiment. As shown in Figure 14, MatrixKV conducts 467 column compactions, each 0.33 GB,

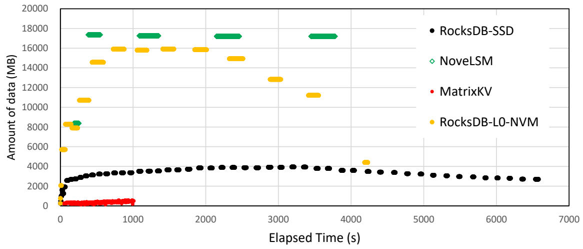

Figure 14: The L_0-L_1 compaction. *Each line segment indicates an L_0-L_1 compaction. The y-axis shows the amount of data involved in the compaction and the length along x-axis shows the duration of the compaction.*

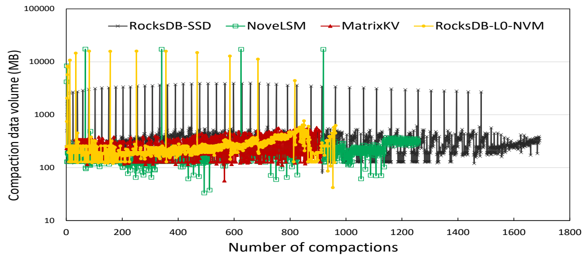

Figure 15: Compaction analysis. *This figure shows the amount of data of every individual compaction during the 80 GB random write.*

written a total of 153 GB data. RocksDB-SSD processes 52 compactions, each 3.1 GB on average, written a total of 157 GB data. MatrixKV processes more fine-grained L_0-L_1 compactions, where each has the least amount of data and the shortest compaction duration. As a result, column compactions have only a negligible influence on foreground requests and finally significantly reduce write stalls. NoveLSM actually exacerbates write stalls since the enlarged MemTables flushed from NVM significantly increase the amount of data processed in each L_0-L_1 compaction.

Overall compaction efficiency: We further record the overall compaction behaviors of four KV stores by recording the amount of data for every compaction during the random write experiment. From the test results shown in Figure 15, we draw four observations. First, MatrixKV has the smallest number of compactions, attributed to the reduced LSM-tree depth. Second, all compactions in MatrixKV process similar amount of data since we reduce the amount of compaction data on L_0-L_1 and does not increase that on other levels. Third, NoveLSM and RocksDB-L0-NVM have fewer compactions than RocksDB-SSD. The reasons are: (1) NoveLSM uses large mutable MemTables to serve more write requests and absorb a portion of update requests, and (2) RocksDB-L0-NVM has an 8 GB L_0 in NVM to store more data. Fourth, the substantial amount of compaction data in NoveLSM and RocksDB stems from the L_0-L_1 compaction.

Reducing LSM-tree depth: To evaluate the technique of flattening LSM-trees, we change level sizes for both RocksDB

	256MB	8GB	256MB	8GB	256MB	8GB
	RocksDB-SSD		MatrixKV		RocksDB-L0-NVM	
L0	0.00	0.00	0.00	0.00	0.00	0.00
L1	0.19	7.95	0.23	8.01	0.24	7.99
L2	2.47	43.92	2.45	44.67	2.45	41.04
L3	24.97		24.99		25.00	
L4	23.72		21.90		21.85	

Figure 16: Reducing LSM-tree depth. *The y-axis shows random write throughputs of RocksDB and MatrixKV when L_1 is 256 MB/8 GB. The table below shows the data distribution among levels (in GB).*

and MatrixKV. The first configuration is $L_1 = 256MB$ (the default L_1 size of RocksDB). The second configuration is $L_1 = 8GB$. The following levels exponentially increased at the ratio of AF=10. Figure 16 shows the throughput of randomly writing an 80 GB dataset. The table under the figure shows the data distribution on different levels after balancing LSM-trees. The test results demonstrate that both RocksDB and MatrixKV reduce the number of levels by enlarging level sizes, i.e., from 5 to 3. However, they exert opposite influences on system performance. RocksDB-SSD and RocksDB-L0-NVM reduce their random write throughputs by 3× and 1.5× respectively as level sizes increase. The reason is that the enlarged L_1 significantly increases the amount of compaction data between L_0 and L_1. RocksDB-L0-NVM is slightly better than RocksDB-SSD since it puts L_0 in NVMs. For MatrixKV, the throughput increases 25% since the fine granularity column compaction is independent of level sizes. Furthermore, the MatrixKV with 256 MB L_1 shows the performance improvement of only addressing write stalls.

Cross-row hint search: To evaluate the technique of cross-row hint search, we first randomly write an 8 GB dataset with 4 KB value size to fill the L_0 in NVMs for MatrixKV and RocksDB-L0-NVM. Then we search for one million KV items from NVMs in uniformly random order. This experiment makes NVMs accommodate 100% of the dataset to fully reflect the efficiency of cross-row hint searches. The random read throughput of RocksDB-L0-NVM and MatrixKV are 9 MB/s and 157.9 MB/s respectively. Hence, compared to simply placing L_0 in NVMs, the cross-row hint search improves the read efficiency by 17.5 times.

5.4 Extended Comparisons on NVMs

To further verify that MatrixKV's benefits are not solely due to the use of fast NVMs, we evaluate more KV stores on the DRAM-NVM hierarchy, i.e., RocksDB, NoveLSM, PebblesDB, SILK, and MatrixKV, where DRAM stores MemTables, and all other components are stored on NVMs.

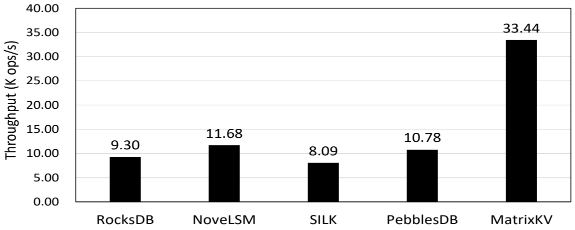

Figure 17: Throughput on NVM based KV stores.

Table 3: Tail latency on NVM-based KV stores

Latency (us)	avg.	90%	99%	99.9%
RocksDB	385	523	701	864
NoveLSM	377	250	808	917
SILK	351	445	575	747
PebblesDB	335	1103	1406	1643
MatrixKV	**209**	**310**	**412**	**547**

Throughput: Figure 17 shows the performance for randomly writing an 80 GB dataset. MatrixKV achieves the best performance among all KV stores. It demonstrates that the enabling techniques of MatrixKV are appropriate for NVM devices. Using NVM as a fast block device, PebblesDB does not show much improvement over RocksDB. SILK is slightly worse than RocksDB since its design strategies have limited advantages over intensive writes.

Tail latency: Tail latencies are evaluated with YCSB-A workload as in § 5.2. Since NVM has a significantly better performance than SSDs, we speed up the requests from clients (60K requests/s). Test results in Table 3 show that with the persistent storage of NVMs most KV stores provide adequate tail latencies. However, MatrixKV still achieves the shortest tail latency.

6 Conclusion

In this paper, we present MatrixKV, a stable low-latency key-value store based on LSM-trees. MatrixKV is designed for systems with multi-tier DRAM-NVM-SSD storage. By lifting the L_0 to NVM, managing it with the matrix container, and compacting L_0 and L_1 with the fine granularity column compaction, MatrixKV reduces write stalls. By flattening the LSM-trees, MatrixKV mitigates write amplification. MatrixKV also guarantees adequate read performance with cross-row hint searches. MatrixKV is implemented on a real system based on RocksDB. Evaluation results demonstrate that MatrixKV significantly reduces write stalls and achieves much better system performance than RocksDB and NoveLSM.

Disaggregating Persistent Memory and Controlling Them Remotely: An Exploration of Passive Disaggregated Key-Value Stores

Shin-Yeh Tsai, Yizhou Shan, Yiying Zhang
Purdue University and University of California, San Diego

Abstract

Many datacenters and clouds manage storage systems separately from computing services for better manageability and resource utilization. These existing disaggregated storage systems use hard disks or SSDs as storage media. Recently, the technology of persistent memory (PM) has matured and seen initial adoption in several datacenters. Disaggregating PM could enjoy the same benefits of traditional disaggregated storage systems, but it requires new designs because of its memory-like performance and byte addressability.

In this paper, we explore the design of disaggregating PM and managing them remotely from compute servers, a model we call *passive disaggregated persistent memory*, or *pDPM*. Compared to the alternative of managing PM at storage servers, pDPM significantly lowers monetary and energy costs and avoids scalability bottlenecks at storage servers.

We built three key-value store systems using the pDPM model. The first one lets all compute nodes directly access and manage storage nodes. The second uses a central coordinator to orchestrate the communication between compute and storage nodes. These two systems have various performance and scalability limitations. To solve these problems, we built Clover, a pDPM system that separates the location, communication mechanism, and management strategy of the data plane and the metadata/control plane. Compute nodes access storage nodes directly for data operations, while one or few global metadata servers handle all metadata/control operations. From our extensive evaluation of the three pDPM systems, we found Clover to be the best-performing pDPM system. Its performance under common datacenter workloads is similar to non-pDPM remote in-memory key-value store, while reducing CapEx and OpEx by 1.4× and 3.9×.

1 Introduction

Separating (or "disaggregating") storage and compute has become a common practice in many datacenters [11, 18] and clouds [3, 4]. Disaggregation makes it easy to manage and scale both the storage and the compute pools. By allowing the storage pool to be shared across applications and users, disaggregation consolidates storage resources and reduces their cost. As a recent success story, Alibaba listed their RDMA-based disaggregated storage system as one of the five reasons that enabled them to serve the peak load of 544,000 orders per second on the 2019 Single's Day [62].

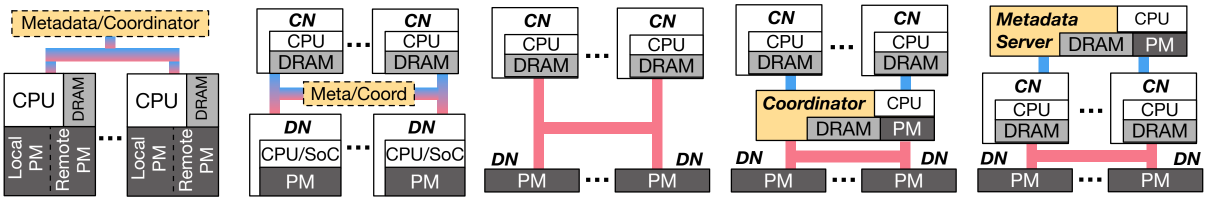
Existing disaggregated storage systems are all SSD- or HDD-based. Today, a new storage media, non-volatile memory (or persistent memory, *PM*) has arrived [27, 29] and has already seen adoption in several datacenters [21, 25, 46]. Existing distributed PM systems [42, 56, 69] have mainly taken a non-disaggregated approach, where each server in a cluster hosts PM for applications running both on the local server and remote servers (Figure 1(a)).

Disaggregating PM could enjoy the same management and resource-utilization benefits as traditional disaggregated storage systems. However, building a PM-based disaggregated system is very different from traditional disaggregated storage systems as PM is byte addressable and orders of magnitude faster than SSDs and HDDs. It is also different from disaggregated memory systems [41, 55], since when treated as storage systems, disaggregated PM systems need to sustain power failure and be crash consistent.

There are two possible design directions in building disaggregated PM systems, and they differ in where management software runs. The first type, and the type that has been adopted in traditional disaggregated storage systems, runs management software at the storage nodes, *i.e.*, actively managing data at where the data is. When applying this model to PM, we call the resulting system *active disaggregated PM*, or *aDPM* (Figure 1(b)). By co-locating data and their management, aDPM could offer low-latency performance to applications. However, aDPM requires significant processing power at storage nodes to sustain high-bandwidth networks and to fully deliver PM's superior performance.

In this paper, we explore an alternative approach of building disaggregated PM by treating storage nodes as *passive* parties that do not perform any data processing or data management tasks, a model we call *pDPM*. pDPM offers several practical benefits and research value. First, pDPM lowers owning and energy cost. Without any processing need, a PM node (we call it a *data node* or *DN*) can either be a regular server that dedicates its entire CPU to other applications or a hardware device that directly attaches a NIC to PM. Second, pDPM avoids DN's processing power being the performance scalability bottleneck. Finally, pDPM is an approach in the design space of disaggregated storage systems that has largely been overlooked in the past. Exploring pDPM systems would reveal various performance, scalability, and cost tradeoffs that could help future researchers and systems builders make better design decisions.

pDPM presents several new challenges, the biggest of which is the need to avoid processing all together from where data is hosted. Existing in-memory data stores heavily rely



(a) non-Disaggregated PM (b) aDPM (c) pDPM-Direct (d) pDPM-Central (e) Clover

Figure 1: **PM Organization Comparison.** *Blue bars indicate two-way communication and pink ones indicate one-way communication. Bars with both blue and pink mean support for both. Dashed boxes mean some but not all existing solutions adopt centralized metadata server (or a coordinator).*

on local processing power for both the data path and the control path. Without any processing power, accesses to DNs have to come all from the network, which makes data operations like concurrent writes especially hard. Moreover, DNs cannot perform any management tasks or metadata operations locally, and each DN can fail independently.

A key question in designing pDPM systems is where to perform data and metadata operations when we cannot perform them at DNs. Our first approach is to let client/compute nodes (*CN*s) perform all the tasks by directly accessing DNs with *one-sided* network communication, a model we call *pDPM-Direct* (Figure 1(c)). After building and evaluating a real pDPM-Direct key-value store system, we found that since CNs cannot be efficiently coordinated, pDPM-Direct performs and scales poorly when there are concurrent reads/writes to the same data. Our second approach is *pDPM-Central* (Figure 1(d)), where we use a central server (the *coordinator*) to manage DNs and to orchestrate all accesses from CNs to DNs. Although pDPM-Central provides a way to coordinate CNs, it adds more hops between CNs and DNs, and the coordinator is a new scalability bottleneck.

To solve the issues of the above two pDPM systems, we build Clover, a key-value store system with a new architecture of pDPM (Figure 1(e)). Clover's main ideas are to separate the location of data and metadata, to use different communication mechanisms to access them, and to adopt different management strategies for them. Data is stored at DNs. Metadata is stored at one or few global metadata servers (*MS*s). CNs directly access DNs for all data operations using *one-sided* network communication. They use *two-sided* communication to talk to MS(s). MS(s) perform all metadata and control operations.

Clover achieves low-latency, high-throughput performance while delivering the consistency and reliability guarantees that are commonly used in traditional distributed storage systems. We designed a set of novel techniques at the data and the metadata plane to achieve these goals. Our data plane design is inspired by log-structured writes and skip lists. This design achieves 1-/2-RTT read/write performance when there is no high write contention, while ensuring proper synchronization and crash consistency of concurrent writes with satisfactory performance. We move all metadata and control operations off performance critical path. We *completely* eliminate the need for the MS to communicate with DNs; it performs space management and other control tasks without accessing DNs. In addition, Clover supports replicated writes for high availability and reliability.

We evaluate Clover, pDPM-Direct, and pDPM-Central using a cluster of servers connected with RDMA network (some acting as CNs and MSs, some acting as emulated DNs). We compare these pDPM systems with two non-disaggregated PM systems [42, 56] and an aDPM key-value store system [30] running on CPU-based servers and on ARM-SoC-based RDMA SmartNIC [44]. We perform an extensive set of experiments to study the latency, throughput, scalability, CPU utilization, and owning cost of these systems using microbenchmarks and YCSB workloads [13, 71]. Our evaluation results demonstrate that Clover is the best-performing pDPM system, and it significantly outperforms traditional distributed PM systems. Clover achieves similar or better performance as aDPM systems under common datacenter workloads, while reducing CapEx and OpEx by 1.4× and 3.9×. However, we also discovered a fundamental limitation of pDPM-based storage systems: no processing at where data sits could hurt write performance, especially under high contention of concurrent accesses to the same data entry. Fortunately, most datacenter workloads are read-most [7]. Thus, we believe pDPM and Clover to be good choices future systems builders can consider, given their overall benefits in cost, performance, and scalability.

Overall, this paper makes the following contributions:

- Thorough exploration of the passive disaggregated persistent-memory architecture, revealing its benefits, tradeoffs, and pitfalls.
- Implementation of Clover and two alternative pDPM key-value stores, all guaranteeing proper synchronization, crash consistency, and high availability.
- A detailed design of how to separate the data plane and the metadata plane under the pDPM model.
- Comprehensive evaluation results that can guide future DPM research.

All our pDPM systems are publicly available at https://github.com/WukLab/pDPM.

2 Background and Related Work

This section includes background and related work on in-memory data stores, RDMA, and PM in datacenter settings.

2.1 PM and Distributed PM Storage

Non-volatile memory (or PM) technologies such as 3D-XPoint [28], PCM, STTM, and the memristor provide byte addressability, persistence, and latency that is within an order of magnitude of DRAM [59, 70]. PM has attracted extensive research efforts in the past decade, most of which focus on single-node environments. The first commercial PM product, Intel Optane DC, has finally come to market [27]. It is pressing to seek solutions to incorporate PM in datacenters.

Existing distributed PM systems [42, 56, 69] have mainly adopted a *symmetric* architecture where each node in a cluster hosts some PM that can be accessed both locally and by other nodes (Figure 1(a)). Some of these systems expose a file system interface [42, 69], and others expose a memory interface [56, 73]. Among them, Orion [69] uses a global server for metadata, and the rest co-locate metadata with data. These systems have fast local-data accesses but lack flexibility in managing compute and storage resources, and they cannot scale these resources independently.

2.2 RDMA and RDMA-Based Data Stores

Remote Direct Memory Access, or *RDMA*, is a network technology that offers low-latency and low-CPU-utilization accesses to memory at remote machines. RDMA supports two communication patterns: *one-sided* and *two-sided*. One-sided RDMA operations allow one node to directly access the memory at another node without involving the latter's CPU. Two-sided RDMA involves both sender's and receiver's CPUs, similar to traditional network messaging.

Because of its performance and cost benefits [22, 36, 49], RDMA has been deployed in major datacenters like Microsoft [63] and Alibaba [2]. Several recent distributed systems such as in-memory key-value stores [15, 16, 38, 47, 48, 58] and in-memory databases/transactional systems [8, 10, 66, 72] use RDMA to perform their network communication. Most of them use a combination of one- and two-sided RDMA or pure two-sided RDMA. For example, FaSST [32] is an RDMA-based RPC system built entirely with two-sided RDMA. FaRM [15, 16], an RDMA-based distributed memory platform, uses one-sided communication for reads and performs both one- and two-sided operations for replicated writes. Pilaf [47] is a key-value store system that uses one-sided RDMA *read* for *get* and two-sided RDMA for *put*. HERD [30, 31] is another RDMA-based key-value store system. For each *get* and *put*, HERD uses two RDMA operations: client sending a one-sided RDMA *write* request to server and server sending an RDMA *send* response to client.

To achieve low-latency performance, most existing systems use busy-polling threads to receive incoming two-sided RDMA requests. They also perform management tasks such as memory allocation and garbage collection at CPUs in data-hosting nodes [15, 72]. Consequently, even when one-sided RDMA operations help reduce CPU utilization, practical RDMA-based data stores still require a CPU and significant amount of energy at each data-hosting server. For example, although FaRM [15] tries to use as much one-sided communication as possible, it still requires processing power at data nodes to perform metadata operations and certain steps in its write replication protocol.

HyperLoop [35] is a recent system that provides a mechanism to extend default one-sided RDMA operations to support more functionalities. These additional functionalities are performed at RDMA NICs without involving host CPU. HyperLoop's computation offloading technique could be applied to pDPM systems to offload certain data operations to DNs, which could potentially improve pDPM's performance. However, it is difficult to offload the more complex metadata operations to RDMA NICs, and HyperLoop still performs them at CPUs. Clover demonstrates how to efficiently separate the metadata plane and run it at a global metadata server.

2.3 Resource Disaggregation

Resource disaggregation is a notion to separate different types of resources into pools (*e.g.*, a compute pool and a storage pool), each of which can be independently managed, configured, and scaled [6, 26, 55]. Because of its efficiency in resource utilization and management, many datacenters and clouds have taken this approach when building storage systems [3, 4, 11, 18, 65].

Disaggregation could take two forms: disaggregating resources and managing them at where they are (active), and disaggregating resources but managing them at the compute pool (passive). Existing storage and memory systems have mainly taken the active approach, with most of them building disaggregated resource pools using regular CPU-based servers [51, 65]. To sustain high-bandwidth networks and fast PM, these systems will require many CPU cores to just poll and process requests. Another way to build active disaggregated systems is to offload computation at storage nodes to hardware [9, 12, 17, 33, 35, 38, 39, 54, 57, 57]. These solutions either require significant hardware implementation efforts (*e.g.*, FPGA-based) or incur performance scalability issues (*e.g.*, ARM-SoC-based).

Compared to active disaggregation, the passive approach of disaggregation largely reduces the owning, energy, and development costs of storage nodes by avoiding busy polling at storage nodes and shifting the rest of the computation to compute nodes. Unfortunately, the passive approach has largely been overlooked in the community. HPE's "The Machine" (Memory-Driven Computing) project [19, 23, 24, 37, 64] is one of the few existing proposals [40, 41] that adopt the passive model. So far, HPE has (separately) built a hardware prototype and a software layer. The hardware prototype [20] connects a set of SoCs to a set of DRAM/PM chips in a rack over a proprietary photonic network. To use this hardware prototype, application developers need to build software layers to manage and access data in DRAM/PM. HPE has also been building a software memory-store solution on top of a Superdome NUMA machine [37, 64]. This solution assumes certain features from future interconnect technologies, does not support data redundancy, and is work done in parallel with us. Although being a significant initial step in passive disaggregation research, the Machine project only explores one design choice and relies heavily on special network to access and manage disaggregated memory. Moreover, its design details are not open to the public.

3 pDPM Overview

This section gives an overview of pDPM, its unique challenges, the interface and guarantees our proposed pDPM systems have, and the network layer they employ. Table 1 summarizes the comparison of our proposed pDPM systems and traditional distributed PM and remote memory systems.

3.1 Passive Disaggregated Persistent Memory

Our definition of the pDPM architecture consists of two concepts: separating PM from compute servers into a PM-based storage pool and eliminating processing needs at these separated PM nodes (DNs).

The first concept is in the same spirit of current disaggregated storage systems and shares many of their benefits: it is flexible to manage and customize the PM storage pool; it offers high resource utilization, since data can be allocated at any DNs; datacenters can scale DNs independently from other servers; and it is easy to add, remove, and upgrade DNs without the need to change existing (compute) servers.

The second concept follows the more aggressive disaggregation approach of forming resource pools with just hardware (PM in our case). Such PM pools can be a set of regular servers equipped with PM or a set of network-attached devices with just network functionality and some PM. The former frees entire server CPUs to perform other tasks, while the latter eliminates the need for a processor and its hardware/server packaging all together, reducing not only the energy cost but also the building cost of DNs. Moreover, by removing processing from DNs, pDPM also avoids DN-side processor being a performance scalability bottleneck.

3.2 pDPM Challenges

pDPM offers many cost and manageability benefits and is now feasible to build with fast, “one-sided” network communication technologies like RDMA. However, it is only attractive when there is no or minimal performance loss compared to other more expensive solutions. Building a pDPM storage system that can lower the cost but maintain the performance of non-pDPM systems is hard. Different from traditional distributed storage and memory systems, DNs can only be accessed *and* managed remotely. A major technical hurdle is in providing good performance with concurrent data accesses. The lack of processing power at DNs makes it impossible to orchestrate (e.g., serialize) concurrent accesses there. Managing distributed PM resources without any pDPM-local processing is also hard and when performed improperly, can largely hurt foreground performance. In addition, DNs can fail independently. Such failures should be handled properly to ensure data reliability and availability.

Different from traditional disaggregated storage that is based on SSDs or hard disks, PM is orders of magnitude faster [70]. Although today’s datacenter network speed has also improved significantly [43], pDPM storage systems should still try to minimize network RTTs.

Different from disaggregated memory systems [40, 41, 55], pDPM is a persistent storage system and should sustain power failures and node failures. Thus, we need to ensure the consistency of data and metadata during crash recovery and provide redundancy for high availability and reliability.

3.3 System Interface and Guarantees

Clover and our two alternative pDPM systems provide the same interface and guarantees to applications. They are key-value stores supporting variable-sized entries, where users can create, read (get), write (put), and delete a key-value entry. Different CNs can have shared access to the same data. All our pDPM systems ensure the atomicity of an entry across concurrent readers and writers. A successful write indicates that the data entry is committed (atomically). Reads only see committed value. We choose to build key-value stores on the pDPM architectures because key-value stores are widely used in many datacenters. Similarly, we choose single-entry atomic write and read committed because these consistency and isolation levels are widely used in many data store systems [30, 47] and can be extended to other levels.

Our pDPM systems are intended for storing data persistently. They provide crash consistency, data reliability, and high availability. After recovering from crashes at arbitrary points, each data entry is guaranteed to contain either only new data values or only old ones. In addition, all our three systems support replicated writes across DNs.

3.4 Network Layer

We choose RDMA as the network technology to connect all servers and DNs. We use RDMA’s RC (Reliable Connection) mode which supports one-sided RDMA operations and ensures lossless and ordered packet delivery. Similar to prior solutions [15, 30, 31, 67], we solve RDMA’s scalability issues by registering memory regions using huge memory pages with RDMA NICs. Note that we use regular RDMA writes as persistent write for our evaluation, since the RDMA durable write commit in the IETF standard takes one network round trip [60], same as non-durable RDMA write.

4 Alternative pDPM Systems

Before Clover, we built two other pDPM systems during our exploration of the pDPM architectures. They follow the same interface and deliver the same consistency and relia-

System	CapEx ($)	R-RTT	W-RTT	Energy	Scalability	Metadata	Performance
Distributed PM	46736	0-N	0-N	High	Neither	Large	Good only when accessing data on local node
aDPM w/ CPU	79888	1	1	High	w/ both⋆	Small	Good overall
aDPM w/ BlueField	80080	1	1	Low	Neither	Small	Good under light load
pDPM-Direct	53096	1	4(4)	Low	w/ DN†	Large	Best for small-sized read
pDPM-Central	58096	2	2(2)	High	Neither	Small	Not good for read-intensive traffic
Clover	58096	1	2(3)	Low	w/ both	Medium	Good overall (unless high write contention)

Table 1: **Comparison of Distributed PM Architectures.** *The CapEx column represents dollar cost to build eight CNs and eight PMs. Section 6 discusses the details of CapEx and energy (CPU utilization) calculation. The R-RTT and W-RTT columns show the number of RTTs required to perform a read and a write (with replication). All RTT values are measured when there is no contention. RTTs in distributed PM's read/write, N, depends on protocols and whether data is local. The Scalability column shows if a system is scalable with the number of CNs, the number of DNs, both, or neither. ⋆ only when there are enough CPU cores. † only scalable when there is no contention. The metadata columns show the space needed to store the metadata of a data entry.*

(b) pDPM-Central

(c) Clover

Figure 2: **Read/Write Protocols of pDPM Systems.**

bility guarantees as Clover. Even though the main system we present in this paper is Clover, we have spent significant amount of efforts on optimizing the performance of these alternative systems and on adding replication and crash recovery support to them. They can be used as stand-alone systems apart from being comparison points of Clover. Because of space constraint, we only briefly present their basic data structures and read/write protocols. We omit the discussion of their replication and crash recovery protocols.

4.1 Direct Connection

Our first alternative pDPM system, *pDPM-Direct*, connects CNs directly to DNs (Figure 1(c)). CNs perform unorchestrated, direct accesses to DNs using one-sided RDMA operations. The main challenge in designing pDPM-Direct is the difficulty in coordinating CNs for various data and metadata operations.

To avoid frequent space allocation (which requires coordination across CNs), we pre-assign two spaces for each data entry, one to store committed data where reads go to (the *committed space*) and one to store in-flight, new data (the *uncommitted space*). CNs allocate these spaces at data-entry creation time with the help of a distributed consensus protocol. Afterwards, their locations do not change until data-entry free time. CNs locally store all the metadata (*e.g.*, the locations of committed and uncommitted spaces) to avoid reading and writing metadata to DNs and the cost of ensuring metadata consistency under concurrent accesses.

To support synchronized concurrent data accesses and to avoid reading intermediate data during concurrent writes, a straightforward method and our strawman version is to always lock a data entry when reading or writing it using a distributed lock. Doing so incurs two additional network RTTs for each data access (one for lock and one for unlock).

For better performance, we adopt a lock-free, checksum-based read mechanism, which allows reads to take only one RTT. Specifically, we associate a CRC (error detection code) checksum with each key-value entry at DNs. To read a data entry, a CN uses its stored metadata to find the location of the data entry's committed space. It then reads both the data and its CRC from the DN with an RDMA read. Afterwards, the CN calculates the CRC of the fetched data and compares this calculated CRC with the fetched CRC. If they do not match, then the read is incomplete (an intermediate state during an ongoing write), and the CN retries the read request. Although calculating CRCs adds some performance overhead, it is much lower than the alternative of locking. Figure 2(a) illustrates pDPM-Direct's read and write protocols.

pDPM-Direct still requires locking for writes. We designed an efficient, RDMA-based implementation of write lock. We associate an 8-byte value at the beginning of each data entry as its lock value. To acquire the lock, a CN performs an RDMA `c&s` (compare-and-swap) operation to the value. The `c&s` operation compares whether the value is 0. If so, it sets it to 1. Otherwise, the CN retries the `c&s` operation. To release the lock, the CN performs an RDMA write and sets the value to 0. Our lock implementation leverages the unique feature of the pDPM model that all memory accesses to DNs come from the network (i.e., the NIC). Without any yprocessor's accesses to memory, the DMA protocol guarantees that network atomic operations like `c&s` are atomic across the entire DN [14, 61].

To write a data entry, a CN first calculates and attaches a CRC to the new data entry. Afterwards, the CN locates the entry with its local metadata and locks the entry (one RTT). The CN then writes the new data (with the CRC) to the un-committed space (one RTT), which serves as the *redo* copy used during recovery if a crash happens. Afterwards, the CN writes the new data to the committed space with an RDMA write (one RTT). At the end, the CN releases the lock (one RTT). The total write latency is four RTTs plus the CRC calculation time (when no contention), and two of these RTTs contain data.

4.2 Connecting Through Coordinator

Our second alternative pDPM system, *pDPM-Central* (Figure 1(c)), uses a central *coordinator* to orchestrate all data accesses and to perform metadata and management operations. All CNs send RPC requests to the coordinator, which handles them by performing one-sided RDMA operations to DNs. We implement our RPC using HERD's RPC design [30]; other RPC designs can easily be integrated too. To achieve high throughput, we use multiple RPC handling threads at the coordinator. Figure 2(b) illustrates pDPM-Central's read and write protocols.

Since all requests go through the coordinator, it can serve as the serialization point for concurrent accesses to a data entry. We use a local read/write lock for each data entry at the coordinator to synchronize across multiple coordinator threads. In addition to orchestrating data accesses, the coordinator performs all space allocation and de-allocation of data entries. The coordinator uses its local PM to persistently store all the metadata of a data entry.

To perform a read, a CN sends an RPC read request to the coordinator. The coordinator finds the location of the entry's committed data using its local metadata, acquires its local lock of the entry, reads the data from the DN using a one-sided RDMA read, releases its local lock, and finally replies to the CN's RPC request. The end-to-end read latency a CN observes (when there is no contention) is two RTTs, and both RTTs involve sending data.

To perform a write, the coordinator allocates a new space at a DN for the new data and then writes the data there. We do not need to lock (either at coordinator or at the DN) during this write, since it is an out-of-place write to a location that is not exposed to any other coordinator RPC handlers. After the write, the coordinator updates its local metadata with the new data's location and flushes this new location to its local PM for crash resistance. The total write latency without contention is two RTTs, both containing data.

4.3 pDPM-Direct/-Central Drawbacks

pDPM-Direct delivers great read performance when read size is small, since it only requires one lock-free RTT and it is fast to calculate small CRC. Its write performance is much worse because of high RTTs and lock contention. Its scalability is also limited because of lock contention during concurrent writes. Moreover, pDPM-Direct requires large space for both data and metadata. For each data entry, it doubles the space because of the need to store two copies of data. The metadata overhead is also high, since all CNs have to store all the metadata.

pDPM-Central largely reduces write RTTs over pDPM-Direct and thus has good write performance when the scale of the cluster is small. Unlike pDPM-Direct, CNs in pDPM-Central do not need to store any metadata. However, from our experiments, the coordinator soon becomes the performance bottleneck when either the number of CNs or the number of DNs increases. pDPM-Central's read performance is also worse than pDPM-Direct with the extra hop between a CN and the coordinator. In addition, the coordinator's CPU utilization is high, since it needs many RPC handler threads to sustain parallel requests from CNs.

5 Clover

To solve the problems of the first two pDPM systems we built, we propose Clover (Figure 1(e)). The main idea of Clover is to separate the location, the communication method, and the management strategy of the data plane and the control plane. It lets CNs directly access DNs for all data operations and uses one or few metadata servers (*MS*s) for all control plane operations.

To avoid MS being the scalability bottleneck, we support multiple MSs, each serving a shard of data entries. Each MS stores the metadata of the data entries it is in charge of in its local PM. We keep the amount of metadata small. The storage overhead of metadata is below 2% for 1 KB data entries. CNs cache the metadata of hot data entries. Under memory pressure, CNs evict metadata with a replacement policy (we currently support FIFO and LRU).

Clover aims to deliver scalable, low-latency, high-throughput performance at the data plane and to avoid the MS being the bottleneck at the control plane. Our overall approaches to achieve these design goals include: 1) moving all metadata operations off performance critical path, 2) using lock-free data structures to increase scalability, 3) employing optimization mechanisms to reduce network round trips for data accesses, and 4) leveraging the unique atomic data access guarantees of pDPM. Figure 2(c) shows the read and write protocol of Clover. Figure 3 illustrates the data structures used in Clover.

5.1 Data Plane

To achieve our data plane design goals, we propose a new mechanism to perform lock-free, fast, and scalable reads and writes. Specifically, we allow multiple committed versions of a data entry in DNs and link them into a *chain*. Each committed write to a data entry will move its latest version to a new location. To avoid the need of updating CNs with the new location, we use a self-identifying data structure for CNs to find the latest version.

We include a *header* with each version of a data entry. The header contains a *pointer* and some metadata bits used for garbage collection. The pointers chain all versions of a data entry together in the order that they are written. A `NULL` pointer indicates that the version is the latest.

A CN acquires the header of the chain head from the MS at the first access to a data entry. It then caches the header locally to avoid the overhead of contacting MS on every data access. We call a CN-cached header a *cursor*.

Read. Clover reads are lock-free. To read a data entry, a CN performs a *chain walk*. The chain walk begins with fetching

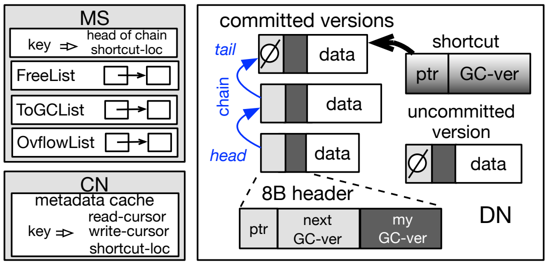

Figure 3: **Clover System Design.**

the data buffer version that the CN's cursor points to. It then uses the pointer in this fetched buffer to read the next version. The CN repeats this step until reading a `NULL` pointer, which indicates that it has read the latest version. All steps in the chain walk use one-sided RDMA reads. After a chain walk, the CN updates its cursor to point to the latest version.

A chain walk can be slow with long chains when a cursor is not up to date [68]. Inspired by skip lists [53], we solve this issue by using a *shortcut* to directly point to the latest version or a recent version of each data entry. Shortcuts are *best effort* in that they are intended but not enforced to always point to the latest version of an entry. The shortcut of a data entry is stored at its DN. The location of a shortcut never changes during the lifetime of the entry. MS stores the locations of all shortcuts. When a CN first accesses a data entry, it retrieves the location of its shortcut from MS and caches it locally.

The CN issues a chain walk read and a shortcut read in parallel. It returns the user request when the faster one finishes and discards the other result. We do not replace chain walks completely with shortcut reads, since shortcuts are updated asynchronously in the background and may not be updated as fast as the cursor. When the CN's cursor points to the latest version of a data entry, a read only takes one RTT.

Write. Clover never overwrites existing data entries and performs a lock-free, out-of-place write before linking the new data to an entry's chain. To write a data entry, a CN first selects a free DN space assigned to it by MS in advance (see §5.2). It performs a one-sided RDMA write to write the new data to this buffer. Afterwards, the CN performs an RDMA `c&s` operation to link this new data to the tail of the entry's version chain. Specifically, the `c&s` operation is on the header that the CN's cursor points to. If the pointer in the header is `NULL`, the `c&s` operation swaps the pointer to point to the new data, and we treat this new data as a *committed* version. Otherwise, it means that the cursor does not point to the tail of the chain and the CN performs a chain walk to reach the tail and then issues another `c&s`.

Afterwards, the CN uses a one-sided RDMA write to update the shortcut of the entry to point to the new data version. This step is off the performance critical path. The CN also updates its cursor to the newly written version. We do not invalidate or update other CNs' cursors at this time to improve the scalability and performance of Clover.

Clover' chained structure and write mechanism ensure that writers do not block readers and readers do not block writers. They also ensure that readers can only view committed data. Without high write contention to the same data entry, one write takes only two RTTs.

Retire. After committing a write, a CN can *retire* older versions of the data entry, indicating that the buffer spaces can be reclaimed. To improve performance and minimize the need to communicate with MS, CNs lazily send asynchronous, batched retirement requests to MS in the background. We further avoid the need for MS to invalidate CN-cached metadata using a combination of timeout and epoch-based garbage collection (see §5.2).

5.2 Control Plane

CNs communicate with MS using two-sided operations for all metadata operations. MS performs all types of management of DNs. We carefully designed the MS functionalities for best performance and scalability.

Space allocation. With Clover's out-of-place write model, Clover has high demand for DN space allocation. We use an efficient space allocation mechanism where MS packages free spaces of all DNs into *chunks*. Each chunk hosts data buffers of the same size. Different chunks can have different data sizes. Instead of asking for a new free space before every write, each CN requests multiple spaces at a time from MS in the background. This approach moves space allocation off the performance critical path and is important to deliver good write performance.

Garbage collection. Clover' append-only chained data structure makes its writes very fast. But like all other append-only and log-structured storage systems, Clover needs to garbage collect (GC) old data. We design a new efficient GC mechanism that does not involve *any* data movement or communication to DN. It also minimizes the communication between MS and CNs.

The basic flow of GC (a strawman implementation) is simple: MS processes incoming retire requests from CNs by putting reclaimed spaces to a free list (*FreeList*). It gets free spaces from the FreeList when a CN requests more free buffers. A free space can be used by any CN for any new writes, as long as the size fits.

Although the above strawman implementation is simple, making GC work correctly, efficiently, and scale well is challenging. First, to achieve good GC performance, we should avoid the invalidations of CN cached cursors after reclaiming buffers to minimize the network traffic between MS and CNs. However, with the strawman GC implementation, CNs' outdated cursors can cause failed chain walks. We solve this problem using two techniques: 1) MS does not clear the header (or the content) of a data buffer after reclaiming it, and 2) we assign a *GC version* to each data buffer. MS increases the GC version after reclaiming a data buffer. It gives this new GC version together with the location of the buffer when assigning the buffer as a free space to a CN, CN_k. Before CN_k uses the space for a new write, the content of this space at the DN contains old data and old GC version. After CN_k uses the space for a write, it contains new data and new GC version. Other CNs that have cached cursors to this buffer need to differentiate these two cases. A CN tells if a buffer contains its intended data by comparing the GC version in its cached cursor to the one it reads from the DN. If they do not match, the CN will discard the read data and invalidate its cached cursor. Our GC-version approach not only avoids the need for MS to invalidate cursor caches on CNs, but also eliminates the need for MS to access DNs during GC.

The next challenge is related to our goal of read-isolation and atomicity guarantees (*i.e.*, readers always read the data that is consistent to its metadata header). An inconsistent read can happen if the read to a data buffer takes long, and during the reading time, this buffer has been retired by another CN, reclaimed by MS, assigned to a CN as a newly allocated buffer, and used to perform a write. We use a read timeout scheme similar to FaRM [15] to prevent this inconsistent case. Specifically, we abort a read operation after two RTTs, since the above steps in the problematic case take at least (and usually a lot more than) two RTTs (one for a CN to submit the retirement request to MS and one for MS to assign the space to a new CN).

The final challenge is the overflow of GC versions. We can only use limited number of bits for GC version in the header of a data buffer (currently 8 bits), since the header needs to be smaller than the size of an atomic RDMA operation. When the GC version of a buffer increases beyond the maximum value, we have to restart it from zero. With just our GC mechanism so far, CNs will have no way to tell if a buffer matches its cached cursor version or has advanced by $2^8 = 256$ versions. To solve this rare issue without invalidation traffic to CNs, we use an epoch-based timeout mechanism. When MS finds the GC version of a data buffer overflows, it puts the reclaimed buffer into an *OvflowList* and waits for T_e (a configurable time value) before moving it to the *FreeList*. All CNs invalidate their own cursors after an inactive period of T_e (if during this time, the CN access the buffer, it would have advanced the cursor already). To synchronize epoch time, MS sends a message to CNs after T_e. Epoch messages are the only communication from MS to CNs during GC.

5.3 Discussion

The Clover design offers four benefits. First, Clover yields the best performance among all pDPM systems; it outperforms pDPM-Direct and pDPM-Central for both reads and writes, and both with and without contention. Achieving this low latency while guaranteeing atomic write and read committed is not easy. Four approaches enable us to reach this goal: 1) ensuring that the data path does not involve MS, 2) reducing metadata communication to MS and moving it off performance critical paths, 3) ensuring no memory copy in the whole data path, and 4) leveraging the unique advantages of pDPM to perform RDMA atomic operations.

Second, Clover scales well with the number of CNs and DNs, since its reads and writes are both lock free. Readers do not block writers or other readers and writers do not block readers. Concurrent writers to the same entry only contend for the short period of an RDMA `c&s` operation. Clover also minimizes the network traffic to MS and the processing load on MS, which enables MS to scale well with the number of CNs and with the amount of data operations.

Third, we avoid data movement and communication between MS and DNs entirely during GC. To scale and support many CNs with few MSs, we also avoid CN invalidation messages. MS does not need to proactively send any other messages to CNs either. Essentially, MS never *pushes* any messages to CNs. Rather, CNs *pull* information from MS. Furthermore, MS adopts a thread model that adaptively lets working threads sleep to reduce MS's CPU utilization.

Finally, the Clover data structure is flexible and can support load balancing very well. Different versions of a data entry do not need to be on the same DN. As we will see in §5.4 and §5.5, this flexible placement is the key to Clover's load balancing and data replication needs.

However, Clover also has its limitation. Each write in Clover requires two RTTs and under heavy contention, its write performance degrades. As we will see in §6, two-sided aDPM systems outperform Clover with write-intensive workloads, since they can complete writes in one RTT. Fortunately, most datacenter workloads are read-most [7], and under common cases, Clover delivers great performance.

5.4 Failure Handling

DNs can fail independently from CNs. Clover needs to handle both transient and permanent failures of a DN. For the former, Clover guarantees that a DN can recover all its committed data after reboot (*i.e.*, crash consistent). For the latter, we add the support of data replication across multiple DNs to Clover. In addition, Clover also handles the failure of MS.

Recovery from transient failures. Clover's recovery mechanism of a single DN's transient failure is simple. If a DN fails before a CN successfully links the new data it writes to the chain (indicating an un-committed write), the CN simply discards the new write by treating the space as unused.

Data redundancy. With the user-specified degree of replication being N, Clover guarantees that data is still accessible after $N-1$ DNs have failed. We propose a new atomic replication mechanism designed for the Clover data structure.

The basic idea is to link each version of a data entry D_N to all the replicas of the next version (*e.g.*, D^a_{N+1}, D^b_{N+1}, D^c_{N+1} for three replicas) by placing pointers to all these

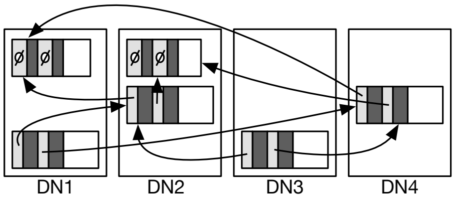

Figure 4: **Replicated Data Entry.** *A replicated data entry on four DNs. The replication factor is two.*

replicas in the header of D_N. Figure 4 shows an example of a replicated data entry (with the degree of replication being 2). With this all-way chaining method, Clover can always construct a valid chain as long as one copy of each version in a data entry survives.

Each data entry version has a primary copy and one or more secondary copies. To write a new version, D_{N+1}, to a data entry whose current tail is D_N with R replicas, a CN first writes the new data to R DNs. In parallel, the CN performs a one-sided `c&s` to a bit, B_w, in the header of the primary copy of D_N to test if the entry is already in the middle of a replicated write. If not, the bit will be set, indicating that the entry is now under replicated write. All the writes and the `c&s` operation are sent out in parallel to minimize latency. After the CN receives the RDMA acknowledgment of all the operations, it constructs a header that contains R pointers to the copies of D_{N+1} and writes it to all the copies of D_N. Once the new header is written to all copies of D_N, the system can recover D_{N+1} from crashes (up to $R-1$ concurrent DN failure).

MS redundancy. MSs manage several types of metadata. Among them, the only type of metadata that cannot be reconstructed is keys (of key-value entries) and the mapping from a key to the location of its data entries in DNs. To avoid MS being the single point of failure, we implement a mechanism to include one or more *backup* MS. When creating (deleting) a new key-value data entry, the primary MS synchronously replicates (removes) the key and the head of the value chain to all the backup MSs. These metadata are the only metadata that cannot be reconstructed. MSs reconstruct all other metadata by reading value chains in DNs.

5.5 Load Balancing

A pDPM system has a pool of DNs. It is important to balance the load to each of them. We use a novel two-level approach to balance loads in Clover: globally at MS and locally at each CN. Our global management leverages two features in Clover: 1) MS is the party that assigns all new spaces to CNs, and 2) data versions of the same entry in Clover can be placed on different DNs. To reduce the load of a DN, MS assigns more free spaces from other DNs to CNs at allocation time. Each CN internally balances the load to different DNs at runtime. Each CN keeps one bucket per DN to store free spaces. It chooses free spaces from different buckets for new writes according to its own load balancing needs.

6 Evaluation Results

This section presents the evaluation results of Clover. We compare it with pDPM-Direct, pDPM-Central, two distributed PM-based systems, Octopus [42] and Hotpot [56], and a two-sided RDMA-based key-value store, HERD [30]. All our experiments were carried out in a cluster of 14 machines, connected with a 100 Gbps Mellanox InfiniBand Switch. Each machine is equipped with two Intel Xeon E5-2620 2.40GHz CPUs, 128 GB DRAM, and one 100 Gbps Mellanox ConnectX-4 NIC.

In order to compare the pDPM architecture with a low-cost aDPM architecture, we use Mellanox BlueField, a SmartNIC that includes an ARM-based SoC and a 100 Gbps Mellanox ConnectX-5 NIC [44]. We port HERD to BlueField by migrating it from x86 to ARM (we call the ported HERD running on BlueField HERD-BF).

Unfortunately, at the time of writing, we cannot get hold of real Intel Optane DC, and we use DRAM as PM. Our experiments run on machines with PCIe 3.0 ×8 (7.87 GB/s), and the bandwidth from RDMA-NIC to DRAM is capped by it, making the effective bandwidth at most 7.87 GB/s. Intel Optane DC's read bandwidth is 6.6 GB/s [70], which is close to PCIe 3.0 ×8. Thus, we envision read results to be similar with real Optane. Optane's write bandwidth is 2.3 GB/s, and there may be some difference in our write results with real Optane. But since our target is read-most workloads, we believe that the conclusion we make from our evaluation will still be valid with real PM.

6.1 Micro-benchmark Performance

We first evaluate the basic read/write latency of Clover and the systems in comparison using a simple micro-benchmark where a CN synchronously reads/writes a key-value data entry on a DN. For this and all the rest of our experiments, we use HERD's default configuration of 12 busy polling receiving side's threads for both HERD and HERD-BF.

Figure 5 plots the read latency with different request sizes. We use native RDMA one-sided read as the baseline. Overall, Clover's performance is the best among all systems and is only slightly worse than native RDMA. pDPM-Direct has great read performance when the request size is small. However, when request size increases, the overhead of CRC calculation dominates, largely hurting pDPM-Direct's read performance. As expected, pDPM-Central's read performance is not good because of its 2-RTT read protocol. HERD performs worse than Clover because it requires some extra CPU processing time for each read. HERD-BF has a constant overhead over HERD mainly because its processing is performed in BlueField's low-power ARM cores.

Figure 6 plots the average write latency comparison. We use native RDMA one-sided write as a baseline here. Among pDPM systems, Clover and pDPM-Central achieve the best write latency. pDPM-Direct's write performance is the worst

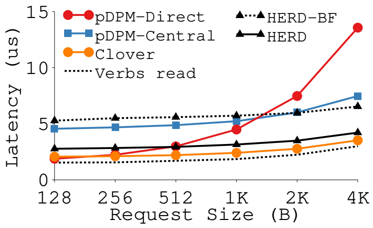

Figure 5: **Read Latency.**

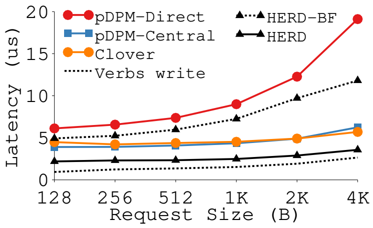

Figure 6: **Write Latency.**

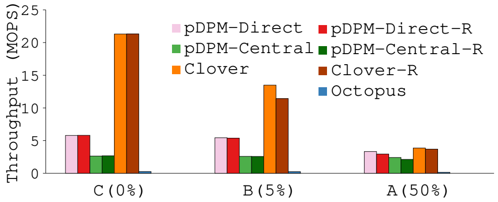

Figure 7: **Throughput Comparison with YCSB.** *Running YCSB on four CNs and four DNs.*

because of its 4-RTT write protocol. Its write performance also gets worse with larger request size because of the increased overhead of CRC calculation. HERD outperforms Clover and other pDPM systems because two-sided communication allows it to complete a write within one RTT. HERD-BF is still a lot worse than HERD because of BlueField's low processing power.

6.2 YCSB Performance and Scalability

We now present our evaluation results using the YCSB benchmark [13, 71]. We use a total of 100K key-value entries and 1M operations per test. The accesses to keys follow the Zipf distribution. We use three workloads with different read-write ratios: read only (workload C), 5% write (workload B), and 50% write (workload A). These three workloads follow common application patterns in datacenters [7] and are the set that previous PM and in-memory store systems used for evaluation [30, 38, 47, 69].

Basic performance. We first evaluate the performance of Clover, pDPM-Direct, pDPM-Central, Octopus, and Hotpot under the same configuration: 4 CNs and 4 DNs, each CN running 8 application threads. Neither Octopus nor Hotpot directly support key-value interface. In order to run the YCSB key-value store workloads, we run MongoDB [50], a key-value store database, on top of Octopus and Hotpot. Note that HERD only supports one DN and we cannot compare with HERD or HERD-BF in this experiment. We also evaluate replication with our three pDPM systems here (with degree of replication 2). Figure 7 shows the overall performance of these systems. Hotpot yields similar performance as Octopus and we omit its results in the figure.

Clover performs the best among all systems for all workloads. We further look into the Clover results and find that the average number of hops during chain walks is only 0.2 to 0.3 for reads and 3.7 to 3.9 for writes. pDPM-Direct performs better with read-most workloads than write-most workloads. This is because without the need to perform any locking, its read performance is not affected by contention. pDPM-Central's performance is the worst among pDPM systems, because under contention (Zipf distribution), the coordinator becomes the bottleneck.

The overall performance of Octopus and Hotpot is more than an order of magnitude worse than all pDPM systems. There are two main reasons. First, these systems do not directly support key-value interface, and running MongoDB on top of them adds overhead. Unfortunately, there is no existing distributed PM systems that directly support key-value interface as far as we know. Second, each read and write operation in these systems involves a complex protocol that requires RPCs across multiple nodes.

Workload	Median	Average	99%
C	1	1	1
B	1	1.26	5
A	1	1.33	6

Table 2: **Clover RTTs.**

To further understand Clover's performance, we measure the number of RTTs incurred when running YCSB on Clover. Table 2 shows the median, average, and 99% RTTs of Clover. Clover requires only one RTT for read-most workloads. Even for 50% write (workload A), Clover only incurs six RTTs at 99% and one RTT at median.

Replication overhead. As expected, adding redundancy lowers the throughput of write operations for all pDPM systems. Even though these systems issue the replication requests in parallel, they only use one thread to perform asynchronous RDMA read/write operations, and doing so still has an overhead. However, the overhead is small.

Scalability. Next, we evaluate the scalability of different systems with respect to the number of CNs and the number of DNs. Figure 8 shows the scalability of pDPM systems, HERD, and HERD-BF when varying the number of CNs with a single DN. Clover and HERD have the best (and similar) performance with workload C. Both systems saturate network bandwidth, and neither have any scalability bottlenecks. With workload B, the performance of Clover is slightly worse than HERD because of increased write contention. HERD-BF performs worse and scales worse than Clover and HERD for both workloads mainly because of its limited processing power. pDPM-Central performs the worst and does not scale well with more CNs. pDPM-Direct also performs poorly with fewer CNs. Apart from the limitation of these system's designs, their inefficient thread models also contribute to their worse performance.

Figure 9 shows the scalability of pDPM data stores w.r.t. the number of DNs (HERD only supports single memory node and we cannot include it in this experiment). Clover scales well with DNs because CNs access DNs directly for data accesses, having no scalability bottleneck. pDPM-

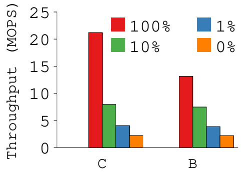

Figure 12: **Effect of Metadata Cache in Clover.**

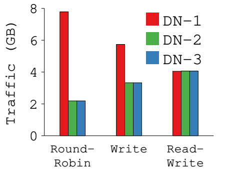

Figure 13: **Load Balancing in Clover.**

Central has poor scalability because of the coordinator being the bottleneck that all requests have to go through. Surprisingly, pDPM-Direct's scalability is also poor. This is because when the number of DNs increases, network bandwidth has not become a performance bottleneck, but CNs need to do more CRC calculation to read/write to more DNs. This computation overhead becomes the performance bottleneck.

6.3 CPU Utilization and Cost

CPU utilization and energy cost. We evaluate the CPU utilization of different systems by calculating the total CPU time to complete ten million requests in YCSB's workloads A, B, and C, as illustrated in Figure 10. We further separate the CPU time used at client side (CNs) and at server side (DNs, the coordinator, MS). The three pDPM systems run four CNs and four DNs. HERD and HERD-BF run four CNs and one DN. Since HERD only supports one DN, to estimate the CPU utilization and energy of a scale-out version of HERD, we hypothetically assume that HERD can achieve perfect scaling (*i.e.*, we reduce HERD's total run time by a factor of four to model it running on four CNs and four DNs). This hypothetical calculation is the optimal performance HERD could have achieved.

We further calculate the total energy cost using the power consumption of our CPU core [34] and the ARM core of BlueField [52]. Figure 11 plots this result. We do not include the energy cost of PM, since it is the same for all systems.

For read-most workload, pDPM-Direct and Clover use less CPU time than pDPM-Central and HERD because they perform one-sided RDMA directly from CNs to DNs. HERD's total CPU time is much longer than Clover even with optimal scale-out calculation, because it uses many busy-polling threads at its server side to achieve good performance (12 threads by default). Surprisingly, HERD-BF's energy is higher than HERD even when the power consumption of an ARM core is more than an order of magnitude lower than our CPU core. HERD-BF's worse performance makes each request to run longer and consumes more power. pDPM-Central has high CPU utilization because the coordinator's CPU spends time on every request, and the total time to finish the workloads with pDPM-Central is long. HERD's write performance and energy are both better than Clover. pDPM systems consume more energy for write-heavy workloads because of their degraded write performance.

CapEx. Table 1 summarizes the cost to build different data stores with 8 CNs and 8 DNs (for distributed PM, we use eight machines in total). The CapEx is calculated with the market price of 128 GB Intel Optane PM ($842 [5]), Mellanox ConnectX-4 NIC ($795 [45]), Mellanox BlueField NIC ($4168 [1]), and a DELL R740 server with the same configuration as what we use in our experiments ($5000). For servers with PM, we adjust the price difference between PM and DRAM to the whole server price ($4144). Distributed PM has the lowest CapEx because it can share PM and only needs eight machines in total. aDPM with CPU requires 16 machines in total (8 for CNs and 8 for DNs). The three pDPM systems and aDPM with BlueField do not require full machines for DNs and we only include PM and NIC costs for them. Surprisingly, the cost of BlueField is similar to a full machine. We suspect that this is because BlueField is in a new and small market, and we expect its price to drop in the future (but still not as low as pDPM).

6.4 Metadata Caching

Each data entry in Clover requires a constant of 8 B metadata (which is much smaller than typical key-value sizes of 100 B - 1000 B [7]). To evaluate the effect of different sizes of metadata cache at CNs in Clover, we ran the same YCSB workloads and configuration as Figure 7 and plot the results in Figure 12. Here, we use the FIFO eviction policy (we also tested LRU and found it to be similar or worse than FIFO). With smaller metadata cache, all workloads' performance drop because a CN has to get the metadata from the MS before accessing a data entry that is not in the local metadata cache. With no metadata cache (0%), CNs need to get metadata from the MS before every request. However, under Zipf distribution, with just 10% metadata cache, Clover can already achieve satisfying performance.

6.5 Load Balancing

To evaluate the effect of Clover's load balancing mechanism, we use a synthetic workload with six data entries, a, b, and $c1$ to $c4$. The workload initially creates a (no replication) and b (with 3 replicas) and reads these two entries continuously. At a later time, it creates $c1$ to $c4$ (no replication) and keeps updating them. One CN runs this synthetic workload on three DNs. Figure 13 shows the total traffic to the three DNs with different allocation and load-balancing policies. With a naive policy of assigning DNs to new write requests in a round-robin fashion and reading from the first replica, write traffic spreads evenly across all DNs but reads all go to *DN-1*. With write load balancing, MS allocates free entries for new writes from the least accessed DN. Doing so spreads write traffic more towards the lighter-loaded *DN-2* and *DN-3*. With read load balancing, Clover spreads read traffic across different replicas depending on the load of DNs. As a result, the total loads across the three DNs are completely balanced.

7 Conclusion and Discussion

This paper explores a passive disaggregated persistent memory architecture where remote PM data nodes do not need any processing. We present Clover, a low-cost, fast, and scalable pDPM key-value store which separates data and control planes. We compare Clover with two alternative pDPM systems we built, existing distributed PM systems, and disaggregated systems that include processing at data nodes. We performed extensive evaluation of these systems and learned both the benefits and the limitations of them. We end this paper by discussing our overall findings and our suggestions to future systems builders.

Cost Implication. pDPM's CapEx cost saving compared to aDPM is apparent: pDPM reduces the cost of a processor and hardware (server) packaging to host the processor. pDPM's OpEx cost saving mainly comes from avoiding polling at storage nodes. aDPM needs to busy poll network requests to achieve the low latency that can match PM's performance. Meanwhile, to sustain high-bandwidth network (*e.g.*, 100 Gbps and above), aDPM requires many CPU cores or a parallel-hardware unit like FPGA to poll and process requests in parallel, adding to more runtime cost.

Performance Implication. The major tradeoff of removing computation from storage nodes in pDPM is the potential increase in network RTTs to access storage nodes remotely. While it is generally true that moving computation towards data could achieve good performance, our pDPM key-value store systems demonstrate that with careful design, RTTs in pDPM systems could be minimized and in many cases be the same as aDPM systems. In other cases (*e.g.*, key-value put with high-contention), aDPM has unavoidable performance loss because of extra RTTs. On the other hand, not having enough processing power in aDPM (*e.g.*, when only using ARM-based SoC) could lead to significant performance loss.

Application Implication. Building applications with the pDPM model requires careful design. As we demonstrated with the three different pDPM key-value store systems, different application design choices could directly affect how well pDPM performs and scales. The best design would minimize RTTs while avoiding scalability bottlenecks, as with Clover. This paper focuses on key-value store systems, as they are widely used in many datacenter applications. Other systems such as remote file systems, databases, object stores, and data sharing can also build on the pDPM model. As systems complexity increases, it will be more difficult to optimize pDPM's RTTs with just RDMA read, write, and atomic operation interfaces. We believe that extended RDMA interfaces such as HyperLoop [35] could help in these cases.

Recommendation. This paper explores the extreme of completely removing computation power at storage nodes, which helps set baselines in designing disaggregated PM systems. Going forward, we believe that future disaggregated PM systems would benefit from a hybrid approach. Computation that fundamentally involves multiple data accesses can be moved to storage nodes, while the rest should be kept at compute nodes. Among the former, those that have require high performance can be placed on FPGA or ASIC to avoid high CPU cost, while those that can tolerate degraded performance can be placed at low-power cores.

Acknowledgments

We would like to thank the anonymous reviewers and our shepherd Anirudh Badam for their tremendous feedback and comments, which have substantially improved the content and presentation of this paper.

Abstract

Modern NVMe solid state drives offer significantly higher bandwidth and lower latency than prior storage devices. Current key-value stores struggle to fully utilize the bandwidth of such devices. This paper presents SplinterDB, a new key-value store explicitly designed for NVMe solid-state-drives.

SplinterDB is designed around a novel data structure (the STB$^{\varepsilon}$-tree) that exposes I/O and CPU concurrency and reduces write amplification without sacrificing query performance. STB$^{\varepsilon}$-tree combines ideas from log-structured merge trees and B$^{\varepsilon}$-trees to reduce write amplification and CPU costs of compaction. The SplinterDB memtable and cache are designed to be highly concurrent and to reduce cache misses.

We evaluate SplinterDB on a number of micro- and macro-benchmarks, and show that SplinterDB outperforms RocksDB, a state-of-the-art key-value store, by a factor of 6–10× on insertions and 2–2.6× on point queries, while matching RocksDB on small range queries. Furthermore, SplinterDB reduces write amplification by 2× compared to RocksDB.

1 Introduction

Key-value stores form an integral part of system infrastructure. Google's LevelDB [22] and Facebook's RocksDB [8] are widely used, both within their companies and outside. Their importance has spurred research into several aspects of key-value store design, such as increasing write throughput, reducing write amplification, and increasing concurrency [1–3,6,8–17,19,21,22,26,30–32,34,35,37,39,42,43,45–47,50–52].

Existing key-value stores face new challenges with the increasing use of high-performance NVMe solid state drives (SSDs). NVMe SSDs offer high throughput (500K-600K IOPS) and low latency (10-20 microseconds).

LevelDB and RocksDB struggle to utilize all the available bandwidth in modern SSDs. For example, we find that for the challenging but common case of small key-value pairs, RocksDB is able to use only 30% of the bandwidth supplied by an Optane-based Intel 905p NVMe SSD (even when using 20 or more cores).

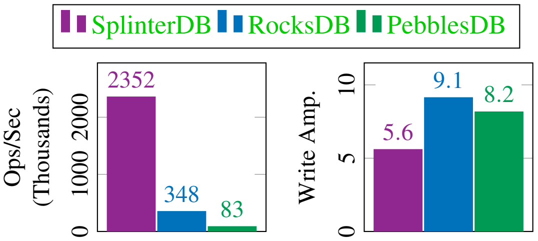

Figure 1: YCSB load throughput and write amplification benchmark results with 24-byte keys and 100-byte values.

We find that the bottleneck has shifted from the storage device to the CPU: reading data multiple times during compaction, cache misses, and thread contention cause RocksDB to be CPU-bound when running atop NVMe SSDs. Thus, there is a need to redesign key-value stores to avoid these CPU inefficiencies.

We present SplinterDB, a key-value store designed for high performance on NVMe SSDs. On workloads with small key-value pairs, SplinterDB is able to fully utilize the device bandwidth and achieves almost 2× lower write amplification than RocksDB (see Figure 1). We show that compared to state-of-the-art key-value stores such as RocksDB and PebblesDB, SplinterDB is able to ingest new data 6–28× faster (see Figure 1) while using the same or less memory. For queries, SplinterDB is 1.5-3× faster than RocksDB and PebblesDB.

Three novel ideas contribute to the high performance of SplinterDB: the ***STB$^{\varepsilon}$-tree***, a new compaction policy that exposes more concurrency, and a concurrent memtable and user-level cache that removes scalability bottlenecks. All three components are designed to enable the CPU to drive high IOPS without wasting cycles.

At the heart of SplinterDB is the STB$^{\varepsilon}$-tree, a novel data structure that combines ideas from log-structured merge trees and B$^{\varepsilon}$-trees. The STB$^{\varepsilon}$-tree adapts the idea of size-tiering (also known as fragmentation) from key-value stores such as Cassandra and PebblesDB and applies them to B$^{\varepsilon}$-trees to reduce write amplification by reducing the number of times a data item is re-written during compaction. The STB$^{\varepsilon}$-tree also introduces a new ***flush-then-compact*** policy that increases

compaction concurrency across the entire tree and exploits locality in the insertion workload to accelerate insertions. By enabling fine-grained, localized compactions, STB$^\varepsilon$-trees push ideas from PebblesDB to their logical conclusion.

Concurrency at the data structural level could be wasted if the data structure is accessed through a cache with poor concurrency. We designed a new user-level concurrent cache for SplinterDB that uses fine-grained, distributed reader-writer locks to avoid contention and ping-ponging of cache lines, as well as a direct map to enable lock-free cache operations. All the data read and written by SplinterDB flows through this concurrent cache.

SplinterDB is not without limitations. Like all key-value stores based on size-tiering, SplinterDB sacrifices the performance of small range queries, although less than one might expect. For large range queries, SplinterDB can use the full device bandwidth. Similarly, size-tiering is known to temporarily increase space usage until multiple versions of a single data item are compacted together. Finally, SplinterDB was designed for the most stringent requirements: small key-value pairs and restricted memory. In cases where key-value pairs are large or memory is plentiful, other choices may prove as good as SplinterDB, and we make some of those comparisons below.

In summary, the contributions of SplinterDB are as follows:

- We introduce the STB$^\varepsilon$-tree, which reduces write amplification and enables fine-grained concurrency in compaction operations (sections 2 to 3).
- We design and build a highly-concurrent memtable that is able to drive enough operations to the underlying STB$^\varepsilon$-tree (section 5).
- We combine the STB$^\varepsilon$-tree, memtable, and user-level cache in SplinterDB, a key-value store that can fully utilize NVMe SSD bandwidth. (section 6).

2 High-Level Design of STB$^\varepsilon$-trees

The basic STB$^\varepsilon$-tree design has three high-level goals:

- Handle inserts using bulk I/O, so that inserts are bandwidth-bound.
- Minimize the number of times each key-value pair gets read or written, so as to reduce write amplifiction, I/O amplification (i.e. read and write amplification), and CPU costs of inserts.
- Maintain sufficient indexing information so that, under normal conditions, each query requires at most one I/O.

In section 3 and section 4, we explain how we refine tree operations to support high concurrency.

The STB$^\varepsilon$-tree shares many ideas with LSM trees, B$^\varepsilon$-trees, and external-memory hash tables from the theory literature. See section 7 for details.

2.1 Overall Structure

The STB$^\varepsilon$-tree is a tree-of-trees, as shown in fig. 2. The backbone of the STB$^\varepsilon$-tree is the ***trunk tree*** (or just trunk). Each node of the trunk has pointers to a collection of B-trees, called ***branch trees*** (or just branches). The branches store all of the actual key-value pairs in the dataset. Each branch also has an associated quotient filter, which serves the same purpose as Bloom filters in LSM trees. Trunk nodes have a fanout of up to F (typically 8 to 16), which is also an upper bound on the number of branch trees. Branch trees have a fanout determined by the number of pivot keys that can be packed into a 4KB node.

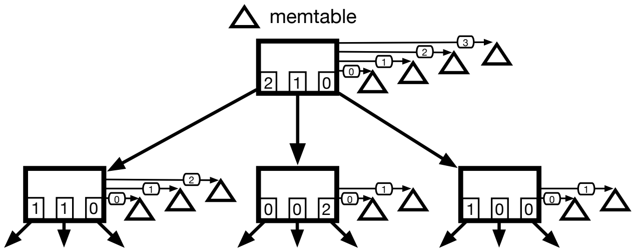

Figure 2: The structure of a STB$^\varepsilon$-tree. The rectangles represent trunk nodes and the triangles represent branch trees and the memtable. The inset boxes indicates the first active branch for each pivot, referencing the pointer labels to the branches.

The overall STB$^\varepsilon$-tree also has a memtable, which is used to buffer insertions, as explained below. The memtable is also a B-tree, just like the branches.

Within a trunk node, the branches are numbered from oldest to youngest, i.e. all the key-value pairs in branch i were inserted before any of the key-value pairs in branch $i+1$. For example, in fig. 2, the root of the trunk tree has four branches, numbered 0 through 3, with branch 0 being the oldest.

Furthermore, stored with each child pointer c in a trunk node is an integer a_c indicating the oldest branch that is ***active*** for that child. Inactive branches are ignored during queries, as explained below. So, for example, in fig. 2, only branches 2 and 3 are active for the root trunk node's leftmost child, branches 1, 2, and 3 are active for its middle child, and all branches (0 through 3) are active for its rightmost child.

2.2 Queries

Queries begin by searching in the memtable. If the queried item is not found in them memtable, then the query proceeds down the trunk tree. Recall that all the data is stored in the branches, and trunk nodes only contain metadata and pointers to branches and filters.

When a query for a key k arrives at a trunk node t, it first searches the pivots of t to determine the correct child c for k. It then iterates over the active branches for c, from youngest to oldest. For each branch b, it first queries b's associated quotient filter. If the quotient filter indicates that k is definitely not in b, then the query moves on to the next branch. Otherwise, is queries for k in b. If it finds a hit, it returns the result to the caller. Otherwise, it moves on to the next branch. If none of the branches contain k, then the query recurses to c.

Analysis. We now explain why queries take at most one I/O in common configurations: those which use at least 32-byte key-value pairs and have RAM which is at least 10% of the dataset size.

The memory used by filters and branch tree indices is bounded as follows. Quotient filters use about 1–2 bytes per key, so the overhead of quotient filters is greatest when key-value pairs are small. With 32-byte key-value pairs, quotient filters will be about 6% of the total database size. Branch trees will have a very high fanout, e.g. ≈ 128 for 4KB nodes, so the interior of the branch trees will be less than 1% of the total database size. Trunk nodes contain only metadata about the branches and filter, and so use negligiable RAM. Therefore all the indexing information will fit comfortably in a RAM that is $\approx 7\%$ of the total database size. For larger keys, e.g. 256 bytes, the branch trees will have a fanout of only about 16, and hence the interior nodes could be up to 6% of the total database size. However, the quotient filters will be less than 1% of the data size, so the indexing data will still be less than 10% of the database size.

Thus the only I/Os during a query will be to load leaves of branch trees. However, the false positive rate of quotient filters with two bytes per key is $< 1\%$, which is low enough to ensure that most queries do not encounter any false positives from the quotient filters that they query. Hence most queries will query exactly one branch tree, which will contain the desired key-value pair. Queries for keys that are not present in the database will usually require no I/Os at all.

2.3 Insertions

When an item is inserted, it is first buffered in the memtable. When the memtable is full, it is added to the root as a new branch, say branch i. We also construct a quotient filter for the memtable at this time. We call the process of adding the memtable to the root of the trunk an ***incorporation***.

The size of the memtable affects performance in the following ways. If the memtable gets too large, then some of its nodes will get evicted from RAM and, once enough nodes spill, a workload of random inserts would require essentially one random I/O per insert, contradicting our goal of handling inserts using bulk I/O. For most systems, this means the memtable should be kept substantially smaller than RAM, e.g. at most a few gigabytes for typical hardware configurations.

On the other hand, the memtable will eventually become a branch, and we want branches to be large enough that scanning a branch can use bulk I/O (i.e. if a branch consisted of only a handful of nodes, then reading the entire branch would be bottlenecked on I/O overheads, rather than bandwidth). Branch scanning performance is critical for compactions and range queries (see Sections 2.4 and 2.6). For most storage devices, it is sufficient to ensure the branches (and hence the memtable) are at least a few megabytes in size.

Thus, for most systems, the memtable can be anywhere from a few megabytes to a few gigabytes in size. Since we are specifically interested in building a system that is robust to low-memory situations, and since making the memtable larger has diminishing returns in terms of scanning throughput, we select a maximum memtable size m that is just comfortably large enough to ensure efficient scanning performance. In our prototype, $m = 24$MB.

2.4 Flushing and Compaction

We cannot keep adding new branches to the root trunk indefinitely. Eventually, the root will fill up and have no more room for branch pointers. This solved by compacting data and flushing it to its children.

This section describes a basic version of flushing and compaction which captures the basic underlying mechanics of a STB$^{\varepsilon}$-tree. In section 3, we describe SplinterDB's more-involved flush-then-compact policy which leverages its B$^{\varepsilon}$-tree structure to expose more compaction concurrency and optimize non-random insertion workloads.

In this simplified version, when a trunk node is full, data is removed from it by repeatedly ***compacting*** some of its branches into a single branch and ***flushing*** the resulting branch to a child until the parent is no longer full (see fig. 3). As in LSM trees, compaction is necessary to keep queries fast. Without compaction, the number of branches that must be queried would grow without bound.

A node p is considered to be full when its branches contain $F \times m$ bytes of active key-value pairs, where F is the fanout and m is the memtable capacity in bytes. When p becomes full, the child c with the most active key-value pairs is chosen and p is flushed into c. We construct a new branch b by compacting all the branches in p that are active for c. Note that the branches in p may contain keys for any of p's children, not just c, so when we compact the branches for a flush to c, we scan over only the portions of each branch that contain keys destined for c. We then add b to c as c's youngest branch. We also build a quotient filter for b and store a pointer to the filter in c. Finally, we mark all the branches in p as inactive for c, so they will not be flushed to c again. Any branches of p that were active only for c are no longer active for any of p's children and can be garbage collected.

Since branches are large, compacting the branches for c can proceed at disk bandwidth. Furthermore, we always flush to the child with the most pending items in the parent. This ensures that the resulting branch b will have at least m items in it, and hence will be efficient to scan when we, at some point in the future, flush it from the child to one of its children.

Analysis. Each time a key-value pair participates in a compaction, it moves one level down the trunk tree. Thus the worst-case write amplification of the STB$^{\varepsilon}$-tree is $O(\log_F N)$, which is the same as in a size-tiered LSM tree. Level-tiered LSM trees and (normal) B$^{\varepsilon}$-trees have a substantially larger write amplification of $O(F \log_F N)$. In Section 3, we describe our flush-then-compact strategy, which enables some key-value pairs to skip compaction at some levels, particularly when the workload exhibits locality.

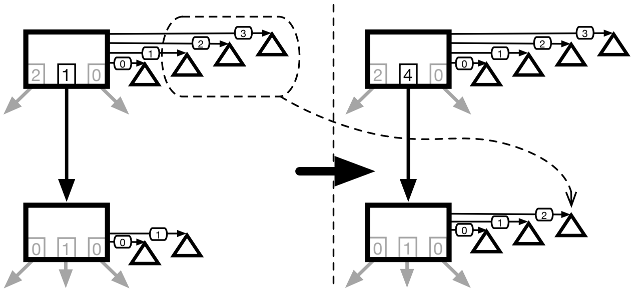

Figure 3: In a STB$^{\varepsilon}$-tree, a flush to a pivot P consists of compacting its active key-value pairs (from its branches) into a new branch in the child. The dashed arrow indicates compaction.

2.5 Splitting

When a trunk leaf is full, it is split, and similarly when a trunk internal node has more than F pivots, it is split. As in standard B-trees and B$^{\varepsilon}$-trees, the I/O costs of splitting and merging do not asymptotically change the costs of inserts. See Section 4 for how we make splitting and merging compatible with hand-over-hand locking in STB$^{\varepsilon}$-trees.

2.6 Iterators and Scans

To construct an iterator starting from key k, we walk the trunk search path for k, constructing B-tree iterators (also starting at k) for each active branch along the path. We then construct a merge iterator on top of the B-tree iterators, which simply returns the smallest key from among all of the underlying B-tree iterators. The merge iterator can be efficiently implemented using a heap.

While constructing the B-tree iterators, we also compute an upper bound u for the leaf of k's search path. As soon as the merge iterator returns a key that is greater or equal to u, we tear down the merge iterator and all the B-tree iterators and rebuild them, starting from u.

2.7 Deletions and Updates

Deletions are implemented through tombstone ***messages***, i.e. a key-value pair with special value indicating that the key has been deleted. More generally, the STB$^{\varepsilon}$-tree supports update messages that encode a function to be applied to the value associated with a key.

3 Flush-then-Compact

This section describes the flush-then-compact algorithm, which improves the I/O and CPU concurrency of compactions during flushing and improves the performance of update workloads with locality, such as sequential workloads. The idea behind flush-than-compact is to decouple the flushing step from the compaction step, as shown in fig. 4.

In a flush, the references to the child's active branches are copied from the parent to the child, along with references to their quotient filters, as shown in fig. 4. The child's active branch counter in the parent is updated to reflect the flush, just as before. At this point the parent and child are in a consistent state and any locks can be released. Since a flush is just a pointer swing, write locks are held very briefly.

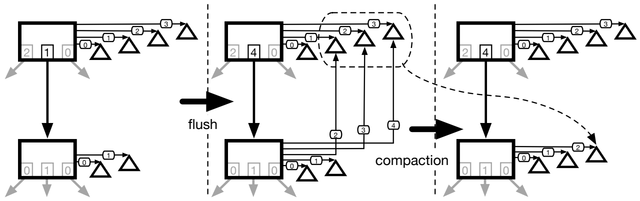

Figure 4: With the flush-then-compact policy, flushes are broken into two steps. First references to the active branches are flushed to the child and removed from the parent (by setting the pivot's active branch number). Then those branches are compacted by an asychronous process. The compaction stage is performed without holding a lock on the node, and during this time it can still flush, be flushed into, split and by queried.

Note that branches can now be referenced by multiple trunk nodes, so branches are reference counted.

From here, if the child is full, we will perform a flush from the child to its children, before initiating any compactions (hence the name "flush-then-compact"). This flush will copy the newly arrived branches from the child to one or more of its children, exactly the same way that the branches were flushed to the child. This process can repeat recursively.

Once all the flushes have completed, we schedule background jobs to compact all the new branches at each node that received a flush. The background jobs will construct the new branches and need to acquire write locks only to replace the old branch pointers with a pointer to the newly created branch.

Flush-then-compact accelerates non-random workloads. Since we perform flushes before compactions, some of the branches involved in a compaction at node p may already be inactive for some of p's children when we perform the compaction. This means we can skip over those keys when we compact those branches. And, since branches are stored as B-trees, we can skip over those key ranges efficiently. Thus we effectively avoid compacting those keys at p's level in the STB$^{\varepsilon}$-tree.

To see why this accelerates non-random insertion workloads, consider an extreme case: a workload of insertions all for a single trunk leaf, ℓ. For simplicity, assume also for the moment that all the nodes on the path from the root to ℓ have zero branches. The memtable will repeatedly fill with key-value pairs for ℓ and get incorporated into the root. Once the root fills, it will flush to its child c along the path to ℓ. This will cause c to immediately become full and flush to its child. This process will repeat until all the branches arrive at ℓ.

At that point, the system will schedule background compactions for each trunk node along the path from the root to ℓ. However, at each node other than ℓ, there will be no live data in any of the branches. The compactions will thus skip all the data in the branches, resulting in empty branches at each interior node. Consequently the interior nodes will again be left with zero branches. Thus only ℓ will have a non-degenerate compaction. As a result, the new key-value pairs will participate in only one compaction, and hence the STB$^\varepsilon$-tree will have a write amplification of 1 for this workload.

Now consider the case when the nodes along the path to ℓ do not have zero branches. The first few times the root fills, it may choose to flush to some child c' that is not along the path to ℓ. This would happen if the root happened to contain more items for c' than c. However, as long as the workload consists only of items for ℓ, eventually the root will contain more items for c than for any of its other children. From that point forward, it will always flush to c. Then the same process will repeat at c. Eventually, each time the root fills, the system will flush all the new branches to ℓ, as described above.

Thus this flushing protocol automatically adapts to the insertion workload without knowing a priori what that workload is. Furthermore, if the workload changes then, after some time, the flushing decisions will adapt to the new workload automatically.

Furthermore, this flushing algorithm exploits less-than-perfect locality automatically. For example, suppose the insertion workload consists almost entirely of key-value pairs for ℓ, but a few random items for other leaves. Almost every time the root fills, it will flush to c, and the process described above will occur. However, each flush will leave a few new items in the root. This cruft will accumulate, eventually causing the root to flush to a child other than c, cleaning out some cruft. After that, the root will resume flushing to c until enough cruft accumulates again. Thus most data will get flushed directly to ℓ, and hence have a write amplification of 1, but a small amount of data will get compacted at every level.

As these examples show, the flush-then-compact algorithm is much more robust than the special-case optimizations frequently implemented for sequential insertions. Special-case optimizations can be foiled by a few random insertions sprinkled into a sequential workload. Flush-then-compact, on the other hand, exploits *locality* rather than *sequentiality*. In section 6.3 we show empirically that flush-then-compact enables SplinterDB to outperform other systems on near-sequential workloads.

Flush-then-compact exposes concurrency. Flush-then-compact improves concurrency by setting up several compactions and then launching them simultaneously, which improves both CPU and I/O parallelism. The hierarchical nature of the B$^\varepsilon$-tree structure makes it trivially safe to perform compactions concurrently at different trunk nodes. In a standard compact-then-flush approach, each time the root is flushed, it initiates a single compaction. The system would not start another compaction until the root is filled (and flushed) again.

4 Preemptive Splitting for STB$^\varepsilon$-trees

Splits and merges pose problems for hand-over-hand locking in B-trees (and B$^\varepsilon$-trees). Hand-over-hand locking proceeds from root to leaf, but splits and merges proceed from the leaves up.

An approach to solving this issue in B-trees is to use preemptive splitting and merging [40]. During a B-tree insert, if a child already has the maximum number of children, then it is split while the insertion thread still holds a lock on its parent. Then the insertion can release the parent's lock and proceed down the tree, assured that the child will not need to split again as part of this insertion. Analogously, deletions merge a child with one of its neighbors if the child has the minimum number of children. This works because insertion and deletions can increase or decrease the number of children of a node by at most 1.

This approach does not work in B$^\varepsilon$-trees, because a flush to a leaf could cause that leaf to split multiple times. In STB$^\varepsilon$-trees with flush-then-compact, we can move all pending messages along a root-to-leaf path to the leaf before performing any compactions, splits, or merges. The total number of messages moved to the leaf is bounded by $O(Fm\log_F N)$, i.e. the capacity of a trunk node times the height of the tree. The leaf can therefore split into as many as $O(\log_F N)$ new leaves of size B. Similarly, a collection of flushes full of delete messages to several leaves of a single parent can reduce the parent's number of children by $O(\log_F N)$. In practice, $\log_F N$ is less than 10 for typical fanouts $F \approx 8$ and dataset size $N \leq 2^{80}$ key-value pairs.

We extend preemptive splitting and merging to STB$^\varepsilon$-trees as follows. We reserve space in each node to accommodate up to $F+H$ children, where H is an upper bound on the tree height, e.g. $H = 10$. We then apply preemptive splitting, except we preemptively split a node during a flush if its fanout is above F. For merges, we take a similar approach. If, during a flush, we encounter a node with less than $F/2$ children, then we merge or rebalance it with one of its siblings.

Thus all operations on the STB$^\varepsilon$-tree—flushes, compactions, splits, and merges—proceed from root to leaf and can therefore use hand-over-hand locking.

The mechanisms for flush-then-compact make it easy to handle branches during splits. Recall that each branch can be marked dead or alive for each child, and branches are refcounted and hence can be shared by multiple trunk nodes. Thus we can split a trunk node by simply giving its new sibling references to all the same branches as the node had before the split. In the new node, we copy the liveness information for each branch along with the children that are moved to the new sibling.

5 From STB$^\varepsilon$-trees to SplinterDB

In this section, we discuss the details of SplinterDB's implementation, which addresses the concurrency and memory bottlenecks associated with driving NVMe devices to full bandwidth.

5.1 Branch Trees and Memtables

SplinterDB uses the same B-tree implementation for both its branches and its memtables, although there are some differences to optimize for their use cases.

Branch trees, extents, and pre-fetching. When a branch is created from a compaction, its key-value pairs are packed into the leaves of the B-tree, and the leading edge of internal nodes are created to index them. The nodes in each level are allocated in extents of 32 pages, and the header of each node stores the address of the following node, but also of the next extent. In this way, the nodes of each level form a singly linked list.

Iteration through a branch is performed by walking the linked list formed by its leaves. Whenever the iterator reaches the beginning of a new extent, it issues an asynchronus prefetch request for the next extent. The extent length is configurable to tune to the latency of the storage device.

Memtables. The basic design of the memtables mirrors that of the branch B-trees, but includes some optimizations to increase their insertion performance and concurrency.

As in the case of the static branch trees, the nodes on each level of the memtable form a singly-linked list, and nodes are allocated in extents. However, because nodes are created on demand as nodes split, we do not try to guarantee that successive nodes reside in the same extent. Furthermore, since memtables are almost always in RAM, we do not perform prefetching during memtable traversals.

The memtable uses hand-over-hand locking together with preemptive splitting, as described by Rodeh [40]. To increase concurrency, write locks are only obtained on internal nodes when a split is required.

To ensure locks are held briefly, especially on nodes near the top of the tree, the tree uses a new technique called ***shadow splitting***. To split a node c, a write lock is obtained on c and the parent p. We allocate a physical block number (PBN) n for the new sibling, c' and add it as part of a new pivot in p. However, in the cache, we initially point n to c. At this point, we can release all locks on p. Now, we fill in the contents of c', update the PBN n to point to c' in the cache, and then release all locks on c'. Finally, we upgrade to a write lock on c, truncate its child list (via a metadata operation) and then release all locks on c.

5.2 User-level Cache and Distributed Locks

SplinterDB has a single user-level cache which keeps recently accessed pages in memory. Almost all the memory that SplinterDB uses comes from this cache, so pages from all parts of the data structure—trunk node pages, branch pages, filter pages and memtable pages—are all stored there. Only cache and file-system metadata, as well as small allocations used to enqueue compaction tasks are allocated from system memory.

This design allows nearly all the free memory to be used for whichever operations are being performed, so that parts of the data structure which are not in use can be paged out.

The cache at a high level is a clock cache, but with several features designed to improve concurrency.

Each thread has a thread-local hand of the clock, which covers 64 pages. The thread draws free pages from the hand, and if it has exhausted them, it acquires a new hand from a global variable using a compare-and-swap. It then writes out dirty pages from the hand which is a quarter turn ahead, and evicts any evictable pages in its new hand. Thus threads clean and evict pages from distinct cache lines within the cache metadata, avoiding contention and cache-line ping-ponging.

SplinterDB uses distributed reader-writer locks [24] to avoid cache-line thrashing between readers. Briefly, a distributed reader-writer lock consists of a per-thread reader counter and a shared write bit. Each reader counter is on a separate cache line to avoid cache-line ping-ponging when readers acquire the lock. Writers set the write bit (using compare and swap) and then wait for all the read counters to become zero. Readers acquire the lock by incrementing their read counter and then checking that the writer bit is 0. If it is not, they decrement their reader counter and restart.

Distributed reader-writer locks allow readers to scale essentially perfectly linearly, at the cost that acquiring a write lock is expensive. However, the design of SplinterDB makes writing rare enough that this is a good trade-off.

We make distributed reader-writer locks space efficent by storing each thread's reader counters in an array indexed by cache-entry index. Each reader counter is one byte, so the total space used by locks is $t \times c$ bytes, where t is the number of threads and c is the number of cache entries.

SplinterDB supports three levels of lock: read locks, "claims", and write locks. A claim is a read lock that can be upgraded to a write lock. Only one thread can hold a claim at a time. After obtaining a read lock, a thread may try to obtain a claim by trying to set a shared claim bit with a test-and-set. If this fails, they must drop the read lock and start over. Otherwise, they can upgrade their claim to a write lock by setting a shared write bit and waiting for all the read counters to go to zero.

5.3 Quotient filters

Bloom filters [7] are the standard filter for most LSMs [8, 22, 39]. However, the cost of Bloom filter insertions can dominate the cost of sorting the data in a compaction. Therefore modern key-value stores often use more efficient filters; for example, RocksDB uses blocked Bloom filters [38];

Similarly, SplinterDB uses quotient filters [4, 5, 36] instead of Bloom filters. A full presentation of quotient filters is out of scope for this paper, but we review their salient features for SplinterDB. See Pandey, et al. for a full presentation on quotient filters [36]. The key feature of quotient filters is that, like blocked Bloom filters, each insert or query accesses $O(1)$ cache lines (and hence $O(1)$ page accesses). Quotient filters are roughly as space efficient as Bloom filters—for the range of parameters used in SplinterDB, quotient filters use between 0.8× and 1.2× the space of a blocked Bloom filter. We view the space as essentially a wash. Quotient filter inserts and lookups also require only one hash function computation. In past work, quotient filter insertions and queries were shown to be 2-4× faster than in a Bloom filter.

A quotient filter for set S stores, without error, $h(S) = \{h(x) \mid x \in S\}$, where h is a hash function. Since the quotient filter stores $h(S)$ exactly, all false positives are the result of collisions under h. Thus each insertion or lookup requires only one hash function computation. Furthermore, a quotient filter stores the elements of $h(S)$ in sorted order in a hash table using a variant of linear probing. Thus most inserts and lookups in a quotient filter access only 1 or 2 adjacent cache lines. As a result, insertions and lookups in quotient filters are typically 2-4× faster than in a Bloom filter. Finally, quotient filters are space efficient, using slightly less space than Bloom filters whenever the false positive rate ε is less than $1/64$, which is typical. For example, a quotient filter with $\varepsilon = 0.1\%$ uses about 10% less space than a Bloom filter [36].

SplinterDB further reduces the CPU costs of filter building during compaction by using a bulk build algorithm. During the merging phase of compaction or when inserting into a memtable, SplinterDB builds an unsorted array of all the hashes of all the tuples compacted or inserted. The array is then sorted (by hash value) and the quotient filter is built. Since the quotient filter also stores the hashes in sorted order, this means that the process of inserting all the hashes is a linear scan of the sorted array and of the quotient filter. Hence it has good locality and can benefit from cache prefetching.

5.4 Logging and Recovery

SplinterDB uses per-thread write-ahead logical logging for recovery. By using per-thread logs, we avoid contention on the head of a single, shared log.

The challenge is to resolve the order of operations across logs after a crash. For this, we use a technique similar to "cross-referenced logs" [25]. Our scheme works as follows. Each leaf of the memtable has a generation number. Whenever a thread inserts a new message into the memtable, it records and increments the generation number of the memtable leaf for the inserted key. It then appends the inserted message to its per-thread log, tagged with the leaf's generation number. During recovery, the generation numbers in the logs give a total order on the operations performed on each leaf (and hence on all the keys for that leaf), so that the recovery procedure can replay the operations on each key in the proper order. When a leaf of the memtable splits, the new leaf gets the same generation number as the old leaf.

6 Evaluation

We evaluate the performance of SplinterDB on several microbenchmarks and on the standard YCSB application benchmark [20]. We compare this performance against that of two state-of-the-art key-value stores, RocksDB and PebblesDB. The following questions drive our evaluation:

- How much does SplinterDB improve insertion performance? To what extent is improvement achieved through reduced write amplification and other factors?
- Despite being size-tired, how much does SplinterDB mitigate [range] query performance? Can SplinterDB utilize device bandwidth for large range queries?
- How much faster are sequential (or otherwise local) insertions in SplinterDB? Do they have lower write amplification?
- Do point lookups scale with the number of threads?

6.1 Setup and Workloads

All results are collected on a Dell PowerEdge R720 with a 32-core 2.00 GHz Intel Xeon CPU, 256 GiB RAM and a 960GiB Intel Optane 905p PCI Express 3.0 NVMe device. The block size used was 4096 bytes.

In general, we use workloads derived from YCSB traces with 24B keys. We generally use 100B values, but also include a set of YCSB benchmarks for 1KiB values. We instrumented dry runs of YCSB in order to collect workload traces for the load and A–F YCSB workloads and replay them on each of the databases evaluated. In order to eliminate the overhead of reading from a trace file during the experiment, the trace replayer `mmaps` the trace file before starting the experiment. We use the same traces for each system.

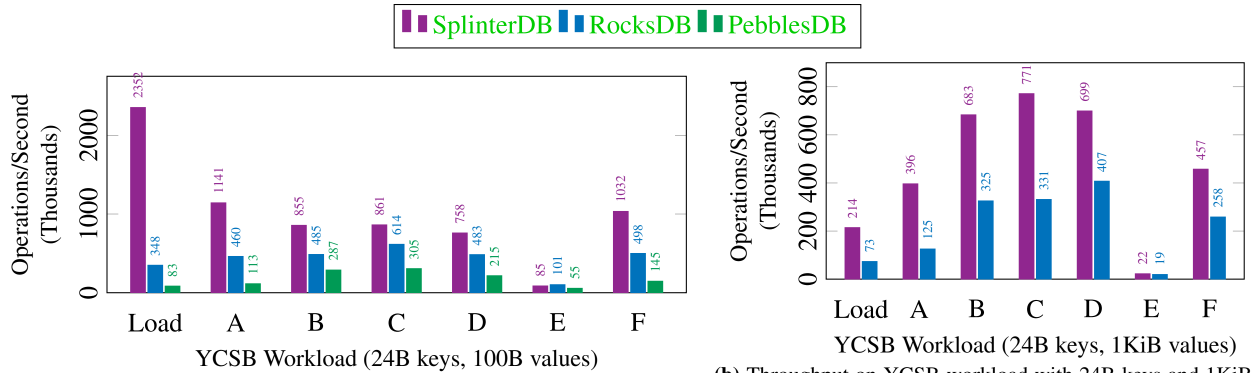
In general, we limit the available memory to 10% of the dataset size or less. In order to perform the benchmarks on reasonably sized datasets, we restrict the available system memory with a type 1 Linux `cgroup`, sized to the target memory size plus the size of the trace, which we pin so that it cannot be swapped out. Unless otherwise noted, the target memory size is 4GiB. PebblesDB has an apparent memory leak, which causes it to consume the available memory, so we allow it to use the full system memory. On the YCSB load benchmarks, this causes it to swap for a small portion at the end, but this was less than 10% of the run time.

Unless otherwise noted, SplinterDB uses a max fanout of 8, a memtable size of 24MiB and a total cache size of 3.25GiB. The difference between this cache size and the target memory size of 4GiB is to accommodate other in-memory data structures maintained by SplinterDB.

Each system is run with the thread count which yields the highest throughput. RocksDB is configured to use background threads equal to the number of cores minus the number of foreground threads, with a minimum of 4. PebblesDB uses its default number of background compaction threads. SplinterDB is configured without background compaction threads.

6.2 YCSB

We measure application performance using the Yahoo Cloud Services Benchmark (YCSB). The core YCSB workloads consist of load phases and run phases. The load phases create a dataset by inserting uniformly random key-value pairs. The run phases emulate various workload mixes. Workload A is 50% updates, 50% reads, workload B is 95% reads, 5% updates), workload C is 100% reads, workload D is read latest (95% reads, 5% insertions), workload E is short range scans (95% scans, 5% insertions) and workload F is read-modify-writes (50% reads, 50% RMWs).



(a) Throughput on YCSB workloads with 24B keys and 100B values. Load is 673M operations, E is 20M operations and others are 160M operations. Higher is better.

(b) Throughput on YCSB workload with 24B keys and 1KiB values. Load is 84M operations, E is 1.3M operations and others are 10M operations. Higher is better.

Figure 5: YCSB throughput and I/O benchmark results.

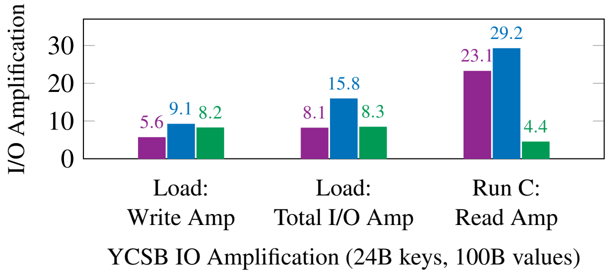


Figure 6: IO amplification on YCSB load and Run C workloads, as measured with iostat. Lower is better.

system	mean	median	P95	P99
SplinterDB	7.0	3.1	12.4	27.7
RocksDB	40.2	29.7	50.5	86.7

Table 1: Insertion latency (μs) for the workload in fig. 5a.

system	mean	median	P95	P99
SplinterDB	46.4	13.3	126.3	216.1
RocksDB	51.1	28.8	108	221.1

Table 2: Read latency (μs) for the workload in fig. 5a.

The results with 100B values and 1KiB values are shown in Figure 5 (both workloads use 24B keys). Figure 6 shows the write and I/O amplification in the 100B-value benchmark.

On the load phase, SplinterDB is faster than RocksDB by almost an order of magnitude. Because of size-tiering and its compaction/flushing policy SplinterDB has about 1/2 the write amplification of the other systems. Note PebblesDB performs almost no reads because it was given unlimited memory. Surprisingly PebblesDB does not show substantially lower write amplification than RocksDB.

On the run phases, which the exception of E, SplinterDB is 40–150% faster than RocksDB, the next fastest system. On E, SplinterDB is roughly 15% slower than RocksDB in the 100B-value case, and about 15% faster than RocksDB in the 1KiB-value benchmark.

Latency. SplinterDB maintains high throughput without sacrificing latency. Table 1 reports insertion latency for SplinterDB and RocksDB. Unsurprisingly, the latency of RocksDB is at least 3x that of SplinterDB on all metrics. This is because mechanisms such as flush-and-compact (Section 3) improve concurrency and eliminate stalls on the write path.

Table 2 reports read latency for SplinterDB and RocksDB. SplinterDB read latency is comparable to RocksDB, because the quotient filters (section 5.3) in SplinterDB behave similarly to Bloom filters in RocksDB.

KVell. KVell [33] is a key-value store also designed to utilize full NVMe bandwidth. It has an in-memory B-tree index that maps all keys to disk page offsets. It does well on large (4KiB) key-value pairs, but on small key-value pairs, the overhead of the in-memory index becomes a significant fraction of the dataset size. In particular, it was impossible to run KVell in a memory `cgroup` of 4GiB. Figure 7 shows KVell's performance on the YCSB workload with 100B values, for different memory sizes. At 22GiB, which is around the size of the in-memory index, KVell's performance starts to drop. At 20GiB, KVell becomes unusable. Therefore in realistic memory settings, KVell is not a viable option for the small key-value sizes that SplinterDB targets.

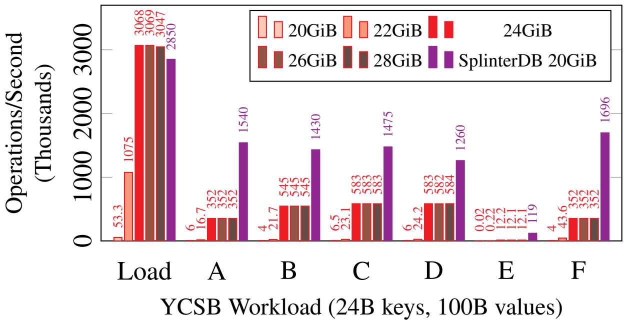

Figure 7: Throughput of Kvell on YCSB workloads with varying amounts of available RAM, 100B values. Throughput of SplinterDB with 20GiB RAM shown for comparison. Load consists of 673M operations, E consists of 20M operations and all other workloads consist of 160M operations. Higher is better.

SplinterDB is designed to work well even under low-memory scenarios (less than 10% of total data size). However, we also run the YCSB experiment with higher memory, 20 GiB, to compare with KVell in a regime where KVell per-

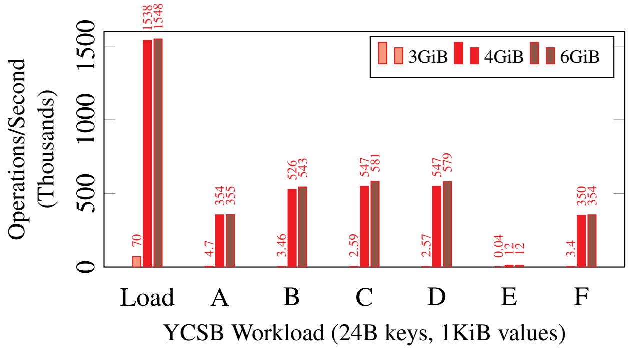

Figure 8: Throughput of Kvell on YCSB workloads with varying amounts of available RAM, 1 KiB values. Load consists of 84M operations, E consists of 1M operations and all other workloads consist of 10M operations. Higher is better.

forms well. As shown in fig. 7, we find that SplinterDB almost matches KVell on insertions, but outperforms KVell by roughly a factor of 2.5 on queries.

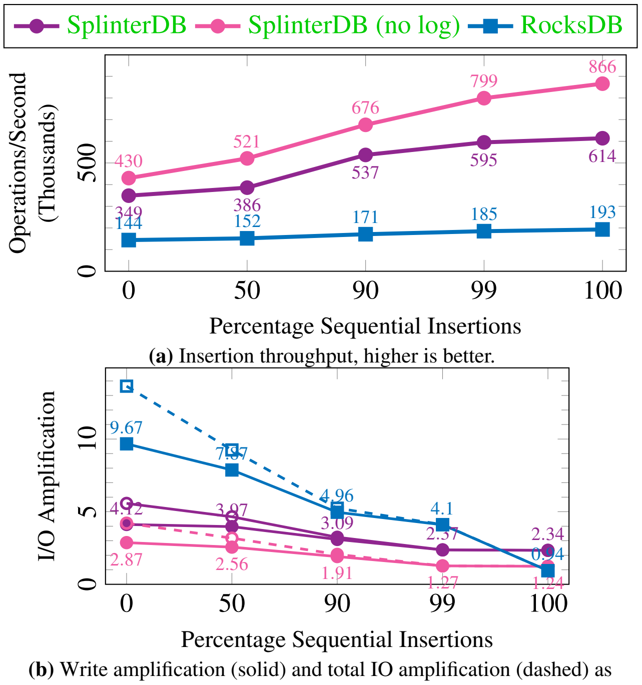
For larger values, the memory cliff for KVell is much lower. We run the same YCSB workload on both systems, but with 1KiB values. In this case, KVell's memory cliff is between 3GiB and 4GiB, as shown in fig. 8. For these larger values, KVell outperforms SplinterDB insertions (see Figure 5b) due to a low write amplification, but still can only achieve 55-77% query throughput of SplinterDB on the other YCSB workloads. KVell's range-query performance (workload E) is particularly lower than SplinterDB's because KVell does not keep key-value pairs sorted. Thus each 1KiB key-value pair in the range requires a separate, random 4KiB I/O, resulting in a read amplification of about 4×. Splinter, on the other hand, sorts and packs key-value pairs into 4KB blocks, for a read amplification close to 1 during range queries.

As soon as the memory cliff hits, KVell exhibits the same performance drop as in the previous experiment. However, when values are so large, this may not be so important, since indexing information can easily fit in RAM.

6.3 Sequential Insertion Performance

Because of the flush-then-compact policy, we expect SplinterDB's performance will improve substantially on insertion workloads with a high degree of locality (see section 3). We demonstrate this by performing 20GiB of single-threaded insertions from a trace composed of interleaved sequential and random keys in different proportions. For comparison, we perform the same workload on RocksDB.

As shown in fig. 9a, SplinterDB's performance improves smoothly from 349K insertions per second for a purely random workload to 614K insertions per second for a purely sequential workload, which is 76% faster. This improvement is partially obscured by the log, which adds a constant additive IO overhead. If we disable the log, SplinterDB improves from 430K insertions per second on a purely random workload to 866K operations per second on a purely sequential workload, 100% faster. Note that we would expect the intermediate



(a) Insertion throughput, higher is better.

(b) Write amplification (solid) and total IO amplification (dashed) as measured with `iostat`. Lower is better.

Figure 9: Single-threaded insertion throughput by varying mixed sequential/random locality percentage. X-axis not to scale.

throughputs in the best case to be the [weighted] harmonic mean of the pure cases, because they are rates. At 50% random, 50% sequential for SplinterDB with no log this is 575K insertions/second, so its actual performance of 521K insertions/second captures a substantial amount of the potential improvement.

RocksDB also improves as the workload becomes more sequential, but this effect is much smaller, a 35% speedup. Furthermore, RocksDB shows less than 20% speedup until the workloads becomes 99% sequential.

Figure 9b shows that as predicted, SplinterDB incurs less IO amplification on more sequential workloads. With the log disabled, its write amp approaches 1 as the workload approaches purely sequential. In contrast, while RocksDB also has less IO amplification on more sequential workloads, it still incurs write amplification of 4.1 even when 99% of the keys are sequential. It is only when the workload becomes 100% sequential that the write amplification becomes close to 1 (because of caching it even falls below 1).

6.4 Concurrency Scaling

SplinterDB is designed to scale with the number of available cores up to the performance limits of the storage device. This is especially true for reads, where the use of distributed reader-writer locks and a highly concurrent cache design, together with a careful avoidance of dirtying cache lines, can avoid almost all contention between threads.

Read Concurrency. We test the read concurrency scaling of SplinterDB by running YCSB workload C with 160M key-value pairs, where, as in fig. 5a each instance of the test divides

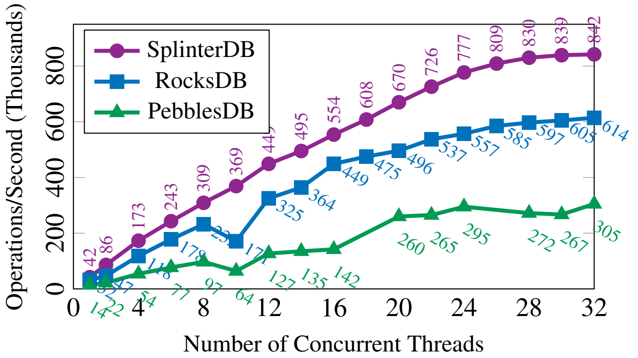


Figure 10: Read concurrency: read throughput (YCSB workload C) by number of threads. Each instance performs 160M reads divided evenly between threads. Higher is better.

the keys evenly into *N* batches, which are then performed in parallel by *N* threads. The results are in fig. 10.

The results show nearly linear scaling—throughput with 24 threads is 18.5× the single-threaded throughput. Between roughly 24 and 32 threads, the scaling flattens out, but at that point the measured throughput is 2.07–2.24 GiB/sec, which is 88–95% of the device's advertised random read capability.

While RocksDB also scales well, its throughput with 24 threads is 17.4× its single-threaded throughput, and with 32 threads it uses 91% of the device's advertized random read capability. Therefore, even though SplinterDB can perform more operations per second, RocksDB is still making nearly full use of the device for reads. We conclude here that SplinterDB is making better use of the available memory for caching, since it has noticeably lower read amplification. Finally, PebblesDB is unable to scale with more threads, flattening out at around 300K reads/sec.

Insertion Concurrency We test the insertion concurrency scaling of SplinterDB by running the YCSB load workload with 673M key-value pairs divided into *N* batches, each of which is inserted in parallel by a different thread. fig. 11 reports throughput for various *N*.

The results show that SplinterDB scales almost linearly up to 10 threads. With 10+ threads, it performs 2.0-2.4M insertions per second with IO amplification around 7.5, which implies that it uses 1.9-2.2GiB/sec of bandwidth, which is at or near the device's sequential bandwidth of 2.2GiB/sec.

RocksDB's insertion performance also scales as the number of threads increase up to 14 threads, by a factor of 2.7. At its peak, it uses 754GiB/sec of bandwidth. PebblesDB scales slightly as well. For both RocksDB and PebblesDB, as many background threads as available are used for flushing and compaction during this benchmark.

6.5 Scan Performance

An inherent disadvantage of size-tiering is that short scans must search every branch along the root-to-leaf path to the starting key. Each of these searches is likely to incur an IO to the device. As a result, as seen in fig. 5a, SplinterDB with 124B key-value pairs has scan throughput on small ranges that is about 85% that of RocksDB. During that workload, SplinterDB performed 2.26 GiB/sec of IO, which is within 96% of the devices advertised random read capability (short scans of small key-value pairs are essentially random reads).

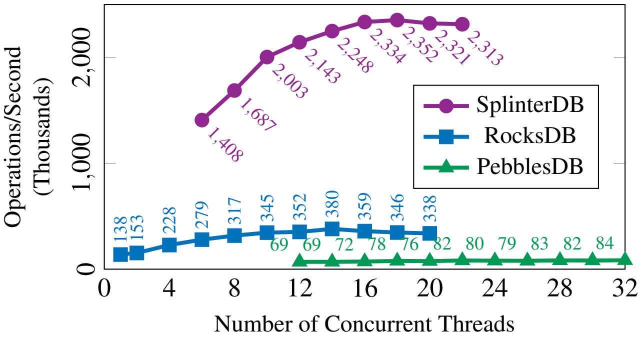

Figure 11: Insertion concurrency: insert throughput (YCSB Load) by number of threads. Each instance performs 673M writes divided evenly between threads. Higher is better.

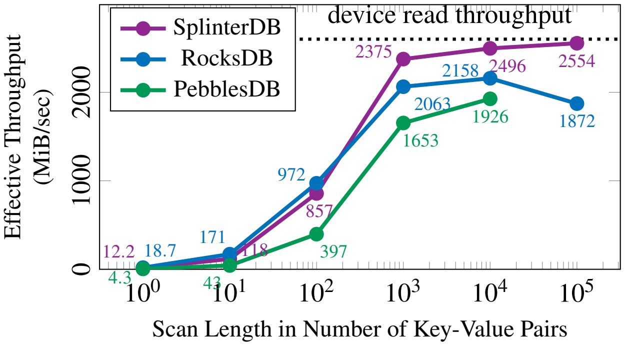

Figure 12: Scan throughput in MiB/sec as a function of scan length. For small scans, the start up cost dominates, but as the scans get longer, the throughput approaches the device's advertised bandwidth (2.6GiB/sec). The x-axis is on a log scale. Higher is better.

However, once the initial search for the successor to the starting key has completed, the root-to-leaf path within each relevant branch will be in memory. Together with prefetching, this allows subsequent keys to be fetched at near disk bandwidth. Therefore, we expect that scans have a relatively high startup cost for the search to the starting key, followed by a very low iteration cost of obtaining subsequent keys.

Thus, when the amount of data requested grows to multiple pages, the disadvantage begins to dissipate. One way this happens is with larger key-value pairs: with 1kib values, SplinterDB is about 16% faster than RocksDB.

Another way this can happen is with scans of more key-value pairs. We modify YCSB workload E to have only fixed-length scans of *N* key-value pairs, where *N* is 1, 10, 100, 1K, 10K or 100K. We perform runs of 10M scans of length 1, 10 and 100, 1M scans of length 1000, 100K scans of length 10000 and 10K scans of length 100000. Each run is performed on a dataset of 80GiB (with 24B keys and 100B values) and 4GiB memory.

The result is shown in fig. 12. Short scans on SplinterDB have low effective bandwidth, and in fact the bandwidth scales close to linearly with the scan length for scans of up to 100 key-value pairs. This suggests that for scans of this length, the startup cost dominates the iteration cost, which is as expected. As the scan length increases, the effective bandwidth of the scans approaches the device's advertised sequential read bandwidth, delivering 91% at scans of 1,000 key-value pairs. At scans as small as 100 key-value pairs, SplinterDB returns data at nearly half the bandwidth of the device.

7 Related Work

The STB$^\varepsilon$-tree is based on a B$^\varepsilon$-tree, a data structure that has been used in several file systems and databases [18, 27–29, 44, 48, 49]. The closest work to ours is Tucana [37], a B$^\varepsilon$-tree optimized for SSDs. They also focus on CPU cost, concurrency, and write amplification. Our work pushes this to the even more demanding case of NVMe devices. SplinterDB improves on techniques that have been applied to log-structured merge (LSM) trees and key-value stores to reduce write amplification and increase concurrency.

Size-Tiering. Cassandra [19], Scylla [42] PebblesDB [39], and RocksDB [8] (in "universal compaction" mode) use size-tiering to reduce write amplification. Size tiering delays compaction of sorted runs in order to reduce write amplification. This can harm query performance because queries must search more runs to find the queried item. Fluid LSMs [16], Dostoevsky [16], LSM bushes [17], and Wacky [17] use hybrids between size-tiering and level-tiering to tune the trade-off between write amplification and query performance. See [39] for a survey of LSM-compaction schemes.

Size-tiering also decreases write amplification in SplinterDB. Because of the design of the STB$^\varepsilon$-tree, SplinterDB further leverages size-tiering for flush-and-compact, which greatly increases the concurrency of background operations.

Write amplification vs. range queries. Several systems sacrifice range-query performance in order to reduce write amplification in other ways. Wisckey [34] reduces write amplification by declustering their key-value store: they log values and only store keys in the LSM-Tree. Since values are stored on disk in arrival order, a range query must gather values from the log. On NVMe, this is not a problem once the values are 4KB or larger. However, for smaller values, this can induce huge read amplification, limiting range query performance to a tiny fraction of device bandwidth. HashKV [10] builds on Wisckey by introducing hash-based data-grouping to further reduce write amplification, but inherits Wisckey's range query performance limitations.

Other approaches improve write amplification by sacrificing range queries altogether. Conway et al. [14] describe a write-optimized hash table, called the BOA, that also uses size-tiering with an LSM. They also introduce the concept of a routing filter, which extends the functionality of Bloom filters, in order to speed up queries. The principle advantage of routing filters is that performance does not degrade as much when they don't fit in RAM. The BOA meets a provable lower bound on the I/O costs of insertions and queries [26]. The downside is that the BOA does not support range queries, which are crucial to many key-value-store applications. LSM-tries [46] organize the LSM tree using tries, resulting in reduced write amplification. However, LSM-tries do not support range queries.

Other approaches. Researchers have also attempted to reduce write amplification by exploiting special hardware features such as flash translation layers [35] and vector interfaces [45]. VT-Tree [43] uses indirection to avoid copying data that is already sorted, similar to "trivial moves" in RocksDB and PebblesDB. TRIAD [1] reduces write amplification by holding hot keys in memory, delaying compaction until different runs have significant key overlap, and by reducing redundancy between log and LSM tree writes. All these techniques are orthogonal to our work and can be used in conjunction with our techniques.

Concurrency is also an important aspect of key-value store performance. One of the first works in increasing concurrency in LSM-based stores was cLSM [21] which introduces a new compaction algorithm. Zuo et al. [52] show how to tune a cuckoo hash for NVM. Such a scheme suffers from high write amplification, since each insertion must re-write all keys in a data block. Zuo et al. do not report write amplification numbers but instead focus on concurrency.

Kourtis, et al. describe several systems-level optimizations for improving key-value-store throughput on NVMe, such as efficient use of user-level asynchronous I/O and low-latency scheduling [31]. Their techniques are largely orthogonal to the work in this paper.

8 Analysis

We begin with a disk-space analysis, showing that, in STB$^\varepsilon$-tree, size-tiered compaction and flush-then-compact do not blow up the on-disk space usage by more than a constant factor. We then use this to analyze memory usage from indexes and filters, and finally summarize STB$^\varepsilon$-tree's asymptotic performance.

Disk-space. Like level-tiered and size-tiered LSM trees and B$^\varepsilon$-trees, the STB$^\varepsilon$-tree can have a space overhead when there are updates to existing keys. This is because all of these data structures buffer updates and apply them lazily. We begin by showing that the space used by the STB$^\varepsilon$-tree is $O(N)$, where N is the number of distinct keys in the database. This compares quite favorably to the space of a size-tiered LSM, which can be as bad as $\Theta(FN)$.

Theorem 1. *Let N be the number of distinct keys in a STB$^\varepsilon$-tree. Then the STB$^\varepsilon$-tree uses $O(N)$ space on disk.*

Proof. We give only a sketch. The four key observations in the proof are that (1) every leaf must be at least half full of distinct keys due to the splitting and compaction policy, (2) each branch has size at most mF due to the flushing policy, (3) each non-leaf trunk node references at most $3F$ branches due to the flushing policy, and (4) the number of non-leaf trunk nodes is at most $O(1/F)$ times the number of leaves. Together, these prove that the total amount of data referenced in the interior of the tree is at most a constant factor times the number of distinct keys in the leaves.

□

For a workload of random updates to existing keys, we estimate that the space blowup would be roughly a factor of 3. If the workload also contains insertions of new keys, then the blowup would be even lower.

Asymptotic analysis. The height of the trunk is $O(\log_F N/Fm)$, and each item gets compacted at most once per level, so the I/O complexity of random insertions are $O(\frac{\log_F N/Fm}{B})$, which is the same as in a size-tiered LSM tree.

Assuming that all index nodes and filters fit in RAM, the I/O complexity of random point queries is $O(1)$ I/Os, since the filters will eliminate all but the correct branch from being searched.

Long sequential insertion workloads will cost $O(1/B)$ I/Os per item. The I/O efficiency comes from the fact that, once the first batch of items gets flushed to a leaf, the root-to-leaf path for future insertions will be in cache, so no more I/O will be needed, except to write out the new data. This also workload has $O(1)$ pass complexity because our flush-then-compact policy will skip compactions at intermediate layers. A straightforward implementation of a size-tiered LSM, on the other hand, will have the same I/O and pass complexity for both random and sequential insertion workloads.

Range queries returning k items cost $O(F \log_F N/Fm)$ I/Os to get started (since the range query must perform a query in every branch along the root-to-leaf path of the query key). Thereafter, they cost $O(k/B)$ I/Os to return all the items. This is comparable to the I/O cost of range queries in a size-tiered LSM tree.

9 Conclusion

Our work shows that, by combining ideas from LSM trees and B$^\varepsilon$-trees, we can build a key-value store that outperforms current key-value stores by up to an order of magnitude on insertions, matches or outperforms on lookups, and is competitive on range queries.

SplinterDB targets the common case of small key-value pairs and non-uniformly random workloads. Many real-world key-value workloads come from different clients, some of which might be performing very localized operations, while others are performing relatively random operations. SplinterDB exploits whatever locality is available.

SplinterDB makes contributions to both the data-structural and systems design of high-performance key-value stores. We show how to get the low write amplification of size-tiered data structure while maintaining the high query throughput and workload-adaptivity of a B$^\varepsilon$-tree. We also describe several systems issues, such as cache, lock, and memtable design, that one must address to extract the full performance of high-performance NVMe devices.

Abstract

Byte-addressable, non-volatile memory (NVM) presents an opportunity to rethink the entire system stack. We present Twizzler, an operating system redesign for this near-future. Twizzler removes the kernel from the I/O path, provides programs with memory-style access to persistent data using small (64 bit), object-relative cross-object pointers, and enables simple and efficient long-term sharing of data both between applications and between runs of an application. Twizzler provides a clean-slate programming model for persistent data, realizing the vision of Unix in a world of persistent RAM.

We show that Twizzler is simpler, more extensible, and more secure than existing I/O models and implementations by building software for Twizzler and evaluating it on NVM DIMMs. Most persistent pointer operations in Twizzler impose less than 0.5 ns added latency. Twizzler operations are up to 13× faster than Unix, and SQLite queries are up to 4.2× faster than on PMDK. YCSB workloads ran 1.1–2.9× faster on Twizzler than on native and NVM-optimized SQLite backends.

1 Introduction

Byte-addressable non-volatile memory (NVM) on the memory bus with DRAM-like latency [23, 38] will fundamentally shift the way that we program computers. The two-tier memory hierarchy split between high-latency persistent storage and low latency volatile memory may evolve into a single level of large, low latency, and directly-addressable persistent memory. Mere incremental change will leave dramatic improvements in programmability, performance, and simplicity on the table. It is essential that operating systems and system software evolve to make the best use of this new technology.

These opportunities motivate us to revisit how programs operate on persistent data. The separation of volatile memory and high-latency persistent storage at the core of OS design requires the OS to manage ephemeral copies of data and interpose itself on persistence operations, a penalty that will consume an increasing fraction of time as NVM performance increases [64]. The direct-access nature of NVM invites the use of load and store instructions to directly access persistent data, simplifying applications by enabling persistent data manipulation without the need to transform it between in-memory and on-storage data formats. Thus, the model that best exploits the low latency nature of NVM is one in which persistent data is maintained as in-memory data structures and not serialized or explicitly loaded or unloaded. To avoid serialization, this model must support *persistent pointers* that are valid in *any* execution context, not just the one in which they were created.

Trying to mold NVM into existing models will not enable its fullest potential, just as SSDs did not reach their full potential until they transcended the disk paradigm. To explore a "clean-slate" approach, we are building Twizzler, an OS designed to take full advantage of this new technology by rethinking the abstractions OSes provide in the context of NVM. Twizzler divides NVM into *objects* within a global object space, and pointers are interpreted in the context of the object in which they reside. This decouples pointers from the address space of an individual thread, providing a data-centric programming model rather than a process-centric one. The result is a vastly simpler environment in which the OS's primary function is to support manipulating, sharing, and protecting persistent data using few kernel interpositions.

We implemented a simple, standalone kernel that supports a userspace for NVM-based applications, with compatibility layers for legacy programs. We wrote a set of libraries and portability layers that provide a rich environment for applications to access persistent data that takes into account both semantics (persistent pointers) and safety (building crash-consistent data structures). We then performed a case-study by writing software for Twizzler, taking into account the new flexibility and power gained by our model and evaluating our software for complexity and performance. We ported SQLite to Twizzler, showing how our approach can provide significant performance gains on existing applications as well.

In a world where in-memory data can last forever, the context required to manipulate that data is best coupled with the *data* rather than the process. This key insight manifests itself in the three primary contributions of this paper:

- We discuss (§ 2) our vision for a data-centric OS and the requirements that it must meet to provide low latency memory-style access to NVM with efficient data sharing.
- We present Twizzler (§ 3) and describe its mechanisms to meet those requirements, including decoupling traditionally linked concerns, reducing kernel involvement in address space management, and providing a rich model for constructing in-memory persistent data structures that can be easily shared between programs and machines.
- We evaluate (§ 4) the ease-of-use, security advantages, and programmability offered by our environment, for both new and existing, ported software (SQLite), along with performance improvements (§ 5) on NVM DIMMs.

2 The Data-Centric OS

Operating systems provide abstractions for data access that reflect the hardware for which they were designed. Current I/O interfaces and abstractions reflect the structure of mutually exclusive volatile and persistent domains, the hallmarks of which are heavy kernel involvement for persisting data, a need for data serialization, and complexity in data sharing requiring the overhead of pipes or the management cost of shared virtual memory. However, the introduction of low latency and directly attached NVM into the memory hierarchy requires that we rethink key assumptions such as the use of virtual addresses, the kernel's involvement in persistent I/O, and the way that programs operate on and share persistent data [30].

The first key characteristic of NVM is low latency: only 1.5–8× the latency of DRAM in most cases [38], so the cost of a system call to access NVM dominates the latency of the access itself. The second key characteristic is that the processor can directly access persistent storage using load and store instructions. Direct, low latency access to NVM means that explicit serialization is a poor fit—it adds complexity, as programmers must maintain different data formats and the transformations between them, and the overhead is intolerable due to NVM's low latency. Hence, we should design the semantics of the programming model around *in-memory* persistent data structures, giving programs direct access to them without explicit persistence calls or serialization methods.

These characteristics imply two basic requirements for OSes to most effectively use NVM:

1. **Remove the kernel from the persistence path.** This addresses both characteristics. System calls to persist data are costly; we must provide lightweight, direct, memory-style access for programs to operate on persistent data.
2. **Design for pointers that last forever.** Long-lived data structures can directly reference persistent data, so pointers must have the same lifetime as the data they point to. Virtual memory mappings are, by contrast, ephemeral and so cannot effectively name persistent data. Persistent data is, by definition, accessed by multiple actors, both simultaneously and over time, and thus must be stored in a form that is conducive to sharing without needing the ephemeral context associated with a particular actor.

We call an OS that meets both of these requirements *data-centric*, as opposed to current OSes, which are *process-centric*. Operations on persistent, in-memory data structures are the primary functions of a data-centric OS, which tries to avoid interposing on such operations, preferring instead to intervene only when necessary to ensure properties such as security and isolation. To meet both of these requirements a data-centric OS must provide effective abstractions for identifying data independent of data location, constructing persistent data relationships that do not depend on ephemeral context, and facilitating sharing and protection of persistent data.

2.1 Existing Interfaces

Current OS techniques do not meet these requirements—file `read` and `write` interfaces, designed for sequential media and later expanded for block-based media, require significant kernel involvement and serialization, violating both requirements. While support for these interfaces can be useful for legacy applications, as we will demonstrate, providing the programmer with abstractions designed *for* NVM both reduces complexity and improves performance.

The `mmap` call attempts to hide storage behind a memory interface through hidden data copies. But, with NVM, these copies are wasteful, and `mmap` still has significant kernel involvement and the need for explicit `msync` calls. "Direct Access" (DAX) tries to retrofit `mmap` for NVM by removing the redundant copy, but this fails to address requirement two! Operating on persistent data through `mmap` requires the programmer to use either fixed virtual addresses, which presents an infeasible coordination problem as we scale across machines, or virtual addresses directly, which are ephemeral and require the context of the process that created them.

Attempting to shoehorn NVM programming atop POSIX interfaces (including `mmap`) results in complexity that arises from combining multiple partial solutions. Given some feature desired by an application, the NVM framework can provide an integrated solution that meshes well with the existing support for persistent data structure manipulation and access, or it can fall-back to POSIX resulting in the programmer needing to understand two different "feature namespaces" and their interactions. An example of this is naming, where a programmer may need to turn to the filesystem to manage names in a completely orthogonal way to how the NVM frameworks handles data references. We will discuss another example, security, in our case study (§ 4).

Additionally, models that layer NVM programming atop existing interfaces often fail to facilitate effective persistent data sharing and protection. PMDK, an NVM programming library, makes design choices that limit scalability, since its data objects are not self-contained and do not have a large enough ID space, resulting in the need to coordinate object IDs across machines [10]. For the same reason, although single-address space OSes [12] somewhat address our first requirement, they do not consider both requirements at once, nor do they provide an effective and scalable solution to long-term data references due to that same coordination complexity [9].

2.2 A Data-Centric Approach

We cannot store virtual addresses in persistent data, so we need a new way to name a word of persistent memory: a *persistent pointer*. The persistent pointer encodes a persistent identification of data (§ 3.3) instead of an ephemeral address, allowing any thread to access the desired word of memory regardless of address space. This approach dramatically improves programmability, as programmers need not worry about the complexity of referring to persistent data with ephemeral constructs, improving data sharing across programs and runs of a program. Twizzler still makes use of virtual memory *hardware* to provide isolation and translation, but persistent data structures should not be written in terms of virtual addresses.

The Death of the Process. Processes as a first class OS abstraction are, like virtual addresses, unnecessary; a traditional process couples threads of control to a virtual address space, a security role, and kernel state. However, with the kernel removed from persistent data access, much of that kernel state (*e.g.* file descriptors) is unnecessary, leading to a decoupling of mechanisms: nothing fundamentally connects a virtual address space (*how* threads access data) and a security context (*what* data they may access). Instead, a data-centric OS can replace the process abstraction with security contexts, allowing greater flexibility for how security policy is managed.

The process abstraction is just one example. Persistent data access plays a key role in OS abstraction design, and we need to avoid complexity arising from combining old and new interfaces. Hence, we need to consider the wide-reaching effects of changing the persistence model on *all* aspects of the system, not just I/O interfaces. NVM gives us an opportunity to design an OS around the requirements of the target programming model instead of trying to mold support libraries around existing interfaces. While it is important that we provide support for legacy applications, it is these applications that should be relegated to support libraries; new applications built for the programming model should get first-class OS support.

Targeting these Constraints with Twizzler. The consequences of meeting the requirements of these hardware trends define a bounded design space for data-centric OSes. We have chosen a point in that space and built Twizzler, our approach to providing applications with efficient and effective access to NVM. In the following section we will discuss how our four primary abstractions—a low level persistent object model, a persistent pointer design, an address space mechanism called *views*, and a security context mechanism—achieve these goals of removing the kernel from the persistent data access path.

3 The Design of Twizzler

Twizzler is a stand-alone kernel and userspace runtime that provides execution support for programs. It provides, as first-class abstractions, a notion of threads, address spaces, persistent objects, and security contexts. A program typically executes as a number of threads in a single address space (providing backwards compatibility with existing programming models), into which persistent objects are mapped on-demand. Instead of providing a process abstraction, Twizzler provides *views* (§ 3.2) of the object space, which enable a program to map objects for access, and *security contexts* (§ 3.4) which define a thread's access rights to objects in the system. Twizzler provides persistent pointers (§ 3.3) for programs, as well as primitives to ensure crash-consistency (§ 3.5). The thread abstraction is similar to modern OSes; the kernel provides scheduling, synchronization, and management primitives. Figure 1 shows an overview of the system organization and how different parts of the system operate on data objects.

Twizzler's kernel acts much like an Exokernel [28,41], providing sufficient services for a userspace library OS, called `libtwz`, to provide an execution environment for applications. The primary job of `libtwz` is to manage mappings of persistent objects into the address space (§ 3.2) and deal with persistent pointers (§ 3.3). Twizzler also exposes a standard library that provides higher level interfaces beyond raw access to memory. For example, software that better fits message-passing semantics can use library routines that implement message-passing atop shared memory. Twizzler's standard library provides additional higher level interfaces, including streams, logging, event notification, and many others. Applications use these to easily build composable tools and pipelines for operating on in-memory data structures without the performance loss and complexity of explicit I/O.

We provide POSIX support with `twix`, a library that emulates Linux syscalls. We modified `musl` [1], a C library which all programs link to, replacing invocations of the `syscall` instruction with calls into `twix`, which internally tracks UNIX state like file descriptors. This is handled entirely in userspace; calls to `read` and `write` often reduce to calls to `memcpy`.

* modified musl to change linux syscalls into function calls

Figure 1: Twizzler system overview. Applications link to `musl` (a C library), `twix` (our Linux syscall emulation library), and `libtwz` (our standard library).

3.1 Object Management

Twizzler organizes data into *objects*, which may be persistent. Each object is identified by a unique 128 bit object ID (though larger IDs would be possible). Objects provide contiguous regions of memory that organize semantically related data with similar lifetime. Applications access objects via mapping services (discussed in the next section) by mapping each object into a contiguous range in the address space, though the address space itself may be densely or sparsely mapped. Objects can be anywhere from 4 KiB (the size of a page) to 1 GiB; the upper bound on object size is a prototype implementation choice, and not fundamental to the design.

Twizzler uses objects as the unit of access control, building off a read/write/execute permissions model which mirrors that of memory management units in modern processors. This is a direct consequence of avoiding the kernel for persistent data access—it can set policy by programming the MMU, but must leave enforcement up to the hardware which, in-turn, defines what protections are possible.

An object, from the programmer's perspective, is flexible in its contents—for example, it could contain anywhere from a single B-tree node to the entire B-tree. Often, an object would contain the entire tree, since the entire tree is typically subject to the same access semantics by programs, and there are overheads associated with objects that can be amortized over larger spaces. Data and data structures that are too large for one object or require different access permissions can span multiple objects with references between them. We demonstrate the benefits of this flexibility in Section 4.

The kernel provides services for object management, such as creating and deleting objects. Objects are created by the `create` system call, which returns an object ID. A program may also optionally provide an existing object ID to the `create` call, stating that the new object should be a copy of the existing one, for which Twizzler uses copy-on-write. The new ID is a number that is unlikely to collide with existing IDs in the 128 bit ID space, and can be assigned using a technique that supports this requirement (random, hashing, *etc*.). Some forms of ID assignment support a form of access control: a program can only access an object whose ID it knows. Twizzler provides object naming as well, discussed in Section 3.3.

Objects may be be deleted via the `delete` system call. Like Unix's `unlink`, objects are reference counted, where a reference refers to a mapping in an address space. Once the reference count reaches zero, the object may be deleted.

3.2 Address Space Management

Although virtual addresses are the wrong abstraction to use for persistent data access, we do leverage virtual address hardware in modern processors for isolation and protection. Twizzler provides access to persistent objects by mapping them into the virtual address space behind-the-scenes (via `libtwz`). This generates many mapping operations to access persistent data, so requiring system calls would be costly. Additionally, our kernel avoidance necessitates an increased address space management responsibility for userspace. For example, executable loading and mapping is handled largely without the kernel.

To support userspace manipulation of address spaces, the kernel and userspace share an object (called a "view") that defines an address space layout. The view is just a normal object, and so standard access control mechanisms apply to enforce isolation. When applications map objects into their address space, they update the view to specify that a particular object should be addressable at a specific location. The kernel then reads the object and determines the requested layout of the virtual address space. The view object is laid out like a page-table, where each entry in the table corresponds to a slot in the virtual address space. Each table entry contains an object ID and read, write, and execute protection bits to further protect object access (like `PROT_*` in `mmap`).

When a page-fault occurs, the fault handler tries to handle the fault by either doing copy-on-write, checking permissions, or by trying to map an object into a slot if the view object requested one. If it cannot handle the fault (due to a protection error or an empty entry in the view object), it elevates the fault to userspace where `libtwz` handles it, possibly by killing the thread, or possibly by mapping an object if the slot is "on-demand". When the kernel maps an object into a slot, it updates the address space's page-tables appropriately.

When threads add entries to a view object they need not inform the kernel—when a fault occurs, the kernel will read the entry as needed. However, when *changing* or *deleting* an entry, threads must inform the kernel so it can update existing page table entries. We provide two system calls for views. The `set_view` call allows a thread to change to a new view, which might be used to execute a new program or jump across programs to, for example, accomplish a protected task. Twizzler's access control system prevents this from happening arbitrarily. The second system call is `invalidate_view`, which lets a thread inform the kernel of changed or deleted entries.

3.3 Persistent Pointers

Section 2 discussed the needs for references that outlive ephemeral actors. Twizzler provides *cross-object* persistent pointers so that a pointer refers not to a virtual address but to an offset within an object by encoding an `object-id:offset` tuple. This enables a pointer to refer to persistent data, but it also allows objects to have *external* pointers that refer to data in any object in the global object space. We highlight cross-object pointers' power and flexibility by demonstrating their ability to express inter-object relationships in Section 4.

To efficiently encode this tuple, we use indirection through a per-object *foreign object table* (FOT), located at a known offset within each object. The FOT is an array of entries that each stores an object ID (or a name that resolves into an object

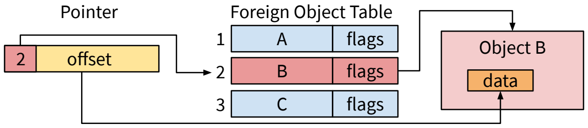

Figure 2: Pointer translation via the FOT. The pointer and the FOT are both contained in the same object (not shown).

ID, as we will see below) and flags. A cross-object pointer is stored as a 64 bit `FOT_idx:offset` value, where the `FOT_idx` is an index into the FOT. This provides us with both large offsets *and* large object IDs, since the IDs are not stored within the pointer itself. If an object wishes to point to data within itself (an *intra-object* pointer), it stores 0 in `FOT_idx`. When dereferencing, Twizzler uses the `FOT_idx` part of the pointer as an index into the FOT, retrieving an object ID. The combination of a FOT and a cross-object pointer logically forms an `object-id:offset` pair, as shown in Figure 2.

Our design (discussed in prior work [9, 10]) differs from existing frameworks [6, 13, 18, 19, 57, 58] because of the indirection. Frameworks like PMDK store entire object IDs within pointers, increasing pointer size and reducing flexibility by removing the possibility of late-binding (discussed below). Additionally, Twizzler extends the namespace of data objects beyond one machine, as machine-independent data references are a natural consequence of cross-object pointers. Existing solutions are limited in this scalability. They either limit the ID space (necessary for storing IDs in pointers) and thus resort to complex coordination or serialization when sharing, or they require additional state (*e.g.* per-process or per-machine ID tables) that must be shared along with the data, forcing the receiving machine to "fix-up" references. Worse still, the fix-up is application-specific, since the object IDs are within any pointer, not in a generically known location. Our per-object FOT results in self-contained objects that are easier to share, thus interacting better with remote shared memory systems.

Part of our motivation for this FOT indirection was to allow a large ID space without increasing pointer size. PMDK, by contrast, increases pointer size to 128 bits for each pointer. Twizzler has no additional space overhead per-pointer, instead adding a 32-byte overhead per FOT entry. The number of FOT entries, however, is typically much smaller than the number of pointers since pointers to the same external object can all use the same FOT entry. As we will see in Section 5, this has a dramatic benefit to performance.

FOT Entries and Late-Binding. The FOT entry's `flags` field has bits for read, write, and execute protections. The protections are *requests*; Twizzler implements separate access control on objects. This allows some pointers to refer to data with a read-only reference while others can be used for writing, reducing stray writes (a single ID can repeat in the FOT with different protections). The FOT entries also enable atomic updates that apply to all pointers using that FOT entry.

Instead of *requiring* programmers to refer to objects via IDs only, we allow names in FOT entries. These entries may contain a pointer to an in-object string table that contains a name. Names enable late-binding [19], a vital aspect of systems, allowing references to objects which change over time, *e.g.* shared library versions. Names are passed to a *resolving* function (specified in the FOT entry). Allowing a program to specify how its names are resolved increases the flexibility of the system beyond supporting UNIX paths. Twizzler provides a default name resolver that uses UNIX-like paths.

The implementation of naming is orthogonal to Twizzler's design. We allow a range of name resolution methods within the system stack and allow objects to specify their own name resolution functions for flexibility. For example, objects could be organized by both a relational database and a hierarchical namer similar to conventional file systems. Non-hierarchical file systems are well studied [3,31,32,54,55], but these systems do not easily cooperate atop a single data space. Since Twizzler uses a flat namespace as its "native" object naming scheme, it enables the required cooperation.

Pointer Translation. Current processors provide only a virtual memory abstraction, so applications must do some extra work to dereference a pointer, *translating* a pointer from its persistent form into a virtual address. This does not affect the *stored* pointer, which is still persistent and independent of any translation or address space. Thus multiple applications, possibly with different address space layouts, can translate the same pointer at the same time without coordination.

Pointer translation occurs with the help of two `libtwz` functions: `ptr_lea` (load effective address) and `ptr_store`. When a program dereferences a pointer, it first calls `ptr_lea`. The pointer is resolved into an object-ID and offset pair through a lookup in the FOT, after which `libtwz` determines if the referenced object is already mapped (by maintaining per-view metadata). If not, it picks an empty slot in the view and maps the object there (a cheap operation that does not invoke the kernel). Once mapped, `libtwz` combines the object's temporary virtual base address with the offset, and returns the new pointer. The `ptr_store` function does the opposite of `ptr_lea`—it turns a virtual pointer into a persistent one. While these are done manually in our implementation, we plan to implement compiler support to emit these calls automatically.

FOT management is handled by `libtwz`. While a lookup in the FOT is a simple array-indexing operation, a store may require adding to the FOT. To avoid duplicate entries, `libtwz` walks the FOT looking for a compatible entry. If one is not found, it atomically reserves a new entry and fills it (flushing cache-lines to persist it) before storing the pointer. The `ptr_store` operation is less common than `ptr_load`, and in the future we may include additional caching metadata that would speed-up the FOT walk (such as storing recent IDs).

Translating pointers has a small overhead (§ 5) and the result can be cached. Twizzler improves performance via a per-object cache of prior translations. The common case, intra-object pointers, does not require an external lookup and is implemented as a simple bitwise-or operation.

3.4 Security and Access Control

Twizzler's focus on memory-based objects requires that we design the security model around hardware-based enforcement, where the MMU checks each access. This design is *inevitable* in a data-centric OS, since the kernel is not involved in every memory access. The kernel merely specifies the access rights when mapping an object and then relies on the hardware to enforce those rights with a low overhead.

A key design choice we make is *late-binding on security*. Applications request access to an object with permissions that they desire; if they access the object in only allowed ways (*e.g.*, only reading a read-only object), no fault occurs. This is because when we map an object (via a view), the kernel is not immediately involved, and so cannot check access rights for a particular access at the time the mapping is setup. Performing an access rights check on time of first access does not make sense either, as it associates a specific access (that might be allowed) with a permissions error. For example, if a program reads object A, and that program is allowed to read A, it should be allowed to perform the read even if it requested read-write access to the object. This late-binding enables simpler programs that need not worry about elevating access rights through remapping data objects. Programs can make progress without knowing in advance the permissions of the objects they might access, thus enabling the reuse of the OS's access control mechanism in applications. We will show the flexibility of this in Section 4, wherein we add access control to a program by changing only a few lines of code.

Threads run in a security context [8, 25, 44], which contains a list of access rights for objects and allows the kernel to determine the access rights of programs. Using these contexts, Twizzler is able to provide analogues to groups and owners in Unix while providing more fine-grained access control if necessary. Unlike past exploration into security contexts, data-centric OSes offer an advantage in simplicity. A security context abstraction in a Unix-like OS needs to maintain access rights to a set of fundamentally different things (such as paths, virtual memory locations, and system calls). Instead, Twizzler's security contexts specify access rights to an object via IDs instead of virtual addresses. This also makes security contexts persistent, allowing us to use them as the primary way we assign security roles to threads.

Security contexts are implemented via virtualization hardware that maps virtual memory to an intermediate "object space" which specifies the access rights, which is then mapped to physical memory [9]. This reduces the number of page-table structures and mappings, as threads in the same security context can share the same page-tables for each object.

3.5 Crash Consistency

Twizzler provides primitives for building crash-consistent data structures. At a low level, it provides a mechanism for writing back cache-lines and appropriate fences. Applications use these primitives today outside of Twizzler to build up larger, more complex support for crash-consistent data structures.

Our goal is to provide low level primitives without restricting programs or prematurely prescribing particular solutions. There is a wealth of research on crash-consistent data structures for NVM [15, 16, 24, 46, 50–53, 65], but it is still in flux. Of course, Twizzler manages *system* data structures, such as FOT entries, views, *etc.*, in a crash-consistent manner using the aforementioned primitives, locking, and fencing.

Twizzler also provides a transactional-persistent logging mechanism. Programmers can write `TXSTART`–`TXEND` blocks to denote transactions and `TXRECORD` statements to record pre-changed values. This is similar to the mechanism provided by PMDK [58]. If applications need more complex transactions using different logging mechanisms, they can use libraries.

Twizzler provides a mechanism for restarting threads when power is restored following a crash. Since views are persistent objects, all mapped objects during a thread's execution are known across power cycles, and are mapped back in. The thread is then started at a special `_resume` entry point, allowing the program to handle the power failure in an application-specific manner with access to the state of the program (data segment, heap, *etc.*) as it was when power was cut.

3.6 Implementation

Twizzler's kernel is similar to many microkernels, providing a small set of key primitives. It is 5,500 lines of architecture-independent code and 5,700 lines of architecture-dependent CPU driver code. The primary complexity in the system is implemented in userspace, as the design of the programming model greatly simplifies the kernel. Twizzler is open-source; more information can be found at https://twizzler.io.

We also built a prototype of Twizzler by modifying the FreeBSD 11.0 kernel before implementing our standalone kernel. This was done both to more rapidly verify our design and to provide a prototyping environment for developers to write code for Twizzler in a familiar environment. We added Twizzler services to FreeBSD by adding system calls, modifying the fault-handling logic, and distinguishing Twizzler threads from FreeBSD threads. This is also a testament to the simplicity of the kernel in our model, since FreeBSD was relatively easy to modify to support the Twizzler userspace. However, the FreeBSD prototype is limited by its need to coordinate with FreeBSD's Unix services, thus the standalone kernel is more efficient and simpler, and provides a better environment for researching kernel design changes in the face of NVM.

4 Evaluation

Our primary goals for evaluating Twizzler were:

1. Show that Twizzler meets the needs of a data-centric OS in enabling programs to directly access persistent data.

2. Demonstrate that the programming model we defined provides sufficient power to easily and effectively build real applications with NVM in mind.
3. Measure the performance of our system to understand where we gain and lose performance.

We approached these goals two ways: porting existing software (SQLite) and writing new software for Twizzler. The first demonstrates both the generality of the programming environment (legacy software can be easily ported) and the potential performance gains to be had even for legacy software. The second demonstrates the true power of Twizzler's programming model and allows us to explore the consequences of our design choices fully without being constrained by legacy designs.

We built three pieces of new software: a hash-table based key-value store (KVS), a red-black tree data structure, and a logging daemon. Each had different characteristics and goals, and together they demonstrate the flexibility that Twizzler offers in allowing simple implementation, nearly-free access control, and the ability to directly express complex relationships between objects. Using our KVS and red-black tree code, we ported SQLite (a widely used SQL implementation) to Twizzler along with a YCSB [17,29] driver (a common benchmark), allowing us to explore Twizzler's model in a larger, existing program that would let us study the performance of Twizzler in a complex system that stores *and processes* data. We present the performance of SQLite and our new software, along with microbenchmarks, in Section 5.

4.1 Case Study: Key-Value Store

We implemented a multi-threaded hash-table based key-value store (KVS), called twzkv, to study cross-object pointers and our late-binding of access control. Our KVS supports insert, lookup, and delete of values by key (both of arbitrary size), and hands out direct pointers to persistent data during lookup. During insert, it copies data into a data region before indexing the inserted key and value. We built twzkv in multiple phases to study how our system handles changing requirements.

We built twzkv in roughly 250 lines of C. Handing out direct pointers into data was trivial to implement with cross-object pointers, requiring only a call to ptr_lea during lookup. The initial implementation maintains two objects, one for data and one for the index. The complexity typically involved when storing both index and data in a single, flat file is not justified in a programming model where we can express inter-object relationships directly at near-zero cost in complexity or performance. In our case, a pointer from the index object to the data object (such as an entry in the hash table) can be written with a single call to ptr_store. This, combined with the simple requirements for an in-memory NVM KVS, resulted in a small implementation that was nonetheless a usable KVS.

Extending Requirements. Next, we added functionality to protect values with access control. We wanted to keep handing out direct pointers to data during lookup and to keep twzkv a library (as opposed to a service). Meeting these goals on an existing system would be difficult without adding significant complexity, such as reimplementing a lot of Twizzler's pointer framework or implementing manual, redundant access control.

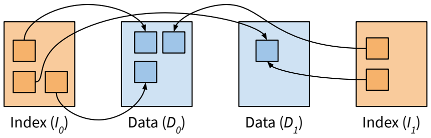

Figure 3: Cross-object pointers in twzkv.

In Twizzler, implementing access control in twzkv involved having the index refer to data in multiple data objects, assigning those objects different access rights, and allocating from those objects depending on desired access rights. We were able to implement this while preserving the original code due to the transparent nature of Twizzler's cross-object pointers. Now, when inserting, the application indicates the data object into which to copy the data, as shown in Figure 3.

By supporting multiple data objects, twzkv can leverage the OS's access control, sidestepping complexity. Unrestricted data can go in D_0 (Figure 3), whereas restricted data can go in D_1. Since each object has distinct access control, a user can set the objects' access rights, then decide where to insert data according to policy. The indexes point to the correct locations regardless of the access restrictions of the data objects, and twzkv still hands out direct pointers, but a user that is restricted from accessing data in D_1 will not be able to dereference the pointer. A further extension is to support secondary indices, as shown in Figure 3, enabling alternative lookup methods and limiting data discovery with index object access control. This extension is easy to implement on Twizzler.

Comparison to Unix Implementation. To compare with existing techniques, we built a similar KVS using only Unix features (called unixkv). It also separates index and data, but it must manually compute and construct pointers. Supporting multiple data objects was complex in unixkv, because we had to store and process file paths in the index and store references to paths for pointers, increasing overhead and code complexity by 36%—a lot for an implementation with relatively few pointers—just to reimplement Twizzler's support. The extra complexity also included code to manually open, map, and grow files, much of which Twizzler handles internally. Development time was extended by bugs that were not present when developing twzkv, due to the manual pointer processing. While twzkv gains transparent access control, unixkv does not due to the lack of on-demand object mapping and late-binding of security. Instead, unixkv needs to know object permissions before mapping, a restriction that limits the ability to reuse OS access control, something that twzkv could leverage through late-binding on security (§ 3.4)[1]. Other frameworks like PMDK that do not integrate access control and late-binding into their models have similar limitations.

[1] unixkv could trap segmentation faults to do this, but that would be application-specific, difficult, and would reimplement Twizzler functionality.

4.2 Case Study: Red-Black Tree

To evaluate the process of writing persistent, "pointer-heavy" data structures, we implemented a red-black tree in C using normal pointers (ramrbt) in 100 lines of code, and evolved it for persistent memory in two ways: manually writing base+offset style pointers, as current systems require (unixrbt), and using Twizzler (twzrbt). Porting existing data structure code to persistent memory will be common during the adoption of NVM, and much of the complexity therein comes from dealing with persisting virtual addresses [47].

In developing unixrbt, we found 83 locations where we had to perform pointer arithmetic for converting between persistent and virtual addresses. Consider an expression such as `root->left->right = foo`. Inserting calls to translate this directly results in `L(L(root)->left)->right = C(foo)`, where `L` converts to a virtual address and `C` converts back, which is heavily obfuscated and took more development time than writing ramrbt in the first place due to debugging.

We built twzrbt like unixrbt, annotating pointer stores and dereferences. However, unixrbt used an application-specific solution for pointer management; if other applications wanted to use the data structures created by unixrbt, they would have to know the implementation details of the pointer system (or share the implementation, thus reimplementing much of Twizzler's library). Additionally, due to Twizzler enabling improved system-wide support for cross-object pointers, these transformations can be made automatic.

Unlike twzrbt, unixrbt's tree is limited to a single persistent object; a limitation that prevents the tree from growing arbitrarily, does not allow it to directly encode references to data outside the tree object, and does not gain it the benefits of cross-object data references that were discussed above for twzkv. Adding support for this to unixrbt would require modifying the core data structures to include paths and significantly altering the code, increasing its length by at least a factor of 2, whereas twzrbt gets this functionality for free.

Another advantage of twzrbt is reduced support code compared to unixrbt; unixrbt needed code to manage and grow files and mappings, while we implemented twzrbt as simple data structure code with Twizzler managing that complexity. The additional error handling code and pointer validity checks in unixrbt (handled automatically in Twizzler) increased development time and implementation complexity.

4.3 Porting SQLite

We ported SQLite to Twizzler to demonstrate our support for existing software and to evaluate the performance of a SQLite backend designed for Twizzler. We used our POSIX support framework, a combination of musl and our library twix, to support much of SQLite's POSIX use. We took a modified version of SQLite called SQLightning that replaced SQLite's storage backend with a memory-mapped KVS called LMDB [14]. We chose this port because LMDB is implemented with mmap'd files as the primary access method and hands out direct pointers to data as one would expect from an effectively designed NVM KVS[2]. Since LMDB's SQLightning port already replaces the storage backend with calls to LMDB, we ported SQLite to Twizzler by taking our KVS and red-black tree code and implementing enough of the LMDB interface for SQLite to run using Twizzler as a backend. Outside of the B-tree source file few changes were needed for SQLite to run on Twizzler. We further ported our modified SQLite backend to PMDK to compare directly with a commonly used NVM programming library that supports persistent pointers.

We also ported a C++ YCSB driver [29], which required porting the C++ standard template library (STL). Since we had already ported a standard C library, the C++ STL was easily ported, demonstrating the ease of porting software to Twizzler. We have also ported some existing UNIX utilities (such as bash and busybox), which largely require only recompiling to run on Twizzler. Of course, to gain *all* of the benefits of Twizzler, programs will be need to be written with NVM in mind (but this is true regardless of the target OS).

Our implementation of the LMDB interface corroborated our experience from the KVS case study: much of the complexity in storage interfaces and implementations comes from the separation between storage and memory. This has been studied before (as we will elucidate in Section 6), but the advent of NVM changes the game significantly by allowing programmers to think directly via in-memory data structures. The result is that interfaces like cursors in a KVS become redundant. We implemented to this interface for LMDB, but the functions were largely wrappers around storing a pointer to a B-tree node and traversing the tree directly without separate loads and copies. The result was an extremely simple implementation (500 LoC) that still met the required interface. Future software for NVM can use Twizzler's programming model to more effectively write software that eschews the need for complexity forced by the two-tier storage hierarchy.

4.4 Discussion

Although these implementations were simple, they represent the applications and data structures we expect in a data-centric system. Pointers we can directly use in our programming languages make computing over persistent data almost transparent, allowing simple implementations that are nevertheless easy to evolve as requirements change.

Not only does twzkv have access control, but it enables concurrent access via cross-object pointers. Applications can load indexes for multiple databases without needing to worry about address space layout and without writing complex pointer management code that would be required by an implementation using mmap. We were able to provide access control without a single line of code in twzkv dedicated to checking

[2] These are not persistent pointers, however, unlike Twizzler's.

or enforcing access rights. Instead, we relied on the system's access control, something not possible with other frameworks that do not support late-binding of access rights and do not consider security as part of their programming model. Twizzler thus removes the need for applications to manage their own access control, which increases the security of the system by divesting programmers from the responsibility of getting it right. Similar functionality for current systems would traditionally require separation of the library and application into a client-server model, but that additional overhead is unneeded here and inappropriate on a persistent memory system.

Although `twzrbt` and `twzkv` had different densities of pointer operations, `twzrbt` being "pointer-heavy" and `twzkv` being "pointer-light", Twizzler improved the complexity of both over manual implementation and improved flexibility over existing persistent pointer methods. Using a system-wide standardized approach to pointer translations not only enables better compiler and hardware support, but it also improves interoperability; because they share a common framework, `twzkv` could use the red-black tree code and data with ease, and even interact with the SQLite database even though they were written separately without that goal in mind. The position-independence afforded by this model enables both composability and concurrency, while also simplifying programming on persistent data to a natural expression of data structures.

Non-Shared-Memory Programs. To push the limits of our model and show that Twizzler does not constrain programmers into a shared-memory model, we implemented a logging framework (similar to `syslogd`). The logging daemon, `logboi`, can receive log messages either synchronously or asynchronously. In both cases, the interface is the same, but synchronous logging uses shared-memory abstractions while asynchronous logging relies on message-passing semantics.

For synchronous logging the thread switches security contexts, which is made possible by decoupling address spaces and security. The call to the logging framework then updates the log and returns. An asynchronous logging event sends data to the logging thread via a stream object (a standard API provided by Twizzler) that `logboi` and the application share. The choice of asynchronous or synchronous is left to the programmer; synchronous can have lower latency and predictable behavior while asynchronous offloads processing to `logboi`.

5 Performance

Our evaluation's primary focus is on the benefits of the programming model, showing new functionality with reduced complexity at an acceptable overhead. Nevertheless, there are many cases where we see significant improvement (such as SQLite) because the programming model has less overhead, and our pointer design is space efficient and fast to translate.

We measured the performance of our KVS and red-black tree, performed microbenchmarks, and evaluated the Twizzler port of SQLite against Linux (Ubuntu 19.10) instances of SQLite, SQLightning, and our port of SQLite to PMDK. Tests ran on an Intel Xeon Gold 5218 CPU running at 2.30 GHz with 192 GB of DRAM and 128 GB of Intel Persistent DIMMs. We compiled all tests against the `musl` C library instead of `glibc` because Twizzler uses `musl` to support Unix programs.

All Linux tests used the NOVA filesystem [69] (a filesystem optimized for NVM) on the NVDIMMs, mounted in DAX mode. This enabled direct access to the persistent memory without a page-cache interposing on accesses.

Table 1: Latency of common Twizzler operations.

Pointer Resolution Action	Average Latency (ns)
Uncached FOT translation	27.9 ± 0.1
Cached FOT translation	3.2 ± 0.1
Intra-object translation	0.4 ± 0.1
Mapping object overhead	49.4 ± 0.2

5.1 Microbenchmarks

Table 1 shows common Twizzler functions' latencies, including pointer translation. The overhead shown for resolving pointers does not include dereferencing the final result, since that is required regardless of how a pointer is resolved. The first row shows the latency for resolving pointers to objects the first time. Twizzler makes a further optimization by caching the results of translations for a given FOT entry. Each successive time that FOT entry is used to resolve a pointer, the result of the original translation is returned immediately, improving the latency as shown on the "cached" row of Table 1. Note that the low latency of these results is expected; the performance critical case of these functions' use is repeated calls, and since these operations are simple, they fit within the processor cache.

Twizzler translates intra-object pointers by first checking if the pointer is internal and, if so, adding the object's base address to it—the same operation required for application-specific persistent pointers. The expanded programming model offered by Twizzler makes this overhead minor relative to the high costs for persistent data access on current systems, which have high-latency for equivalent operations.

We compared our pointer translation to Unix functions. Resolving an external pointer with an ID corresponds roughly to a call to `open("id")`, which has a latency of 1036 ± 15 ns. The comparison is not exact, of course; the pointer resolution also maps objects, and the call to `open` must handle file system semantics. However, the direct-access nature of NVM results in pointer translation achieving the same goal as opening a file does today. The pointer operations in Twizzler accomplish much of the same functionality as the heavier-weight I/O system calls on Unix with more utility and less overhead.

A more direct comparison is object mapping, which has low latency compared to `mmap` (658.7 ± 12.7 ns—a 13.3× speedup) though the two have similar functionality. Since map-

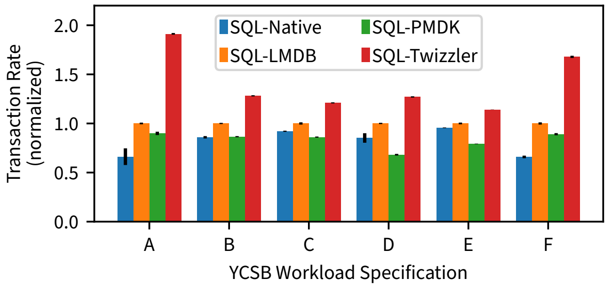

Figure 4: YCSB throughput, normalized (higher is better).

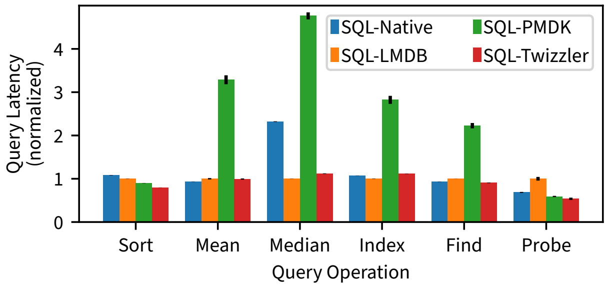

Figure 5: Query latency, normalized (lower is better).

ping occurs entirely in userspace, cache pollution is reduced. While both `mmap` and Twizzler's mapping require page-faults to occur before the data is actually mapped, this overhead is similar in Twizzler and Unix, and so is not shown.

5.2 SQLite

We ran four variants of SQLite, three on Linux and one on Twizzler, and compared their performance: "SQL-Native" (unmodified SQLite), "SQL-LMDB" (SQLite using LMDB as the storage backend), "SQL-PMDK" (SQLite using our red-black tree on PMDK), and "SQL-Twizzler" (our port of SQLite running on Twizzler). SQL-Native was run in `mmap` mode so that both it and SQL-LMDB used `mmap` to access data. We ran each on the same hardware and normalized the results.

Figure 4 shows the three variants' throughput under standard YCSB workloads. The performance improvement of the LMDB and Twizzler variants over SQL-Native is likely due to handing SQLite direct pointers to data. However, in the Twizzler case we get an additional benefit of operating on data structures directly while LMDB has an abstraction cost.

Figure 5 shows the latency of queries on a one million row table. This is common data processing—loading and then examining data in a variety of ways. We measured the performance of calculating the mean and median, sorting rows, finding a specific row, building an index, and probing the index. SQL-Twizzler had similar performance to SQL-LMDB and SQL-Native despite comparing its extremely simple storage backend to optimized B-tree backends (that benefit from scan operations). As a more direct comparison, SQL-Twizzler significantly out-performed SQL-PMDK in most tests. PMDK's pointer operations are more expensive than Twizzler's, requiring up to two hash table lookups per translation [5]. Additionally, PMDK's pointers are 128 bits, while Twizzler does not increase pointer size. Increased pointer size results in significantly worse cache performance, especially in a pointer-heavy data structure like a persistent red-black tree.

5.3 Key Value Store

We compared `twzkv` to `unixkv` by inserting one million distinct key-value pairs, followed by looking up each in-order.

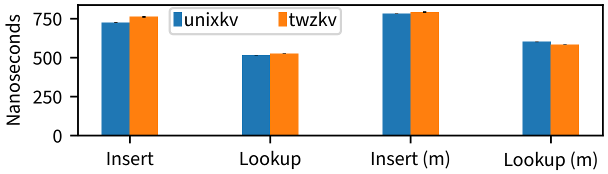

Figure 6: Latency of insert and lookup in `twzkv` and `unixkv`. An "(m)" indicates support for multiple data objects.

The inserted items were 32-bit keys and 32-bit values, chosen to reduce the overhead of data copying since we were focusing on pointer translation overhead. Both were compared under two modes, single-data-object and multiple-data-objects. Both KVSes translated between virtual and persistent addresses when storing and retrieving data, but for multiple-data-objects, we allow for storing the data in an arbitrary object.

Figure 6 shows the latency of lookup and insert, demonstrating that not only is the memory-based index and data object structure that can hand out direct data pointers sufficiently low latency to take advantage of NVM, but the additional overhead of cross-object pointers is minimal. Compared to `unixkv`, `twzkv` has minimal overhead in the single-object case, and improves lookup performance in the multiple-object case. The minor overhead in other cases comes with improved flexibility, simplicity, and access control support (`unixkv` does not support access control). Finally, multithreaded access on `twzkv` and `unixkv` did not improve performance; despite the pointer translations, they ran at memory bandwidth (for NVM).

5.4 Red-Black Tree

We measured the latency of insert and lookup of 1 million 32-bit integers on both `unixrbt` and `twzrbt`. The insert and lookup latency of `twzrbt` was 528 ± 3 ns and 251.8 ± 0.5 ns, while insert and lookup latency of `unixrbt` was 515 ± 2 ns and 213 ± 1 ns. The modest overhead comes with significantly improved flexibility, as `unixrbt` does not support cross-object trees, and less support code (`unixrbt` manually implements mapping and pointer translations). Note that even though there is lookup overhead in `twzrbt`, this overhead did not predict the results of a larger program—the SQL-Twizzler port used this red-black tree, and saw performance benefits over block-based implementations.

6 Related Work

Twizzler's design is shaped by fundamental OS research [12, 18, 26–28, 41, 42], which, while approaching similar topics described in Section 2, often did not consider *both* design requirements simultaneously, resulting in an incomplete picture for NVM. Recent research on building NVM data structures [15, 16, 22, 37, 45, 65], often focuses on building data structures that provide failure atomicity and consistency. In contrast, we explore how NVM affects programming models. We draw from recent work on providing OS support for NVM systems [11] and work providing recommendations for NVM systems [48], integrating object-oriented techniques and simplified kernel design to provide high-performance OS support for applications running on a single-level store [4, 61].

Multics was one of the first systems to use segments to partition memory and support relocation [6, 19]. It used segments to support location independence, but still stored them in a file system, requiring manual linkage rather than the automated linkage in Twizzler. Nonetheless, Multics demonstrated that the use of segmenting for memory management can be a viable approach, though its symbolic addresses were slow.

The core of Twizzler's object space design uses concepts from Opal [12], which used a single virtual address space for all processes on a system, making it easier to share data between programs. However, Opal was a single-address space OS, which is insufficient for NVM [9, 10], and it did not address issues of file storage and name resolution. It also required a file system, since there was no way to have a pointer refer to an object with changing identity, whereas our approach removes the need for an explicit file system. Other single-address space OSes, such as Mungi [34], Nemesis [56], and Sombrero [63], show that single address spaces have merit, but, like Opal, did not consider how the use of NVM would alter their design choices; in particular, how the use of fixed addresses results in a great deal of coordination that is unnecessary in our approach. OSes such as HYDRA [68] provide functionality similar to cross-object pointers; however, in Twizzler, we extend their use from procedures-referencing-data to a more general approach. Furthermore, they required heavy kernel involvement, an approach incompatible with our design goals.

Single-level stores [21, 60, 62] remove the memory versus persistent storage distinction, using a single model for data at all levels. While well-known, "little has appeared about them in the public literature" [60], even since the EROS paper. Our work is partially inspired by Grasshopper [21], AS/400, and orthogonal persistence systems, but while these are designed to provide an illusion of persistent memory, Twizzler is built for real NVM and focuses on providing a truly global object space with global references without cross-machine coordination. Clouds [20] implemented a distributed object store in which objects contained code, persistent data, and both volatile and persistent heaps. Our approach uses lighter-weight objects, allowing direct access to objects from outside, unlike Clouds. Software persistent memory [33], designed to operate within the constraints of existing systems, built a persistent pointer system using explicit serialization without cross-object references, in contrast to Twizzler. Meza [49] suggested hardware manage a hybrid persistent-volatile store with fine-grained movement to and from persistent storage. Since persistence in Twizzler is to NVM, we need not interpose on movement between storage and memory, instead simply managing memory mappings of persistent objects, reducing OS overhead.

Recently, several projects have considered the impact of non-volatile memories on OS structure. Bailey, *et al.* [4] suggest a single-level store design. Faraboschi, *et al.* [30] discuss challenges and inevitable system organization arising from large NVM, and we follow many of their recommendations. The Moneta project [11] noted that removing the heavyweight OS stack dramatically improved performance. While Moneta focused on I/O performance, not on rethinking the system stack, we leverage their approach to reduce OS overhead as much as possible, even when the OS must intervene. Lee and Won [43] considered the impact of NVM on system initialization by addressing the issue of system boot as a way to restore the system to a known state; we may need to include similar techniques to address the problem of system corruption.

IBM's K42 [42] inspired the high level design of Twizzler. The object-oriented approach to designing a micro or exokernel used in K42 is an efficient design for implementing modular OS components. Like K42, Twizzler lazily maps in only the resources that an application *needs* to execute. Similar techniques for faulting-in objects at run-time have been studied [36]. Communication between objects in Twizzler is, in part, implemented as protected calls, similar to K42.

Emerald [39, 40] and Mesos [35] implemented networked object mobility, which we can also support. Emerald implemented a kernel, language, and compiler to allow objects mobility using wrapper data structures to track metadata and presenting objects in an object-oriented language, impacting performance via added indirection for even simple operations.

The Twizzler object model was shaped by NV-heaps [15], which provides memory-safe persistent objects suitable for NVM and describes safety pitfalls in providing direct access to NVM. While they have language primitives to enable persistent structures, Twizzler provides a lower-level and uninhibited view of objects like Mnemosyne [65], allowing more powerful programs to be built. Languages and libraries may impose further restrictions on NVM use, but Twizzler itself does not. Furthermore, Twizzler's cross-object pointers allow external data references by code, whereas NV-heap's and DSPM's [59] pointers are only internal. Existing work beyond Multics on external references shows and recommends hardware support [58, 66], but provides a static or per-process view of objects, unlike Twizzler, limiting scalability and flexibility.

Projects such as PMFS [24] and NOVA [69] provide a file system for NVM. Twizzler, in contrast, provides direct NVM access atop of a key-value interface of objects. Although Twizzler does not supply a file system, one can be built atop it. While NOVA and PMFS provide direct access to NVM, NOVA adds indirection with copies. Both use `mmap` (which falls short as discussed above) and, unlike Twizzler, require significant kernel interaction when using persistent memory.

Our kernel that "gets out of the way" is influenced by systems such as Exokernel [28] and SPIN [7], both of which drew on Mach [2]. In Exokernel, much of the OS is implemented in userspace, with the kernel providing only resource protection. Our approach is similar in some respects, but goes further in providing a single unified namespace for all objects, making it simpler to develop programs that can leverage NVM to make their state persistent. In contrast, SPIN used type-safe languages to provide protection and extensibility; our approach cannot rely upon language-provided type safety since we want to provide a general purpose platform.

7 Future Work

Compiler and Hardware Support. Clean-slate NVM abstraction reopens the possibility of coevolving OSes, compilers and languages, and hardware. Standardized OS support for cross-object pointers enables compiler support more effectively than application-specific solutions [47] or simple libraries [58]. Twizzler's pointer translation functions are simple enough to be automatically emitted by a compiler. Similarly, designing an OS for cross-object pointers allows us to better state our needs to hardware, which can alleviate performance overheads for pointer translation [66, 67].

Security. Although we discussed the Twizzler security model briefly, there is still much to do. The current model provides access control, a basic ability to define and assign roles based on security contexts, and simple sub-process fault isolation through the ability to switch security contexts. We are exploring a *flexible* security model that allows programmers to easily trade-off between security, transparency, and performance using capability-based verification. For example, we are implementing a call-gating mechanism that will allow us to restrict control-flow transfers between application components, improving the security against malicious components and reducing the possibility of memory-corrupting bugs.

Networking and Distributed Twizzler. One of the key principles of Twizzler is to focus the programming model on data and away from ephemeral actors such as processes and nodes. This is enabled by our identity-based references that decouple location from references, and by ensuring all the context necessary to understand these relationships is stored with the data. Because our data relationships are independent of the context of a particular machine, applications can more easily share data. This easy sharing, combined with a large ID address space, motivates a *truly* global object ID space.

We are building a networking stack and support for a distributed object space into Twizzler. Our networking stack is based around extensive use of hardware virtualization in modern NICs. This design, which is in use in existing kernel-bypass strategies, will mesh well with our core OS design of reducing kernel interposition. At a higher level, we are considering how distributed applications change in our model. For example, an increase in data mobility facilitated by our location-independent data references and identities means that we can manifest both data and code where they are needed without complex marshalling, turning distributed computation into a rendezvous problem. We plan to build distributed applications atop Twizzler to demonstrate this approach.

Of course, for compatibility we will provide a traditional sockets-based networking stack. However, we can use existing userspace libraries that, *e.g.*, implement TCP in userspace. Because we implemented our POSIX compatibility library in userspace, applications can gain many benefits afforded by kernel-bypass networking frameworks while still using traditional socket interfaces.

8 Conclusion

Operating systems must evolve to support future trends in memory hierarchy organization. Failing to evolve will relegate new technology to outdated access models, preventing it from reaching full potential, and making it difficult for OSes to evolve in the future. Twizzler shows a way forward: an OS designed around NVM that provides new, efficient, and easy to use semantics for direct access to memory. Cross-object pointers in Twizzler allow programmers to easily build composable and extensible applications with low overhead by removing the kernel from persistent data access paths, thereby improving the flexibility and performance. Our simpler programming model improved performance despite the (small) pointer translation overhead. Even a memory hierarchy with large RAM but without persistent memory benefits from our design by enabling programs to operate on large, shared, in-memory data with ease. Our programming model is easy to work with compared to existing systems, and we were able to both quickly prototype real applications with advanced access control features and port existing software (SQLite). Twizzler will give us a system from which we can build a full NVM-based OS around a data-centric design and explore the future of applications, OSes, and processor design on a new memory hierarchy.

Availability Twizzler is available at `twizzler.io`.

Abstract

In this work, we conduct a security analysis of container networks, identifying a number of concerns that arise from the exposure of unnecessary network operations by containerized applications and discuss their implications. We then present a new high-performance security enforcement network stack, called BASTION, which extends the container hosting platform with an intelligent container-aware communication sandbox. BASTION introduces (*i*) a *network visibility service* that provides fine-grained control over the visible network topology per container application, and (*ii*) a *traffic visibility service*, which securely isolates and forwards inter-container traffic in a point-to-point manner, preventing the exposure of this traffic to other peer containers. Our evaluation demonstrates how BASTION can effectively mitigate several adversarial attacks in container networks while improving the overall performance up to 25.4% within single-host containers, and 17.7% for cross-host container communications.

1 Introduction

Among the leading trends in virtualization is that of containerized application deployment at industrial scales across private and public cloud infrastructures. For example, Google has been a significant adopter of container-based software deployment using its container orchestrater, *Kubernetes* [26] to spawn more than two billion containers per week [17]. Yelp uses containers to migrate their code onto AWS, and launches more than one million containers per day [56]. Netflix spawns more than 3 million containers per week within Amazon EC2 using its Titus container management platform [25].

With this growing attention toward the large-scale instantiation of containerized applications also comes a potential for even small security cracks within the container software ecosystem to produce hugely destructive impacts. For example, Tripwire's container security report [50] found that 60% of organizations already had experiences of security incidents in 2018, assessing that these incidents arose primarily due to the pressures to achieve deployment speed over the risks from deploying insecure containers. In recognition of such risks, several efforts [10, 14, 36] have arisen to help identify and warn of possible vulnerabilities in containers.

In addition, the shared kernel-resource model used by containers also introduces critical security concerns regarding the ability of the host OS to maintain isolation once a single container is infected. Indeed, many researchers (and industry) have proposed strategies to address the issue of container isolation. For example, AppArmor [1], Seccomp [40], and SELinux [41] can provide much stronger isolation of containers by preventing various system resource abuses. In fact, several commercial products introduce container security frameworks [2, 44, 51], which can monitor containers at runtime and impose dynamic policy controls.

However, while there continues to emerge a variety of approaches to secure containerized applications, less attention has been paid to bounding these applications' access to the container network. Specifically, there has been significant adoption of containers as microservices [31], in which containers are used to create complex cloud and data-center services. Although current container platforms often utilize IP-based access control to restrict each container's network interactions, there are limitations in such controls that offer opportunities for significant container abuse.

This paper begins by discussing several of the challenges that arise from the current reliance on the host OS network stack and virtual networking features to provide robust container-network security policies. The paper will present five examples of inherent limitations that arise in using the Host OS network stack to manage the communications of container ecosystems as they are deployed today. Informed by these existing limitations, we introduce BASTION, a new extension to container network stack isolation and protection. BASTION instantiates a security network stack per container, offering isolation, performance efficiency, and a fine-grained network security policy specification that implements the least privileged network access for each container. This approach also provides better network policy scalability in network policy management as the number for hosted containers increases, and greater dynamic control of the container ecosystem as containers are dynamically instantiated and removed.

BASTION is composed of a manager and per-container network stacks. The manager solicits network and policy information from active containers, and deploys a security enforcement network stack into each container. Then, in the network stack, all security enforcement is conducted through two major security services: *a network visibility service* and *a traffic visibility service*. Based on a set of inter-container dependencies, the network visibility service mediates the container discovery process, filtering out any access to containers and hosts that are deemed irrelevant given the dependency map. The traffic visibility service controls network traffic between the container and other peer containers, while also verifying the sources of the traffic. This service enables traffic to flow among the containers through an efficient forwarding mechanism that also isolates network communications between senders and recipients. Whenever there is any change in container environments, the manager dynamically updates the network stack of each container with no service interruption.

The paper explains how BASTION mitigates a range of existing security challenges, while also demonstrating that BASTION can improve the overall performance up to 25.4% within the same host and 17.7% across hosts.

Contributions. Our paper contributions are as follows:

• A security assessment of container networks, illustrating security challenges that arise in current container network stacks and security mechanisms.

• The introduction of a novel security-enforcement network stack for containers, which restricts the network visibility of containers and isolates network traffic among peer containers with high performance.

• The presentation of the prototype system, BASTION, including an analysis of how it addresses network security challenges in current container environments.

2 Background and Motivation

Here, we provide the background of container networks and identify how the underlying architectural limitations of current network security services impact container environments.

2.1 Current Container Networks

Docker Platform: Docker [12] uses bridge networks to provide inter-container connectivity, by default. As an example, Figure 1 illustrates the architecture of two microservices. The microservice chains that compose a network service are shown in the upper panel, while the logical networking of the microservice containers, which are networked under separate bridges, is depicted in the lower panel. To provide network flow control, Docker applies network and security policies into bridge networks using `iptables` [34].

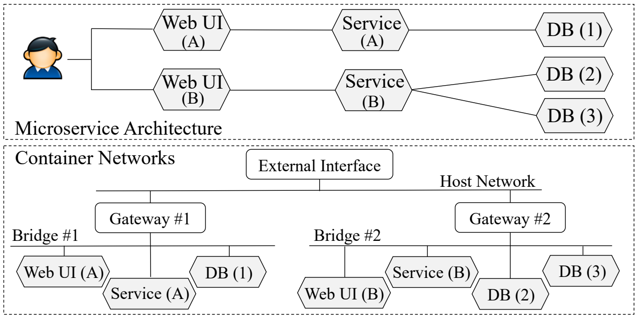

Figure 1: Overview of Docker Bridge Networking. Upper panel: a conceptual microservice architecture involving two independent services. Lower panel: separate bridged networks are instantiated to manage container network flows.

Kubernetes Orchestration System: Kubernetes [26] supports the management of large numbers of Docker containers across multiple nodes (e.g., physical *host* servers), enabling cross-host container applications to work as a logical unit. Thus, while Docker uses bridge networks for containers within the same host (node), Kubernetes uses various overlay networks (e.g., Flannel [11], Weave [55], Calico [49]) to provide inter-container connectivity across multiple nodes. For example, in the Weave overlay network [55], each node has a special bridge interface, called `weave`, to connect all local containers. The weave bridges, run at each node, are logically linked as a single network. While Kubernetes uses Docker containers, it does not utilize Docker networking features to manage network flow control. Rather, it separately applies network policies using `iptables`. Calico [49] similarly applies network and security policies using `iptables`. In the case that operators want further security enforcement, they may use Cilium [7], a security extension that conducts API-aware access control (e.g., HTTP method) by redirecting all network traffic to its containerized security service (envoy).

Network-privileged Containers: Besides the typical use of containers, there are special cases in which an operator wants to directly expose containerized services using the host IP address (e.g., HAProxy [8], OpenVPN [28], and MemSQL [30]). In such cases, by sharing the host namespace with a container, the container is provided access to the host network interfaces, and directly exposes its services. In this work, we refer to such cases as *network-privileged containers*.

2.2 Challenges in Container Networks

While current container platforms mostly utilize OS-level IP-based access control (e.g., `iptables`) to enforce container network security policies, there are significant limitations in their ability to constrain the communication privileges of today's container topologies. The following are five concerns that arise from these current OS-level architectural limitations, which motivate the BASTION design.

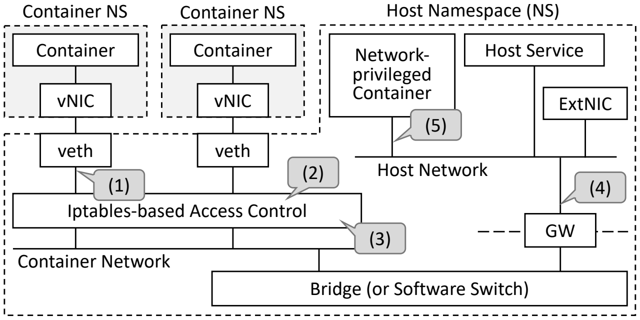

Figure 2: Five critical challenges in container networks: (1) Loss of container context, (2) Limitations of IP-based access controls, (3) Network policy explosion (performance degradation), (4) Unrestricted host access, and (5) No restriction on network-privileged containers.

(1) Loss of container context: As shown in Figure 2, each container has its own virtual interface, but this is only visible inside of the container. Thus, container platforms effectively create a twin virtual interface corresponding to it on a host. This virtual interface is connected to the bridge, enabling connectivity with others. Unfortunately, one security-relevant problem of this design is that each packet produced by a container will lose its association with the source container at the moment that it transitions into the host network namespace, which means that the packet already flows into a container network. Hence, all decisions for further security inspection (e.g., source verification and network flow control) and packet forwarding should be solely made based on the packet header information, and a malicious container can directly forge packets on behalf of any other containers, allowing lateral attacks and traffic poisoning when any container is compromised.

(2) Limitations of IP-based access controls: The primary method for imposing network flow control among container platforms is through `iptables`, an IP-based access control provided by a Linux kernel. However, the IP addresses of containers can be dynamic, and adjustments are then required whenever containers are spun up and down. Thus, it can be a challenge to specify security policies for containers in terms of both performance and security, since these policies must be updated whenever containers are re-created, and the policy tables of `iptables` should be also locked during policy updates. Furthermore, although operators enforce various security policies, container networks are still vulnerable to layer-2 attacks, due to the limited scope of `iptables`.

(3) Network policy explosion: Finer grained network policies inherently require larger sets of network policies. Further, since each container may require different policies, the overall number of policies will tend to increase with the heterogeneity and size of the container ecosystem. Unfortunately, `iptables` is a centralized mechanism for all network interfaces in the host, which results in monolithic network rules that can be daunting to manage and at worst produce

(b) Network interfaces visible by a network-privileged container

Figure 4: Network visibility according to container privileges: upper panel - a general container sees only its own network interfaces, lower panel - a network-privileged container shares the network namespace with a host; thus, it can see all network interfaces in the host.

a network policy explosion (the number of security policies will rapidly increase as a large number of containers are deployed). Consequentially, if the number of security policies in `iptables` increases beyond hundreds, the container ecosystem may face a significant performance degradation [37].

(4) Unrestricted host access: Each container network has a gateway interface for external accesses, which is connected to the host network, as shown in Figure 2. Unfortunately, an inherent security concern arises as a container can thus access a service launched at the host-side. In Kubernetes, containers can even access all other hosts (nodes) through the gateway IP addresses assigned to them. If a service running in a host opens a certain network port, as shown in Figure 3, a container can directly access the service through the gateway IP address. In the worst case, a malicious container can exploit the service in a manner that can subvert/harm the availability of the host.

(5) No restriction on network-privileged containers: While a network-privileged container can gain a performance advantage as its traffic does not pass through additional network stacks (e.g., container networks), such a container also raises significant concerns with respect to operational isolation. As shown in Figure 4, network-privileged containers can access not only the host network interfaces, but can also monitor all network traffic from deployed containers in the

Host Network Namespace Abuse	✔	✔	✔	✔	✔	✔	✘

Table 1: Potential of network attacks across container network interface plugins. Feasible (✔): network attack can be successfully executed over the container network interface plugin. Probable (▲): network attack remains possible, but may be blocked with appropriate application of network security policies. Infeasible (✘): network attack is always blocked.

host and are unrestrained in their ability to inject malicious packets into container networks. Furthermore, current security solutions do not consider security policies for such containers; hence, operators must design and specify a secure policy configuration for the containers by themselves.

2.3 Assumptions and Threat Model

Assumptions: Consider the case of containers connected to each other in order to operate as microservices using Docker or Kubernetes network configurations. Let us assume that an attacker possesses enough skill (e.g., gaining a remote shell to execute arbitrary commands inside a container) to perform a remote hijacking of an Internet-accessible container application that is operating as a part of a microservice, using published container vulnerabilities [45,52]. For example, even certain images provided by the official Docker hub include known vulnerabilities [47]. Given this, we consider what an attacker may do after getting into the subverted container.

Threat Model: The scope of threat models considered in this work focuses on network-based lateral attacks launched from a compromised container, rather than system-based attacks that may occur within a container. Unlike network-based attacks, system-based attacks have been actively explored in other work, such as abusing privileged and unprivileged containers [33] and modifying Linux capabilities within a container [53], and defense techniques based on status inspection of namespaces [24]. Thus, we believe that an operator would properly deploy containers with system-wide security policies, and we therefore do not consider system-wide threats (e.g., attacks against the host kernel) in this paper.

Here, a specific attack case involves one in which a compromised container is employed "as is", as the launching point for these lateral attacks, where *no privilege escalation* is required within the container to conduct further exploitation. Also, an attacker can acquire a base understanding of the compromised container's network configuration by investigating several system files (e.g., `/proc/net/arp`, `/proc/net/route`).

2.4 Limitations of Container Network Interface Plugins

Here, we briefly discuss the limitations of current container networking plugins. Table 1 presents the feasibility of network threats that abuse the above security challenges.

Docker, Flannel, WeaveNet: Docker [12], Flannel [11], WeaveNet [55] operate on bridge-based L2 forwarding, which is tightly coupled with the networking features and the IP-based access control provided by the host OS. Hence, they have the same security challenges discussed in Section 2.2 and are vulnerable to all network threats presented in Table 1.

Calico: Calico [49] employs IP-in-IP-based L3 routing, and uses a single MAC address (`EE:EE:EE:EE:EE:EE`) for all containers which makes L2 attacks infeasible. However, it remains vulnerable to L3/4 attacks (e.g., TCP SYN floods, DNS reflection attacks, ICMP spoofing attacks etc.). In addition, while the host-service abuse is infeasible because Calico uses a virtual gateway IP address (`169.254.1.1`) for all containers, it does not provide security mechanisms that guard against the host-network namespace abuse.

Open vSwitch: Open vSwitch (OVS) [27] provides more flexible networking features than the host OS; thus, it might be viewed as an alternate solution for bolstering container network security. OVS can derive which virtual port a container is connected to and this could be used to prevent spoofing attacks. However, one critical concern is that OVS does not support a `NOT operation`, meaning that we need to install all possible flow rules from each container to other containers, which at least contain (the virtual port and the MAC/IP addresses of a source container, the IP address and the service port of a destination one) matching fields for source verification and spoofing attack prevention. In addition, frequent rule updates are inevitable (as in the case of iptables) whenever containers are spun up and down. While OVS may be able to block unauthorized host IP address accesses, it still allows containers to access host services using gateway IP addresses since OVS is located at the host network namespace. Unfortunately, OVS would still need a large number of security policies against all possible host accesses from each container. In addition, OVS provides no protection in the case of network-privileged containers.

Cilium: Cilium [7] operates at the L3 routing level and provides advanced network security mechanisms for implementing L3-7 firewalls. In addition, L2 attacks are not feasible, as in the case of Calico. However, other network threats remain possible. Although Cilium provides support for a range of network policies (e.g., identity and label-based policies), which can block accesses to specific containers or hosts, the feasibility of such network threats depend on the operator and deployment considerations. For example, even though an operator carefully defines network policies to restrict service-to-service communications based on container identities, containers may still conduct L3/4-based lateral attacks to neighbors in the same service. Network-privileged containers are beyond its threat model, meaning that Cilium is still vulnerable to them.

BASTION: BASTION is designed as a transparent container-network security extension that protects against diverse security challenges discussed in Section2.2. Unlike existing container network interface plugins that rely on operator-defined network policies to protect containers from various network threats, BASTION automatically discovers inter-container dependencies from container platforms, and provides an intelligent container-aware communication sandbox that protects inter-container communications. In the following section, we will describe BASTION in greater detail.

3 BASTION Design

As we discussed in Section 2.2, many of the security limitation that arise from the use of the OS network stack to service container process are less well studied than other container security mechanisms. To address these limitations, we begin by identifying the design considerations that BASTION addresses, followed by a presentation of its design.

R1: *Container-aware least privilege communications enforcement.* A container's connectivity should be a function of the interdependencies between itself and those containers whose communications are required to compose a service.

R2: *Scalable and fine-grained network policy expression.* Network policy expression and enforcement performance within the container network should scale well to the dynamism and size of modern host container topologies.

R3: *Policy control over intra-container communications.* While the gateway interface plays as a key role in the communications with external networks, the network stack should filter out the direct access of the gateway interface to prevent the abuse of the host namespace.

R4: *Policy enforcement for network-privileged containers.* Network policy enforcement should be capable of fine-grained access control over network-privilege-enabled containers that share the host network namespace for the direct access of the host interfaces.

R5: *Unauthorized eavesdropping and spoofing prevention.* Communication mediation should prevent access to third-party packets (i.e., eavesdropping) and false packet production (i.e., preventing both ARP spoofing and traffic injection among local containers).

R6: *Competitive performance that scales well with any container topology.* The network stack should deliver low latency and high throughput communications while securing container networks.

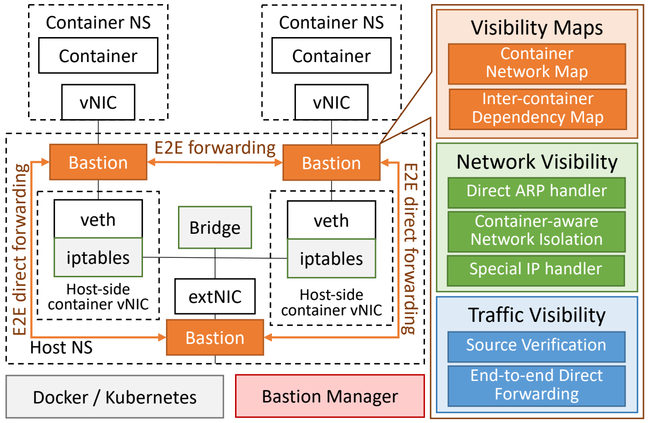

Figure 5: BASTION Architecture Overview. Orange box: BASTION network stack. Red box: manager that maintains the global view of container networks. Green box: network visibility service that restricts container reachability. Blue box: traffic visibility service that controls inter-container traffic while concealing irrelevant traffic from containers.

3.1 Architectural Overview

BASTION represents the opposite spectrum of prior container network stack designs, which implement network policy enforcement in a centralized manner. BASTION implements a decentralized, per-container, network stack. That is, all BASTION security enforcement occurs before a container's packets are delivered into the container network. This approach enables BASTION to provide individualized control over the network traffic coming from each container, mitigating the security challenges discussed in Section 2.2.

Figure 5 illustrates the overall architecture of BASTION. BASTION is composed of a manager, which maintains the global network view of all containers with their security dependencies, and per-container network stacks that include two security services (i.e., network and traffic visibility services). A BASTION network stack maintains the container network map for the corresponding container, which includes the network information of all reachable containers that have peer dependencies (e.g., microservice composition), and an inter-container dependency map, including the security policies on dependent containers only (R2).

When packets arrive at the BASTION network stack, the network visibility service proactively filters any discovery processes of irrelevant containers by dealing with ARP requests based on the container network map (R1, R5), and restricts the communications between containers according to security policies specified in the inter-container dependency map (R1). In addition, a special IP-handler restricts unauthorized access to special IP addresses (e.g., gateway IP addresses) (R3). The traffic visibility service conducts secure packet-forwarding between containers. This service first verifies the packets with the identity of the container (R4-5), directly passing packets

Figure 6: BASTION computes a container network map that captures the network interface attributes for each hosted container, and an inter-container dependency map that indicates the links and dependencies between containers.

Algorithm 1 Extracting Inter-Container Dependencies

```
Input: $C$, which is the set of all active containers
for each container $u \in C$ do
    for each container $v \in C$ where $u \neq v$ do
        if $v \in u.explicitDependents$ then
            $p_{uv} = u.EgressPolicies \cap v.IngressPolicies$
            add $v$ into $u.dependencyMap$ with $p_{uv}$
        else if $u.containerSet \neq v.containerSet$ then
            for each service pair $s \in S_{set}(v.ContainerSet)$ do
                $p_{us} = u.EgressPolicies \cap s.Port$
                add $s.IP$ into $u.dependencyMap$ with $p_{us}$
    for each service pair $s \in S_{microservice}$ do
        $p_{us} = u.EgressPolicies \cap s.Port$
        add $s.IP$ into $u.dependencyMap$ with $p_{us}$
```

from the source container to the destination containers using their interface information (R6). Since this direct packet forwarding occurs at the network interface level, packets are no longer passed through the container network (host-side), eliminating any chance for unauthorized network traffic exposure (even to network-privileged ones) (R4-5).

In terms of cross-host inter-container communications, a specialized BASTION network stack is utilized at the external interface of each node. It only maintains the container network map for all containers deployed in each node since all security decisions are already made at the network stack of each container. Thus, when it receives packets from other nodes, it simply conducts a secure forwarding from the external interface to destination containers. Overlay network composition among hosts (nodes) are beyond the coverage of BASTION; thus, it utilizes existing overlay networks (e.g., WeaveNet over IPSec). BASTION also retains the existing mechanisms of container platforms to handle inbound traffic from external networks.

3.2 BASTION Manager

The BASTION manager performs two primary roles. It collects the network information of all active containers from container platforms and manages the BASTION network stacks deployed to the active containers.

(1) Container Collection. The BASTION manager first maintains two hash maps (i.e., a global container network map and the inter-container dependency map for all containers) for the security evaluation of each container. As shown in Figure 6, BASTION uses a container platform to retrieve the network information for all containers, and to build the inter-container dependency map by extracting the dependencies among containers based on the retrieved information and their ingress/egress security policies. In addition, because containers can be dynamically spun up and down, the manager periodically retrieves containers' network information to update the maps. While a notification-based mechanism would provide greater efficiency, a polling-based mechanism was selected to provide a transparent and compatible solution that can be integrated with already-deployed container environments without any required modifications.

Extracting inter-container dependencies: BASTION automatically extracts dependencies among containers. To do this, a container network model is defined, in which a microservice is composed of one or more container sets, and each container set has one or more containers that play the same role (due to scaling and load-balancing). Each container set exposes internal service ports to communicate with other container sets, while a microservice exposes global service ports to redirect accesses from the outside world to some of the internal service ports. We then define four constraints for implicit dependencies in inter-container communications: (1) containers with the same container set are not granted interconnectivity, (2) containers in different container sets only communicate via internal service ports (explicitly exposed by configurations), (3) containers that are unrelated to each other may talk through global service ports, (4) all other communications are not allowed by default. Based on the container network model, all inter-container dependencies are extracted using Algorithm 1.

Discovering inter-container dependencies: As no container network can be made secure without proper network policies that restrict communications to the minimum required access, BASTION also discovers inter-container dependencies not explicitly defined by a container operator. During the flow control of inter-container traffic, BASTION produces network logs that capture the network accesses from/to containers. At the same time, it compares these logs with the inter-container dependency map, classifying them into three cases: *legitimate accesses, missing policies, and excessive policies.*

If the pair of observed containers are not in the precomputed inter-container dependency map, BASTION considers that there is either a missing network policy or an invalid access. Then, it informs an operator to review the specific flows to determine whether to produce a missing network policy. In addition, it identifies network policies for which no flows have been encountered. Such cases may represent an over-specification of policies that enable unnecessary flows for the container network's operations. In these cases, BASTION informs an operator to review the specific policy that may require to be updated in the current configuration.

(2) Network Stack Management. The manager maintains the BASTION secure network stack for each container. For newly spawned containers, it installs the network stacks at their interfaces with the container network and inter-container dependency maps. With respect to map size, each container only requires a part of the network information to communicate with dependent neighbors. Thus, to reduce the size of security services, BASTION filters irrelevant information per container. The manager also performs change detection of inter-container dependencies, automatically updating the maps in the network stacks of the corresponding containers.

3.3 Network Visibility Service

The network visibility service restricts unnecessary connectivity among containers and between containers and external hosts. To do this, the following three security components are introduced to handle container discovery, inter-container communications, gateway/service-IP accesses, respectively.

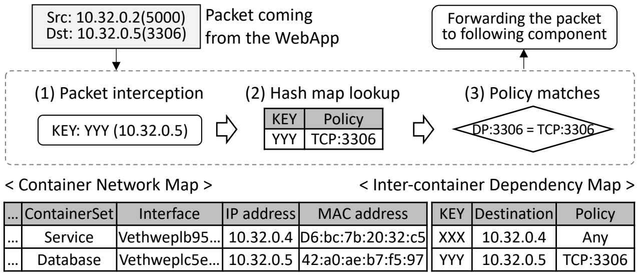
3.3.1 Direct ARP Handler

For inter-container networking, container discovery is the first step to identify other containers (communication targets). Containers use ARP requests to identify the necessary network information (i.e., MAC addresses) of target containers. Unfortunately, this discovery process can be exploited to scan all containers connected to the same network by malicious containers, as current network stacks do not prevent ARP scan. Indeed, they offer no mechanism to control non-IP-based communications.

BASTION's direct ARP handler filters out any unnecessary container discovery that does not pertain to the present container's dependency map. When a container sends an ARP request, the handler intercepts the request before it is broadcasted, verifying if the source container has a dependency on the destination container. This analysis is done using the inter-container dependency map. If accessible, the handler generates an ARP reply with the MAC address of the destination container in the container network map, and sends the reply back to the source container (while no ARP requests flow into the container network). If not, it drops the request.

3.3.2 Inter-container Communications Handler

Although the direct ARP handler prevents containers from performing unbounded topology discovery, its coverage is limited to container-level isolation. It does not address malicious accesses among dependent containers. Hence, to further restrict the reachability of containers, a second component implements container-aware network isolation.



KEY	Policy
YYY	TCP:3306

...	ContainerSet	Interface	IP address	MAC address
...	Service	Vethweplb95...	10.32.0.4	D6:bc:7b:20:32:c5
...	Database	Vethweplc5e...	10.32.0.5	42:a0:ae:b7:f5:97

KEY	Destination	Policy
XXX	10.32.0.4	Any
YYY	10.32.0.5	TCP:3306

Figure 7: Workflow of container-aware network isolation. The WebApp container accesses a service of the Database container in a container network shown in Figure 6, and the container-aware network isolation in the WebApp's network stack inspects their dependency and security policies.

To illustrate how BASTION implements container-aware network isolation, we consider the example in Figure 6, which illustrates an interdependence between WebApp and Database containers. In mediating the WebApp's packets, as shown in Figure 7, BASTION first checks the dependency between the WebApp and the destination by examining the inter-container dependency map using the destination IP address as a key. If any policies exist in the map, it concludes that the WebApp has a dependency on the destination - in this case the Database. The connection is allowed if matched to the policy for the Database, otherwise it is dropped.

BASTION implements a per-container rule partitioning strategy, which simplifies rule conflict evaluation, as only the container-relevant rules are considered, at deployment and evaluation times. In addition, it offers a minimized policy enforcement performance impact, as the match set is container-specific rather than host-global (as occurs with `iptables`). This approach offers an inherent key advantage over host global network policy rule enforcement as the number of containers increases. A natural strategy for managing large sets of global (host layer) network security rules is to apply a global rule optimization algorithm (e.g., aggregating the rules into a reduced set). Unfortunately, as containers are dynamically spun up and down, particularly within large orchestrated container ecosystems, their corresponding security rules would also require frequent updating. In such situations, global rule optimization could prove less effective and even be a new performance bottleneck over our rule partitioning strategy.

3.3.3 Gateway and Service-IP Handler

In container environments, it is possible for a subverted container to exploit the gateway to probe services within the host OS. To address this concern, BASTION's gateway-IP handler filters direct host accesses. When a network connection targets non-local container addresses, it includes the gateway MAC address and the IP address of the actual destination. Based on this fact, the gateway-IP handler blocks any direct host accesses by checking if both IP and MAC addresses be-

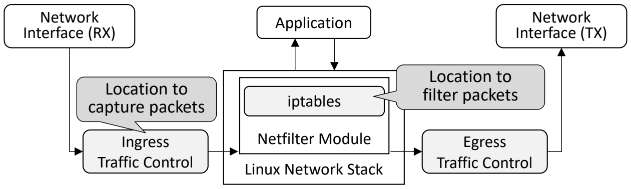


Figure 8: An illustration of the network packet processing sequence performed within the Linux kernel. While packets are filtered after delivered into the network stack, those can be still exposed during packet capture with nothing missed.

long to the gateway. It would be also possible that a network flow might access the gateways of other container networks, since these gateways are connected to the host network as well. Hence, the gateway-IP handler also filters unauthorized host accesses by comparing packets with the other gateways.

In Kubernetes environments, there is another special IP address, called a service IP address that is a virtual IP address used for the redirection to actual containers. Unfortunately, since service IP addresses do not belong to container networks, they can be simply considered as external IP addresses. Thus, BASTION additionally extracts the pairs of {service IP address, port} and {corresponding container IP address, port} from Kubernetes, and maintains a service map in each BASTION network stack. Then, when a container sends a packet with a service IP address and port, the service-IP handler overwrites the service IP address and port to an actual container IP address and port according to the service map. As a result, all inter-container communications can be conducted with the existent IP addresses, and the other security components can process packets as intended.

3.4 Traffic Visibility Service

The traffic visibility service provides point-to-point integrity and confidentiality among container network flows. Here, we present how BASTION hides irrelevant traffic from containers using two security components: source verification and end-to-end direct forwarding.

3.4.1 Source Verification

To precisely track the actual source of inter-container traffic, BASTION leverages the kernel metadata of incoming packets (e.g., ingress network interface index). The BASTION network stack of each container statically contains the network information (i.e., IP/MAC addresses and the metadata of container-side and host-side interfaces) of the corresponding container, and BASTION verifies the incoming traffic by comparing not only the packet header information but also its metadata to the container's information embedded in the BASTION network stack. If either the packet header information or the metadata is not matched with the container network information, BASTION identifies the incoming traffic as spoofed

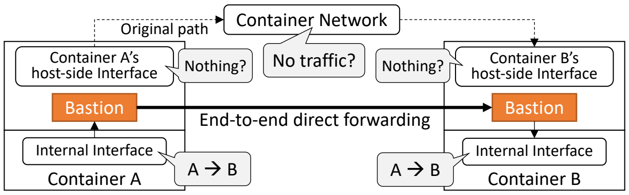

Figure 9: An illustration of how BASTION implements end-to-end direct packet forwarding to bypass exposure of intra-container traffic to other containers.

and drops it. Furthermore, even though network-privileged containers can inject spoofed packets into other containers, BASTION will drop their spoofed packets since the packet metadata would not be matched with the container network information. As a result, BASTION can effectively eliminate the spectrum of disruption and spoofing threats.

3.4.2 End-to-end Direct Forwarding

Current network stacks cannot prevent the exposure of inter-container traffic from other containers as the filter position is behind the capture point, as illustrated in Figure 8. Thus, if a malicious container has a capability to redirect the traffic of a target container to itself, it can monitor the traffic without restriction. In the case of network-privileged containers, they have the full visibility of all container networks: they can directly monitor the network traffic of others with no need to redirect the traffic.

To implement least-privilege traffic exposure, BASTION provides an end-to-end direct forwarding component. As shown in Figure 9, this component performs direct packet delivery between source and destination containers in the network interface level, bypassing not only their original network stacks (container-side) but also bridge interfaces (host-side); thus, it can prevent eavesdropping by peer containers. As soon as BASTION receives an incoming network connection from a container, it retrieves the interface information of a destination from the container network map. If the destination is a container in the same node, BASTION directly injects the packet stream into the destination container. If the destination is a container in another node, BASTION injects the packet to the external interface of a host. Then, once the special BASTION network stack of the external interface at the target node receives the packet, it directly injects the packet stream into the destination container. This traffic isolation prevents any traffic disclosure by other containers, preventing even network-privileged containers to view third-party traffic.

4 Implementation

We implement BASTION with 2.2K lines of C code and 5.1K lines of Python code on the Linux 4.16 kernel, which include two subsystems: a manager, and a network stack.

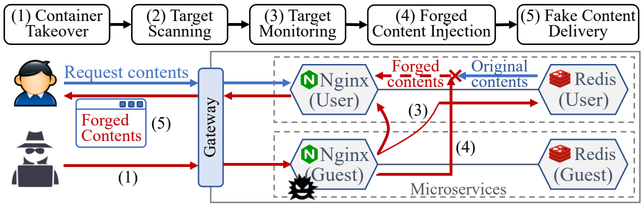

Figure 10: An example attack scenario within a Kubernetes environment. A compromised container from one service conducts a series of network attacks to hijack communications between other containers in a peer service.

BASTION Manager: For container collection, the manager periodically captures the attributes (e.g., NetworkSettings) of active containers from the Docker engine and the Kubernetes API server. Especially, in terms of explicit inter-container dependencies, it utilizes specific keywords (e.g., "*link*" and "*depends_on*"). In the case of Kubernetes, it does not have a way to explicitly define inter-container dependencies; thus, the manager utilizes `labels` to define explicit inter-container dependencies (e.g., "*dependencies: container A*"). In terms of network security policies, it extracts "*ingress*" and "*egress*" network security policies from `iptables` in a host and Kubernetes.

BASTION Network Stack: The security enforcement network stack for each container is implemented using eBPF [22] and XDP [19, 21], and the security services in the network stack inspect raw incoming packets in the `xdp_md` structure provided by XDP. During the inspection, they look up two hash maps (i.e., the container network and inter-container dependency maps), and these maps are synchronized with the maps in the corresponding management thread of the manager using BPF syscalls. Then, they use three types of XDP actions: 'XDP_TX' sends a packet back to the incoming container (the direct ARP handler), 'XDP_REDIRECT' injects a packet into the transmit queue of a destination (the end-to-end direct forwarding), and 'XDP_DROP' drops packets.

5 Security Evaluation

This section introduces a scenario that abuses the security holes in the current container network with real containers, and demonstrates how BASTION mitigates network attacks.

5.1 Scenario Validation

Figure 10 illustrates two independent services that are deployed along with common microservices [20, 54] in a Kubernetes environment. One is a service for legitimate users, and the other is a service for guest users. These services use Nginx [35] and Redis [38] container images retrieved from Docker Hub [13]. In this scenario, an attacker forges legitimate user requests, after infiltrating into the public-facing Nginx server by exploiting web application vulnerabilities.

Attack!

(d) Injecting packets with forged contents (before / after)

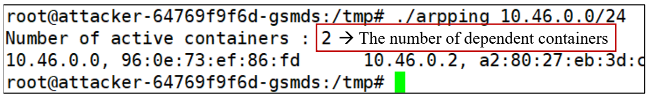
Figure 11: Screenshots demonstrating the attack scenario in a Kubernetes environment between two services.

In this attack kill chain, the attacker leverages three network-based attacks to compromise the Nginx-Guest container and successfully execute a man-in-the-middle attack. In the first step, he discovers active containers around the network through ARP-based scanning. Since all containers are connected to an overlay network and ARP packets are not filtered by `iptables`, the attacker can easily collect the network information of containers as shown in Figure 11-(a). Then, the attacker injects fake ARP responses into the network to make all traffic between the Nginx-User and the Redis-User containers passes through the Nginx-Guest. As shown in Figure 11-(b), we can see that the MAC address of the Redis-User in the ARP table of the Nginx-User is replaced with that of the Nginx-Guest, and the attacker monitors all traffic between the Nginx-User and the Redis-User (Figure 11-(c)). Lastly, the attacker replaces the response for the legitimate user with forged contents by internally dropping the packets delivered from the Redis-User and injecting forged packets. Then, the Nginx-User returns the forged contents back to the user instead of the original ones (Figure 11-(d)). In the end, the user receives forged contents as the attacker intended.

5.2 Effectiveness of Security Functions

Here, we focus on validating the effectiveness of BASTION against a range of network-oriented attacks. *For the following experiments, we disabled some of BASTION's security functions to show the before and after differences.*

Container Discovery: When a compromised container is used to conduct peer discovery to locate other containers, as shown in Figure 11-(a), the current container network stack allows an attacker to discover all neighboring containers. On the other hand, as shown in Figure 12, BASTION's



```

11:11.995848 IP 10.46.0.4.8000 > 10.46.0.3.33452: Flags [.],
11:11.995866 IP 10.46.0.3.33452 > 10.46.0.4.8000: Flags [.],
```

(B-2) Invisible injected RST packets (Nginx-User's view)

Figure 14: Restriction of Packet Injection. Panel A-1 shows the attacker injecting RST packets, and A-2 shows the victim session terminated by attacker's RST packet. Panel B-1 shows the trials of RST packet injections, and B-2 shows the failure of RST packet injection due to source verification.

direct ARP handler and container-aware network isolation reduce the reachability of each container based on its container dependencies (R1). As a result, the infected container (i.e., Nginx-Guest in Figure 10) has only one dependent container (i.e., Redis-Guest in Figure 10), and BASTION ensures that the container observes only its gateway and that dependent.

Passive Packet Monitoring: As discussed previously, a compromised container may be able to sniff the network traffic of a target container. Further, when an attacker compromises a "network-privileged" container, the attacker is provided access to all network traffic, with no restriction. BASTION mitigates these concerns by implementing end-to-end direct container traffic forwarding.

Figure 13 illustrates the utility of BASTION's direct forwarding. The upper panel, Figure 13-(a), shows the visible network traffic of a target container (i.e., Nginx-User) after spoofing the container without direct forwarding. The lower panel, Figure 13-(b), demonstrates the use of direct forwarding. When direct forwarding is applied, the only visible traffic from a given interface is that of traffic involving the container itself (R4, R5). *To highlight the differences, we intentionally make the flow from a source to a destination visible.* As a result, while the attacker can observe the source-to-destination flow, he can no longer observe the traffic in the reverse direction. If we fully apply end-to-end forwarding for all traffic, the attacker will see no traffic between them.

Active Packet Injection: Network-based attacks frequently rely on spoofed packet injection techniques to send malicious packets to target containers. BASTION prevents these attacks by performing explicit source verification. To illustrate its impact, we demonstrate before and after cases from the attacker and victim perspectives. In the following example, we enable source verification only at the IP-level and allow an attacker to conduct ARP spoofing attacks.

Figure 14-A illustrates cases without source verification. Here, the attacker spoofs the Nginx-User and receives the traffic of the Nginx-User. Further, the attacker injects RST packets to terminate the session of the Nginx-User. As soon as the attacker injects the RST packets, as shown in panel A-2, the Nginx-User receives the injected RST packets (see the received times of the RST packets), causing its session to be immediately terminated. This situation is remedied with explicit source verification. Although the attacker tries to inject RST packets, as shown in panel B-2, the RST packets are rejected by the source verification component and prevented from reaching the Nginx-User (R5).

6 Performance Evaluation

This section summarizes our measurement results of BASTION's performance overhead with respect to latencies and throughputs between containers under various conditions.

Test Environment: We used an experimental testbed comprising of three machines to construct a Kubernetes environment with the Weave overlay network and evaluate the BASTION prototype. One system served as the Kubernetes master node, while the others acted as container-hosting nodes. Each system was configured with an Intel Xeon E5-2630v4 CPU, 64 GB of RAM, and an Intel 10 Gbps NIC. `netperf` [18] and `iperf` [23] were respectively used to measure round-trip latencies and TCP stream throughputs.

6.1 Network Stack Deployment Overhead

BASTION periodically retrieves the container information from container platforms (1 second in our case) and deploys the network stacks for newly detected containers.

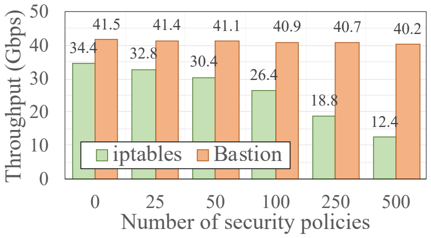

Figure 15: Inter-container throughput variations with the increasing number of security policies within a host.

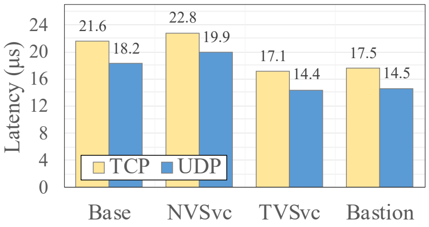

Figure 16: Inter-container latency measurements with different combinations of BASTION's services within a host.

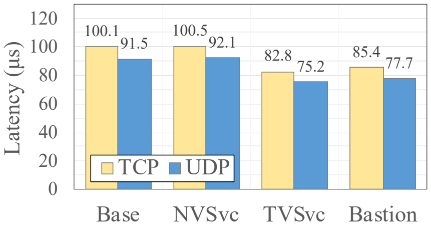

Figure 17: Inter-container latency measurements with different combinations of BASTION's services across hosts.

To see how long it takes to deploy a new network stack, we measured the deployment time while creating 100 containers. The result shows that it took 13.03 μs on average, meaning that BASTION's network stack would be deployed almost right after a new container is detected, while it can take a couple of seconds for containers to initialize their services (i.e., pulling container images from repositories, configuring container isolation, and starting services).

6.2 Security Policy Inspection Overhead

We compared the matching overheads with both `iptables`-based access control and BASTION, and Figure 15 shows the TCP throughputs with different numbers of security policies. For a fair comparison, we defined the same number of policies to each container for the overhead measurements of BASTION.

In the case of `iptables`, security policies for all containers are maintained collectively in the host kernel. Thus, when packets arrive from containers, `iptables` first looks up the policies for the corresponding containers and inspects them individually with the incoming packets. Also, `iptables` requires a large number of field matches (at least, source and destination IP addresses and ports for each policy) since it is designed for general access control. As a result, as shown in Figure 15, the throughput degraded by 23.3% with 100 policies and 64.0% with 500 policies. This trend points to a fundamental scaling challenge with the current policy enforcement approach for container networks. In contrast, the throughput degradation caused by BASTION was barely noticeable as the number of policies increased (3.2% with 500 policies) (R2). Such performance gains stem from BASTION's matching process optimized for containers, which comprises of a hash-based policy lookup for specific destinations and their port matches while there is no need to match source IP addresses and ports. Note that BASTION's performance gain with no security policy is because of the end-to-end direct forwarding that bypasses the host-side Linux network stack.

6.3 Performance: Single-Host Deployment

Here, we evaluated latencies and throughputs between containers hosted in the same node to measure the overhead of BASTION. Figure 16 provides the round-trip latency comparison of four test cases within a single node. The base case provides latency measurements for a default configuration of two containers that interacted with no security services, which were 21.6μs and 18.2μs for TCP and UDP packets respectively. When we applied BASTION's network visibility service, the latencies slightly increased by 5.7% and 9.3% due to the newly applied security functions requiring additional packet processing to derive the reachability check between containers. When we applied BASTION's traffic visibility service, the overall latencies were noticeably improved by 26.3% because our secure forwarding directly fed inter-container traffic into destination containers while bypassing the existing container networks. Finally, we observed the overall performance improvement with respect to the base case of 23.0% and 25.4% for TCP and UDP packets when all BASTION security functions were fully applied (R6). Table 2 also shows that the overall throughput of BASTION was improved by 20.6% compared to that of the base case within a host.

Throughput (Gbps)	Base	Network Visibility	Traffic Visibility	Bastion
Within a host	34.4	33.7	41.8	41.5
Across hosts	4.28	4.23	4.91	4.83

Table 2: Inter-container throughput measurements for the base case (no security) and BASTION's services.

6.4 Performance: Cross-Host Deployment

Next, we measured the latencies and throughput for cross-host container deployments. Figure 17 illustrates the measurement results with different combinations of BASTION's security services. Compared to the intra-host measurements, the overall latencies significantly increased due to physical link traversal and tunneling overheads between hosts; thus, the latency of the base case became 100.1μs and 91.5μs for TCP and UDP packets respectively. Also, given the network impact, the overhead caused by BASTION's network-visibility service receded (less than 1%). Next, when we introduced BASTION's traffic-visibility service, the latencies were reduced by 21.3%

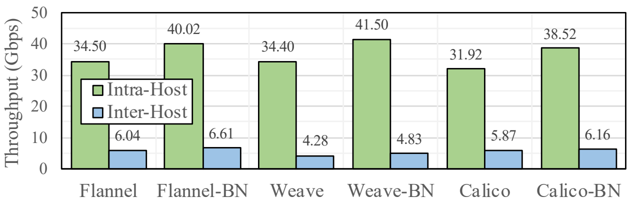

Figure 18: Throughput comparison with different types of container networks. BN = (when BASTION is deployed).

on average because our secure forwarding directly passed network packets from the source container to the destination container via the external interfaces. Finally, when we applied all security services, the latencies decreased by 17.7%, a significant improvement compared to the base case (R6). These latency improvements translated to a cross-host throughput improvement of 12.9%, as shown in Table 2.

6.5 Performance: Networking Plugins

Lastly, we compared the throughput variations in different types of container networks when BASTION is deployed. Figure 18 shows the TCP-stream throughputs between intra-host and inter-host containers in three container networks (i.e., Flannel, WeaveNet, and Calico). From the results, we see that the intra-host throughputs are improved 16.0% in the Flannel network, 20.6% in the Weave network, and 20.7% in the Calico network through BASTION. In terms of the inter-host throughputs, we also see the performance improvements (9.4%, 12.9%, and 4.9% respectively) through BASTION. In sum, we ascertain the fact that BASTION can provide not only further network isolation and security enforcement but also better performance in various container networks.

7 Related Work

Container Security Analysis. There have been several efforts [15, 16, 24, 32, 33, 53] that have analyzed the security issues of container implementations. For example, Dua et al. [15] analyzed various container implementations, concluding that they are yet insecure from the perspective of the filesystem, network, and memory isolation. More specifically, Jian et al. [24] demonstrated a Docker *escape attack*, which allows an adversary to break out of the isolation of a Docker container by exploiting a Linux kernel vulnerability. Another research area [43, 45, 47, 48, 52] of container security focuses on container images. Shu et al. [43] and Tak et al. [47, 48] have performed a large-scale vulnerability assessment of Docker images on Docker Hub and shown that many images were outdated and vulnerable. While these studies broadly point out the security issues of containers, their goals differ from our work. Rather, BASTION focuses on container networks.

Container Security and Isolation. Bacis et al. introduced DockerPolicyModules (DPM) [4] that allow Docker image maintainers to specify and ship SELinux policies within their images. Sun et al. [46] proposed security namespaces that enable containers to independently define security policies and apply them to a limited scope of processes. SCONE [3] presented a secure container mechanism for Docker containers by isolating them inside of SGX enclaves. LightVM [29] wraps containers in lightweight virtual machines (VMs). X-Containers [42] isolate containers that have the same concerns together on top of separate library OSes. These efforts are complementary to the network-focused objectives of BASTION, and could be combined to deliver security services that span both the system and networking services.

Container Network Security. Most container network solutions [57, 58] have focused on container network performance, with little attention to fine-grained policy enforcement. A few recent studies investigated the security issues in container networks. Bui [5], Comb et al. [9] and Chelladhurai et al. [6] analyzed Docker container security, finding that Docker is vulnerable to ARP spoofing and MAC flooding attacks in default settings. Our work extends these results by identifying broader class of attacks, and we present system extensions that address these problems. With respect to security policies for inter-container communications, while most solutions [39, 49, 55] have adopted `iptables`, Cilium [7] provides its own API-aware security mechanisms for L3/4/7 policies. As we discussed previously, while Cilium pursues API-level network security filtering to define and enforce both network- and application-layer security policies, BASTION fundamentally redesigns a network stack per container to construct an inherently secure container networking system.

8 Conclusion

Containerization has emerged as a widely popular virtualization technology that is being aggressively deployed into large-scale enterprise and cloud environments. However, this adoption could be stifled by critical security issues, which remain understudied. We have analyzed the security challenges involved in the current container network stack, and addressed these challenges by presenting BASTION, an intelligent communication sandbox for securing container-network communications, using Linux kernel features. In this work, we raise awareness of several security problems that lie within today's container networks, and offer security services for halting these problems in real-world container deployments.

Abstract

Ensuring high reliability and availability of virtualized NVMe storage systems is crucial for large-scale clouds. However, previous I/O virtualization systems only focus on improving I/O performance and ignore the above challenges. To this end, we propose Spool, a reliable NVMe virtualization system. Spool has three key advantages: (1) It diagnoses the device failure type and only replaces the NVMe devices with actual media errors. Other data link errors are handled through resetting the device controller, minimizing data loss due to unnecessary device replacement. (2) It ensures the consistency and correctness of the data when resetting the controller and upgrading the storage virtualization system. (3) It greatly reduces the restart time of the NVMe virtualization system. The quick restart eliminates complaints from tenants due to denial-of-service during a system upgrade and failure recovery. Our evaluation shows that Spool provides reliable storage services with performance loss smaller than 3%, and it reduces restart time by 91% when compared with SPDK.

1 Introduction

In large-scale public clouds, the cores and memory are virtualized and shared by multiple tenants. A single physical server can serve up to 100 virtual machines (VMs) from either the same or different tenants [41]. On the physical server, VMs are managed with VM hypervisors, such as VMware [13], KVM [25], and Xen [14]. The hypervisors are also responsible for handling the interactions between the guest operating system in the VMs and the host operating system on the physical server.

Virtualizing I/O devices so that tenants can share them has attracted the attention of both industry and academia [15, 23, 31, 33, 40, 42]. A guest VM mainly stores and accesses its data on local devices through the I/O virtualization service with high throughput and low latency. For instance, the Big Three of cloud computing (Amazon EC2 I3 series [2], Azure Lsv2 series [3], and Alibaba ECS I2 series [1]) are providing the next generation of storage optimized instances for workloads that require high I/O throughput and low latency. These products are driven by local devices that eliminate the long latency over the network [8]. At the same time, accessing data from local devices increases the risk of a single point of failure as the reliability of data is dependent on the reliability of the host node.

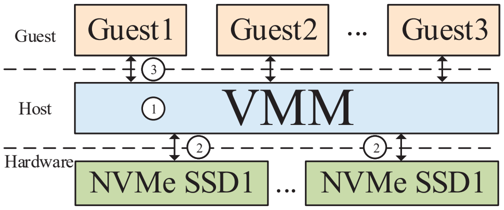

Figure 1: Virtualizing NVMe-based storage system.

Solid-state drives (SSDs) are often adopted as storage devices due to their high throughput and low latency compared to those of hard drives. In particular, the recent NVM Express (NVMe) interface [9] further increases the I/O performance of SSDs compared with the traditional SATA interface. Mainstream storage virtualization solutions, such as Virtio [29], support NVMe devices. Because serious performance degradation is observed in I/O virtualization [22], userspace NVMe driver in QEMU [43], Storage Performance Development Kit (SPDK) [38], SPDK vhost-NVMe [39], and Mdev [27] have been proposed to further improve the I/O throughput of virtualized NVMe devices.

While prior researchers focused on improving the read/write throughput and reducing the latency of virtualized NVMe devices, they ignored the reliability problem although it is equally important. In large-scale public clouds, NVMe device failures occur due to heavy use and the need for NVMe virtualization systems to be upgraded often to add new features or apply new security patches. Emerging NVMe virtualization systems fail to handle failure recovery and system upgrades efficiently. To better explain this problem, Figure 1 shows an example where multiple tenants share a virtualized NVMe storage system on a physical node.

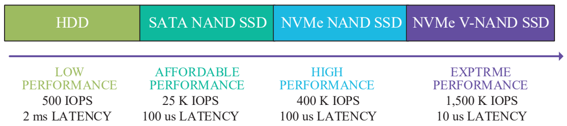

Figure 2: Development of the hardware I/O performance.

With emerging virtualized storage systems, to fix an NVMe device failure on a node, the administrator directly replaces the failed device through either cold-plug or hot-plug. This failure recovery mechanism results in unnecessary data loss from the failed NVMe device. The statistics of our in-production cloud show that only 6% of 300,000 device failures involve media errors that can only be resolved by replacing with a new device. Other device failures are caused by data link errors that can be resolved by resetting the NVMe device controller. Resetting an NVMe device's controller would not result in data loss from the device, and we can perform the reset operation fast without removing the failed device (② in Figure 1) and restarting the virtualization system (① in Figure 1).

The standard procedure for upgrading the virtualized storage system on a node is stopping the daemon process that runs the system, updating the binary file, and then initializing the whole software stack of the virtualization system again [17]. In this period, all the I/O devices on the node are inaccessible due to the lack of an I/O virtualization system. Our measurement shows that the software initialization procedure already spends approximately 2.5 s probing all the I/O devices and SPDK's Environment Abstraction Layer (EAL) [38] (to be discussed in detail in Section 5). This long downtime hurts the user experience. A possible solution to reduce the impact of the upgrade is migrating the VMs (and the corresponding data) to other nodes [19, 41]. However, live VM migration is too costly for regular backend updates, especially when a large amount of backend requires updating, for example, when applying an urgent security patch.

However, the data written by the Guest VMs may be lost when resetting the controller or performing the upgrade (③ in Figure 1). The loss happens in the case that the data persisted in the NVMe device (still in the submit queue) when the reset operation or the process restart was performed. No prior work on NVMe virtualization has considered such a reliability problem.

To resolve the above problems, we propose *Spool*, a holistic reliable virtualized NVMe storage system for public clouds with local disks. Compared with prior NVMe virtualization systems, Spool has the following key advantages: (1) It diagnoses the device failure type and only replaces the NVMe devices with actual media errors. Other data link errors are handled through resetting the controller, minimizing data loss due to the unnecessary disk replacement. (2) It ensures the consistency and correctness of the data when resetting the controller and upgrading the virtualization system. (3) It greatly reduces the restart time of the NVMe virtualization system to approximately 100 milliseconds. The quick restart eliminates complaints from tenants due to denial-of-service during system upgrades and failure recovery.

To be more specific, Spool is comprised of a *cross-process journal for recovery*, an *isolation-based failure recovery component*, and a *fast restart component*. The cross-process journal resides in the shared memory and records the data status from all the VMs. Even if Spool is restarted, the data in the journal is accessible for the new Spool process. Furthermore, an instruction merge is proposed to eliminate the inconsistency of the journal with minimal overhead. An "instruction" is a step within a transaction that updates the journal. The failure recovery component diagnoses the NVMe device error. Based on the error code, Spool either isolates and replaces the devices that have media errors or resets the controller (using the journal for reliability). The restart component records the runtime data structures of the current Spool process in the cross-process journal. By reusing the data structures at the restart for a system upgrade, we significantly reduce the downtime.

To the best of our knowledge, Spool is the first holistic virtualized system that is capable of handling hardware failure and NVMe virtualization system upgrades reliably. Spool is currently deployed in an in-production cloud that includes more than 20,000 physical nodes and 200,000 NVMe-based SSDs.

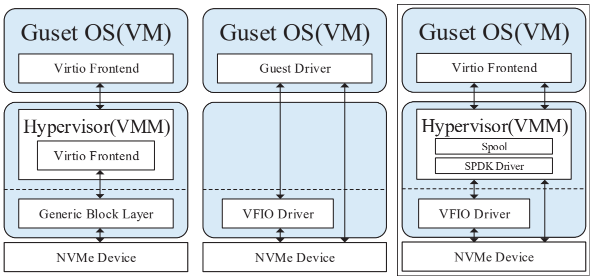
The main contributions of this paper are as follows.

- **An instruction merge-based reliability mechanism.** The instruction merge eliminates data inconsistent with the cross-process journal for recovery even if abnormal exits occur.
- **A restart optimization method.** The method greatly reduces the downtime of Spool during the upgrade and enables frequent system upgrades for adding new features and applying patches without affecting the tenants.
- **A hardware fault processing mechanism.** The mechanism diagnoses the device failure types and only replaces the NVMe devices with media errors, minimizing data loss due to unnecessary disk replacement.

Our experimental results show that Spool provides reliable storage services based on a shared memory journal with less than 3% performance loss, and it reduces the system restart time by 91% when compared to SPDK.

2 Background and Motivation

In this section, we introduce the virtualized NVMe storage systems and the motivation behind the design of Spool.



(a) Virtio (b) Passthrough based on VFIO (c) Spool based on SPDK

Figure 3: Comparison of NVMe virtualization mechanisms.

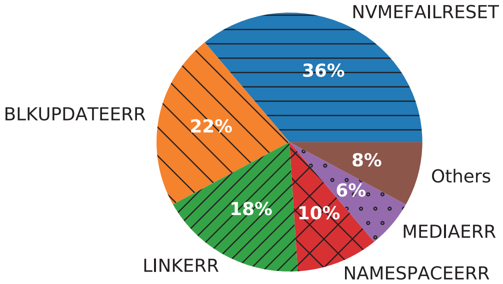


Figure 4: Breakdown of NVMe hardware failures.

2.1 Virtualized NVMe Storage Systems

The performance of an I/O device is impacted by both the storage media and the I/O software stack. As shown in Figure 2, Samsung NVMe SSD devices based on the latest V-NAND technology have increased the IOPS to 1.5 million and reduced the latency to 10 microseconds. In this scenario, the traditional SATA (Serial ATA) [34] interface for storage devices has become the performance bottleneck for such SSDs. Due to the limitation of the Advanced Host Controller Interface (AHCI) architectural design, the theoretical data transmission speed of the SATA interface is only 600 MB/s [34]. To solve the I/O bottleneck brought by the interface, the NVMe (Non-Volatile Memory Express) protocol [9] is designed and developed using a PCIe interface instead of SATA. Currently, NVMe supports deep queues with up to 64K commands to devices within a single I/O queue [9].

In public clouds, instead of selling raw hardware infrastructure, cloud vendors typically offer virtualized infrastructure as a service to maximize hardware resource utilization [16, 18]. Virtualization technology has shown its heroism, especially in the birth of hardware virtualization technology, such as Intel VT technology, which has greatly expanded the application scope of virtualization technology. There are three parts to the realization of virtualization: *CPU virtualization, memory virtualization*, and *I/O virtualization*. Among them, I/O virtualization requires more focus, and its performance directly determines the performance of the guest VM [22, 30, 32].

There are generally three I/O virtualization mechanisms: Virtio [29], VFIO [36], and SPDK-based userspace applications [38]. Figure 3 shows a comparison between Virtio, VFIO, and our SPDK-based design, Spool.

As for Virtio, the frontend exists in a guest OS, while the backend is implemented in a hypervisor, such as QEMU [12]. The frontend transfers I/O requests to the backend through the virtqueue, implemented as ring buffers, including *available ring* and *used ring* buffers. Available ring buffers could save multiple I/O requests driven by the frontend and transfer them to the backend for batch processing, which can improve the efficiency of information exchange between the client and hypervisor. However, a problem remains that each I/O request passes through the I/O stack twice for guest and host, whereas in modern storage devices based on NAND flash, the throughput and latency of VMs can only achieve 50% of the native performance [27].

As for VFIO, VMs directly access an NVMe device through passthrough, relying on hardware support (e.g., Intel VT-d). A VM approaches near-native performance on both latency and throughput with passthrough. However, a single device can only be assigned to one guest client. On the contrary, a host often runs multiple clients in a virtualized environment. It is difficult to ensure that each client can get a directly assigned device. Also, a large number of devices are allocated to clients independently, increasing the number of hardware devices as well as the cost of the hardware investment.

The Storage Performance Development Kit (SPDK) provides a set of tools and libraries for writing high-performance, scalable, user-mode storage applications. The bedrock of SPDK is a userspace, polled-mode, asynchronous, lockless NVMe driver [38]. SPDK enables zero-copy, highly parallel access direct to SSDs from a userspace application. User-mode drivers help improve the stability of the host operating system because they can only access the address space of the processes running them, and a buggy implementation does not cause system-wide problems. Spool is proposed based on the SPDK NVMe driver but focuses on the reliability of the virtualized storage system.

2.2 Reliability Problems

All the above I/O virtualization mechanisms ignore the high availability and reliability problems, although they are equally important in public clouds. To be more specific, state-of-the-art SPDK-based applications result in *unnecessary data loss* and *poor availability* when dealing with failed NVMe devices and upgrading applications, respectively.

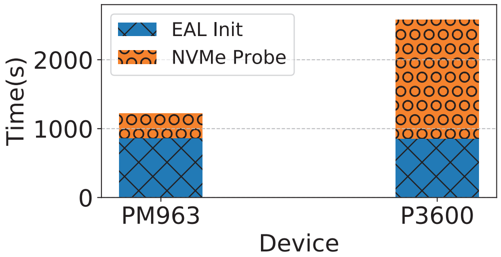

Figure 5: Breakdown of SPDK's start time on two NVMe SSDs.

2.2.1 Unnecessary Data Loss

If an NVMe device failure is detected on the hardware node, the device is in the failed state. When a device failure occurs on a node, all the VMs on the node are de-allocated and migrated to a healthy node by a standard procedure [11, 41]. After that, all the data on the failing node are securely erased. The victim tenants' data are lost and the tenants must proactively load their data on the new node again. With emerging virtualized storage systems like SPDK, to fix an NVMe device failure on a node, the administrator directly replaces the failed device through hot-plug.

The above method results in significant unnecessary data loss because a single NVMe device may store data from multiple tenants, and NVMe devices have higher storage density, more vulnerable components (e.g., a Flash Translation Layer), and relatively higher failure rates. To demonstrate this problem in detail, we collected 300,000 NVMe device failures in our in-production environment. Figure 4 shows the breakdown of device failures. Most of the failures, 36%, are due to the NVMe controller failure error (NVMEFAILRESET). BLKUPDATEERR is the block update error. LINKERR is the PCIe interconnect link error. NAMESPACEERR is the NVMe device's namespace error. The pie chart shows that only 6% of the hardware failures are due to real media errors (MEDIAERR). Our investigation shows that most failures are caused by errors in the data link layer (e.g., namespace error, hardware link error, NVMe reset fail error), and these failures can be resolved by simply resetting the NVMe controller.

In summary, the current failure recovery method with SPDK results in significant unnecessary data loss.

2.2.2 Poor Availability

I/O virtualization systems tend to be upgraded frequently to add new features or apply security patches. When upgrading an I/O virtualization system, the key requirement is minimizing the I/O service downtime while ensuring the correctness of the data. There are two methods available to cloud vendors: VM live migration and live upgrade. Unfortunately, VM live migration is too costly for regular backend updates, especially when a large amount of backend requires updating, for example, when applying an urgent security patch, and for storing optimized instances with local NVMe storage , VM live migration is not even supported by cloud vendors [11]. The only way for us is to support the live upgrade and eliminate the downtime as much as possible.

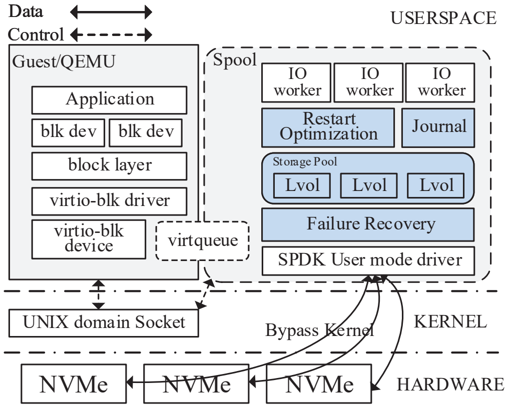

Figure 6: Design of Spool.

The I/O virtualization system must be restarted to complete the upgrade. With SPDK, we need to initialize the DPDK EAL library, probe the NVMe devices, and initialize the internal data structure of SPDK itself. SPDK spends a different amount of time in the "probe devices" step when resetting the controllers of different devices. The time required for each step is shown in Figure 5. As can be observed from this figure, the service downtime caused by the live upgrade is up to 1,200 ms for Samsung PM963 SSD. For Intel P3600, the total service downtime will be longer and lasts up to 2,500 ms.

In summary, the long downtime hurts the availability of the I/O virtualization system.

2.3 Design Principle of Spool

To resolve the unnecessary data loss and poor availability problems, we propose **Spool**, a holistic NVMe virtualization system. Spool is designed based on three principles:

- It should be able to identify the causes of device failure and adopt different methods to handle each failure. In this way, Spool eliminates most unnecessary NVMe device replacement.
- It should be able to optimize the restart procedure during a live upgrade so that the downtime can be minimized.
- It should be able to ensure that data access requests from the guest OS are not lost during a controller reset and live system upgrade.

3 Methodology of SPOOL

Figure 6 shows the design architecture of Spool, where the blue components are new relative to SPDK. Based on Spool, the NVMe devices on a node are virtualized and organized into a *Storage Pool (hence, "Spool")*. The virtualized NVMe devices are divided into multiple logical volumes that are managed through the buddy system [28]. The logical volumes are exposed to the guest OS in the form of block devices. As shown in the figure, the guest drivers communicate with Spool over shared memory. Specifically, the I/O worker on the host node polls I/O requests from the vhost virtqueue of block devices and submits to the corresponding physical devices. Spool is comprised of a *cross-process journal*, an *isolation-based failure recovery component*, and a *fast restart component*. Based on the three components, Spool ensures high reliability and availability of the storage pool.

The cross-process journal records each I/O request and its status to avoid data loss. The journal provides data access across process lifecycles, even if Spool restarts for an upgrade or exits abnormally. An instruction merge mechanism is proposed to eliminate the possible inconsistency of the journal itself due to an abnormal exit and to avoid the copy overhead of atomic operations.

The restart component records the runtime data structures of the current Spool process in shared memory. Spool catches the termination signals including *SIGTERM* and *SIGINT* to ensure the completion of all INFLIGHT I/O requests before actual exit. Spool reuses the data structures at the restart, thus significantly reducing the downtime spent on initializing the Environment Abstraction Layer (EAL) and resetting the device controller.

Spool diagnoses the device failure type online through self-monitoring, analysis, and reporting technology (S.M.A.R.T.) data [35]. For media errors, the failure recovery component isolates the failed device so that the administrator can replace the failed device through hot-plug. All the other NVMe devices are unaffected by the failed device. For data link errors, the recovery component resets the device's controller directly, thus minimizing data loss due to unnecessary disk replacement.

We implement Spool based on the SPDK userspace NVMe driver. Spool combines the advantages of Virtio and VFIO (Figure 3). Furthermore, instead of implementing the actual Virtio datapath, we offload the datapath from QEMU to Spool adopting the vhost-user protocol. Adopting this protocol, the guest OS directly interacts with Spool without QEMU's intervention. In addition, by adopting the SPDK userspace polled driver specification [38], Spool eliminates the overhead of system calls and data copies between kernel space and userspace stacks on the host and achieves high I/O performance.

4 Reliable Cross-Process Journal

In this section, we describe the reliability problem in the Virtio protocol that virtualizes the NVMe device, and we present the design of a cross-process journal that improves reliability.

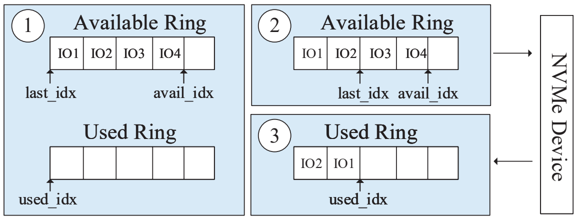

Figure 7: Design of Virtio block virtualization protocol.

4.1 Problem Statements

Figure 7 shows the design of the Virtio block driver that handles I/O requests in the guest OS. The I/O requests are processed in a *producer-consumer* model, where the guests are producers and the storage virtualization system is the consumer.

Specifically, the Virtio driver of each guest OS maintains an available ring and a used ring to manage its I/O requests. ① When an I/O request is submitted, the descriptor chain of the request is placed into the descriptor table. The descriptor chain includes the metadata, buffer, and status of the request. The metadata indicates the request type, request priority, and the offset of read or write. The guest driver places the index of the head of the descriptor chain into the next ring entry of the available ring, and the available index of the available ring ("`avail_idx`" in Figure 7) is increased. Then, the driver notifies the storage virtualization system that there is a pending I/O request. ② Meanwhile, the storage virtualization system running in the host obtains the several head indexes of the pending I/O requests in the available ring, increases the last index of the available ring ("`last_idx`" in Figure 7), and submits the I/O requests to NVMe device hardware driver. ③ Once a request is completed, the storage virtualization system places the head index of the completed request in the used ring and notifies the guest. Here, it is worth noting that the available ring and used ring are allocated by the guest, and the `avail_idx` is maintained by the guest, while both the `last_idx` and `used_idx` are maintained by the storage virtualization system.

The storage virtualization system may adopt either interrupt or polling to obtain I/O requests from the guest OS. Polling is able to fully utilize the advantages of NVMe devices to reap significant performance benefits [27, 37, 38], and Spool uses a dedicated I/O thread to poll I/O requests from the guest and data from the NVMe device instead of interrupts. This mechanism is implemented based on the SPDK userspace NVMe driver.

In general, the storage virtualization system runs well with the above procedure. However, if the storage virtualization system restarts for an upgrade or the NVMe device controller is reset, data loss may occur.

In the case of Figure 7, the storage virtualization system obtains two I/O requests, *IO1* and *IO2*. Then, the `last_idx` is incremented from *IO1* to *IO3* in the available ring. If the storage virtualization system restarts at this moment, the last available index will be lost, which means that it does not know where to proceed with I/O requests after the restart. Even if the last available index persists, there is no way to know whether the obtained *IO1* and *IO2* have been completed. If we simply continue to process the next request based on the last available index, the previously obtained incomplete request will be lost.

When we reset the controller of an NVMe device, all the admin and I/O queue pairs are cleared. Suppose that *IO1* and *IO2* have been submitted but they are still in the device I/O queue and have not been processed. Due to the lack of an I/O request state, the submitted I/O request in the cleared I/O queue pairs will never be checked as completion from the NVMe device.

In summary, a journal is needed to maintain I/O consistency.

4.2 Design of the Journal

We propose a cross-process journal of data that persists in shared memory to solve the problem of data loss caused by the storage virtualization system restart or device controller reset. Spool persists the following data in the journal.

- Last available index (`last_idx`) of the available ring. The index references to the starting descriptor index of the latest request that the Virtio backend reads from the available ring.

- The head index of each request in the available ring. The index refers to the head of a descriptor chain in the descriptor table.

With the `last_idx` in the journal, Spool knows which requests have been processed after restarting for the upgrade and is able to continue processing the remaining to-be-processed requests. If a request's starting descriptor index is referenced between `last_idx` and `avail_idx` of the available ring, it is a to-be-processed request.

Algorithm 1 Algorithm of cross-process journal

```
Require: head1: The head index of request in the available ring;
Require: head2: The head index of completed request from the driver;
Require: req[]: A ring queue to mark each I/O reqeust in the journal;
Require: aux: A temporary union variable to record multiple variables;
 1: poll head1 from the available ring;
 2: aux.state = START;
 3: aux.last_idx = journal->last_idx+1;
 4: aux.last_req_head = head1;
 5: *(volatile uint64_t *)&journal->val = *(volatile uint64_t *)&aux.val;
 6: req[head1] = INFLIGHT;
 7: journal->state = FINISHED;
 8: submit I/O request to driver;
 9: poll head2 completion;
10: journal->usd_idx++;
11: req[head2] = DONE;
12: put head2 to the used ring, may goto 10 or 13;
13: update used_index of the used vring with usd_idx of journal;
14: req[head2] = NONE;
```

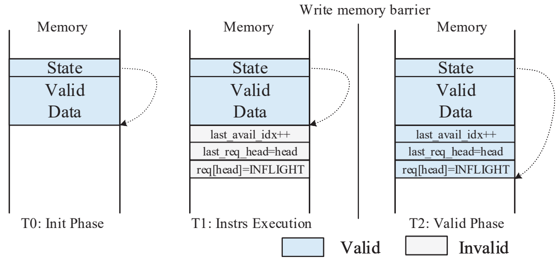

Figure 8: Transactional execution of multiple memory access instructions.

At the same time, when processing an I/O request in Spool, the request is given one of three states: INFLIGHT, DONE, or NONE. The cross-process journal uses Algorithm 1 to manage the I/O requests. To be more specific, when Spool gets a request from the frontend, it persists the head index of this request and marks the request as INFLIGHT, updates `last_idx`, and submits the request to the hardware driver. Once the I/O request completes, Spool updates the persisted `used_idx` in the journal and marks the request as DONE. After that, Spool returns the result of this request to the frontend, updates the used index of the frontend, and marks the request as NONE.

Adopting this method, if Spool restarts, the new Spool process can find out which request was not completed before the restart. In this way, the new Spool process resubmits the requests in the INFLIGHT state.

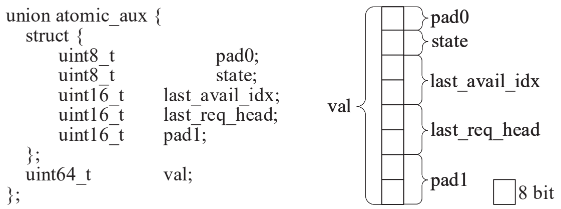
4.3 Merging Journal Update Instructions

An intuitive idea is to use shared memory as a journal to save this information with low latency overhead. However, it is challenging to ensure the consistency of the journal itself because Spool must update the journal multiple times during the processing of an I/O request.

Specifically, the process of each I/O request in Spool involves updating the last available index and marking the state of the request as INFLIGHT. During the processing, if Spool restarts or the controller is reset between the first two instructions, this request is lost.

If we can guarantee that instruction 3 (increase `last_idx`) and instruction 6 (change the request's status) in Algorithm 1 are executed in an atomic manner, the request loss problem can be resolved. However, only reading or writing a quadword aligned on a 64-bit boundary is guaranteed to be carried out atomically [7] in the memory, and the two instructions are not atomic when operating on the cross-process journal that resides in the memory.

To resolve the above problem, we design a multiple-instruction transaction model to guarantee atomic execution of the two instructions. As shown in Figure 8, each transaction consists of three phases. In T0, the init phase, we make a copy of the variable to be modified, such as `last_idx`, and in T1,



```
union atomic_aux {
    struct {
        uint8_t          pad0;
        uint8_t          state;
        uint16_t    last_avail_idx;
        uint16_t    last_req_head;
        uint16_t    pad1;
    };
    uint64_t        val;
};
```

Figure 9: Aux data structure that enables the update of multiple indexes using a single instruction.

the transaction will be in the START state. After all the instructions complete, the transaction will be in the FINISHED state in T2. Because the state is guaranteed to be carried out atomically, once the last available index updates, the related request is recorded as INFLIGHT in the journal. If any failure occurs in one transaction, we rollback the transaction to erase all data modifications with the copy.

As shown in Figure 9, we also design an auxiliary data structure carefully to eliminate the overhead of making a copy in T0 using a union type. The state, last available index, and head index of the related request are padding to 64 bits and a union memory block with a 64-bit value. We could update these three records within one instruction in Algorithm 1 step 5. This is a valuable trick to efficiently maintain journal consistency.

4.4 Recovering I/O Requests from Journal

Spool uses Algorithm 2 to recover the unprocessed I/O requests before the restart. With multiple journal transactions and an auxiliary structure, the new Spool process before the restart only needs to check the state and decide whether to redo the transactions or not.

Algorithm 2 Algorithm for recovering I/O requests

```
if (state == START) {
    req[last_get_req_head] = INFLIGHT;
    state = FINISHED;
}
jstate = (last_used_idx == used_idx) ? NONE : INFLIGHT
change all requests with done status to jstate;

last_used_idx = used_idx;
submit all requests marked as INFLIGHT;
```

The recovery algorithm works based on the value of the used index of vring and the last used index in the journal. If they are equal, Spool may crash after step 13 in Algorithm 1, but we do not know whether step 14 completes. Therefore, Spool tries to execute step 14 again and changes the states of the DONE requests to NONE. Otherwise, the request's process may be broken between steps 10 and 12. In this case, we do not know whether the request in the state DONE has been submitted to the frontend. To avoid losing any I/O request, we roll back the status of all the DONE requests to INFLIGHT. Because the frontend always has correct data, we synchronize the last used index in the journal with the frontend used index. In the last step, Spool resubmits all the requests that are in the INFLIGHT state.

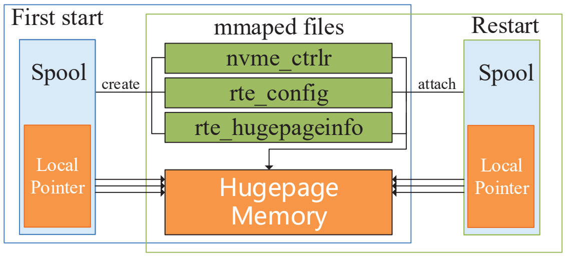


Figure 10: Boosting the restart of Spool by reusing the stable configurations.

Now, in Spool, the size of a single journal is only 368 bytes because it only records the metadata and the indexes of the requests in the available ring. Note that the above algorithm does not take precautions against the journal wrapping around; this is not possible because the journal is the same size as the available ring, so the guest driver will prevent such a condition.

5 Optimizing Spool Restart

As shown in Figure 5, when restarting a storage virtualization system, it initializes the EAL (Environment Abstraction Layer) in the DPDK driver and probes the NVMe devices in the SPDK driver on the host node. The relatively long restart time (ranging from 450 ms to 2,500 ms) hurts the availability as the whole storage system is out of service before the restart completes. In this section, we describe the method of optimizing the restart procedure in Spool.

5.1 Reusing Stable Configurations

During EAL initialization, the DPDK driver reserves all the memory in an IOVA-contiguous manner and sets up the huge pages for memory usage, such as I/O request buffers that are shared by the host userspace datapath and the physical device to perform DMA transactions. To be more specific, DPDK maps all the available huge pages to the process address space of DPDK, reads "`/proc/self/pagemap`" from the host OS to find the corresponding physical addresses of the huge pages, and sorts and merges the physical addresses into large contiguous chunks. After that, DPDK uses the physically continuous huge page chunks as memory segments. This design choice enables better hardware data prefetching and results in higher communication speed. Our experiment shows that the whole time spent on obtaining the physical memory layout information of huge pages is approximately 800 milliseconds, accounting for 70.9% of the total down time for a Samsung PM963 NVMe device. In our cloud, all the SSDs are restarted by more than 800,000 times in total in a single year. More restarts are required to periodically update the SPDK driver or apply new security patches. The long EAL initialization results in a long restart time and poor tenant experience.

Based on the above findings, we optimize the initialization steps of Spool. Specifically, the new Spool process after restart reuses the memory layout information from the current Spool process. Figure 10 shows the way we enable memory layout reuse. As shown in the figure, after the first startup of Spool, we store the related information (e.g., the huge pages in use and the virtual addresses of the huge pages) in the memory-mapped files that reside in the memory. If Spool restarts, it directly obtains the required information from the memory-mapped files in the memory with short latency and operates normally. Specifically, the "`rte_config`" file stores the global runtime configurations, and the "`ret_hugepageinfo`" file stores the memory layout information related to the huge page chunks used by Spool.

The above design does not guarantee that the new Spool after the restart will still use the largest continuous physical memory. This is because other processes may release huge pages and form larger continuous physical memory chunks. This design choice eliminates the long scan time of huge pages and does not degrade the performance of Spool.

5.2 Skipping Controller Reset

When probing the NVMe devices during the restart of the SPDK driver, more than 90% of the time is spent resetting the controller of NVMe devices. On an Intel P3600 SSD, the NVMe probe stage takes more than 1500 milliseconds (Figure 5). During the reset of the controller, SPDK frees the current admin queue, the I/O queue[1] in the controller, and creates them again for the controller after the reset.

Compared with SPDK, Spool skips the controller reset step during restart and reuses the data structures of the controller. This design is valid because the restart of Spool is not caused by media errors or data link errors. In this case, the data structures of the NVMe device controllers are not broken. To achieve reuse, Spool saves the NVMe device controller-related information in the memory-mapped file "`nvme_ctrlr`", as shown in Figure 10). After Spool restarts, it reuses the data of the device controller.

The challenging part here is that the context of the I/O request has disappeared with the exit of Spool. Therefore, we need to ensure the admin queue and I/O queue are completely clean.

In general, various signals are used to terminate one running process for an OS, such as *SIGTERM*, *SIGINT*, and *SIGKILL*. The default action for all of these signals is to cause the process to terminate. To gracefully terminate, we catch the termination signals including *SIGTERM* and *SIGINT* to ensure the completion of all INFLIGHT I/O requests before actually terminating. In that case, we could skip the reset operation after restart. Regarding the *SIGKILL* signal, which could not be handled in process or abnormal exit, we reset the controller after restart as usual.

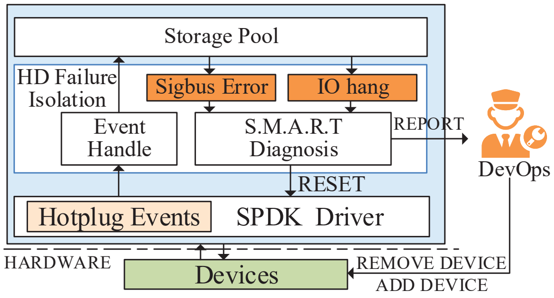

Figure 11: Handling hardware failures in different ways.

6 Hardware Fault Diagnosis and Processing

Traditionally, any NVMe device hardware failure causes the whole machine to be offline and repaired, and all VMs on the failing node need to be proactively migrated to a healthy node. With emerging virtualized storage systems like SPDK, to fix an NVMe device failure on a node, the administrator directly replaces the failed device through hot-plug. On one hand, this causes data loss for users, and on the other hand, it increases operating costs.

To minimize data loss and reduce operating costs, we have implemented a fault diagnosis to identify the type of hardware fault and effectively avoid unnecessary hardware replacement.

6.1 Handling Hardware Failures

In large-scale cloud-based productions, hardware failures are frequent and may cause *SIGBUS* error and I/O hang, as shown in Figure 11.

Spool adopts the SPDK userspace NVMe driver to access a local NVMe PCIe SSD. Base address register (BAR) space for the NVMe SSD will be mapped into the user process through VFIO, which allows the driver to perform MMIO directly. The BAR space will be accessed by Spool while guest VMs send I/Os to the devices. However, the BAR space may become invalid while the device fails or is hot-removed. At this time, it will trigger *SIGBUS* error and cause the host process to crash if guest VMs still send I/O requests to the failed device of the host.

To improve reliability, a *SIGBUS* handler is registered into Spool. Once guest VMs send I/O requests to failed devices and access illegal BAR space, the handler will capture the *SIGBUS* error and remap the invalid BAR space to a dummy virtual address so that the *SIGBUS* error will not be triggered

[1] There are two types of commands in NVMe: Admin Commands are sent to Admin Submission and Completion Queue. I/O Commands are sent to I/O Submission and Completion Queues [9].

Table 1: Experimental configuration

Host configuration	
CPU & Memory	2x E5-2682v4 @2.5GHz; 128GB DDR4 Memory
NVMe devices	2 Samsung PM963 3.84TB SSDs
OS info	CentOS 7 (kernel verison 3.10.327)
Guest OS configuration	
CPU & Memory	4 vCPU; 8 GB
OS info	CentOS 7 (kernel verison 3.10.327)

again. Then, it sets the NVMe controller state to failure and fails all the internal requests in NVMe qpairs of the failed device.

6.2 Failure Model

The S.M.A.R.T. diagnosis collects and analyzes S.M.A.R.T. data to identify the failure type. S.M.A.R.T. data is disk-level sensor data provided by the firmware of the disk driver, including smart-log, expanded smart-log, and error-log, which can be used to analyze internal SSD errors.

Once a hardware media error is verified, Spool proactively fails the submitted I/O requests and returns I/O errors. After that, all the subsequent I/O requests to the failed device will return errors to guest VMs directly. Meanwhile, the S.M.A.R.T. diagnosis will send a report to DevOps. The hot-plug feature in the driver layer of SPDK is utilized in Spool; hence, the failed device can be replaced directly.

For the other hardware errors, such as a data link layer failure, diagnosis informs Spool to reset the controller. During the reset process, the I/O requests from the guest VMs hang. After the device is fixed, the INFLIGHT requests in the journal are resubmitted automatically.

7 Evaluation of Spool

In this section, we evaluate the performance of Spool in resolving hardware failure and supporting live upgrades. We first describe the experimental setup. Then, we evaluate the reliability of Spool in fixing an NVMe device's hardware failure without affecting other devices and correctly tolerating system upgrades at random times. After that, we show the effectiveness of Spool in reducing the system restart time, followed by a discussion on the impact of Spool on the I/O performance and the extra overhead caused by the cross-process journal. Lastly, we discuss the effectiveness of Spool on an in-production large-scale public cloud.

7.1 Experimental Setup

We evaluated Spool on a server equipped with two Intel Xeon E5-2682 processors operating at 2.5 GHz with 128 GB memory. For the NVMe devices, we adopted a mainstream SSD device: Samsung PM963 NVMe SSD. Table 1 summarizes the hardware and software specifications of the experimental platform.

For extensive evaluation, we use the Flexible I/O tester (FIO) [6] as our performance and reliability evaluation benchmark. FIO is a typical I/O tool meant to be used both for benchmark and stress/hardware verification and is widely used in research and industry. When evaluating the I/O performance, we use different parameters, as shown in Table 2, to demonstrate metrics, including IOPS and average latency recommended by Intel [5] and Alibaba [4]. To emulate the real-system cloud scenario, we split each NVMe SSD into three partitions (each partition was 100 GB) and allocated each partition to an individual VM.

We used libaio (Linux-native asynchronous I/O facility) [21] as the FIO load generation engine. Table 2 lists the generated FIO test cases. To obtain accurate performance, we tested raw SSDs without any file system.

Table 2: FIO test cases

Tested metrics	Test cases	FIO Configuration (bs, rw, iodepth, numjobs)
Bandwidth	Read	(128K, read, 128, 1)
	Write	(128K, write, 128, 1)
IOPS	Randread	(4K, randread, 32, 4)
	Mixread	(4K, randread 70%, 32, 4)
	Mixwrite	(4K, randwrite 30%, 32, 4)
	Randwrite	(4K, randwrite, 32, 4)
Average Latency	Randread	(4K, randread, 1, 1)
	Randwrite	(4K, randwrite, 1, 1)
	Read	(4K, read, 1, 1)
	Write	(4K, write, 1, 1)

7.2 Reliability of Handling Hardware Failure

When an NVMe device suffers from hardware failure, Spool isolates the failed device and performs device replacement or controller reset accordingly. When handling such failure, Spool should not affect the I/O operations on other devices of the same node, and the VMs that are using the failed device should receive I/O errors instead of exiting abnormally.

We designed an experiment to evaluate Spool in the above scenario. In the experiment, we launched two VMs on a hardware node equipped with two NVMe devices and configured the two VMs to uses different NVMe devices in Spool. The two VMs randomly read data from NVMe devices in the beginning, and we manually removed an NVMe device and observed the behavior of the two VMs.

Figure 12 presents the I/O performance of the two VMs when the NVMe device ("SSD2") was hot-removed at time 80 s. The hot remove was performed by writing a non-zero value to "`/sys/bus/pci/devices/.../remove`". Observed from this figure, the I/O performance of VM1 that uses the NVMe device SSD1 is not affected when SSD2 is removed. Meanwhile, VM2 does not exit abnormally after SSD2 is removed. Once a new SSD device replaces the failed SSD2 or the controller of SSD2 is reset correctly at time 95 s, VM2 is able to directly use SSD2 without any user interference.

Spool can successfully handle the above hardware failure because it catches the hardware hot-plug event and diagnoses the device failure type first. Hardware failures are handled

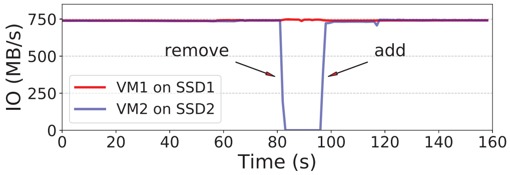

Figure 12: Handling hardware failure with Spool.

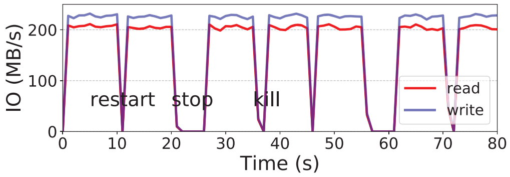

Figure 13: Data consistency at live upgrade with Spool.

in two ways: media errors are solved by hot-plugging a new SSD, and then the storage service automatically recovers, where the related logical devices are automatically mapped to new devices, while data link failure is handled by controller reset instead of replacing a SSD. On the contrary, if the traditional SPDK is used to manage SSDs, the hardware failure can only be solved by hot-plugging new devices, resulting in unnecessary data loss, and the storage service of SPDK needs to be reset manually for recovery.

7.3 Reliability of Handling Random Upgrades

To validate the reliability of Spool in handling upgrades without resulting in data loss, we designed an experiment that *restarts* purposely *stops and starts* and randomly *kills and restarts* Spool. In the experiment, we relied on the data verification function in FIO to check the data consistency. By enabling the data verification function, FIO verifies the file contents after writing 10 blocks contiguously with crc32 and reports whether any data corruption occurred or not. If FIO runs completely without errors, data consistency is verified.

Figure 13 shows the read and write performance to the SSD when we restart on purpose, stop and start, and randomly kill and restart Spool at time 10 s, 20 s, and 35 s. As can be observed from the figure, the I/O operations to the SSD complete correctly with Spool, even if Spool is directly killed and restarted for an upgrade.

Spool can guarantee data consistency during upgrades due to the cross-process journal. The journal persists the current states of all the NVMe devices. Whenever Spool is restarted, it is able to recover the states before the restart and continue to complete the unprocessed I/O requests. On the contrary, with SPDK, there is no mechanism to guarantee data consistency for INFLIGHT I/Os.

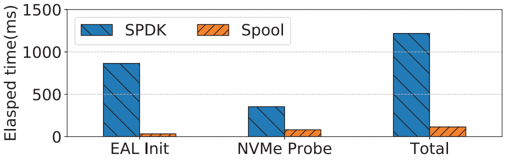

Figure 14: Restart times of Spool and SPDK.

7.4 Reducing Restart Time

Observed from Figure 13, the downtime due to the restart is short with Spool. In more detail, Figure 14 shows the restart time breakdown of Spool and SPDK.

As can be observed from this figure, Spool significantly reduces the total restart time from 1,218 ms to 115 ms on a Samsung PM963 SSD. This significant restart time reduction originates from the reduction of EAL initialization time and the NVMe probe time.

SPDK suffers from a long EAL initialization time and a long NVMe probe time because it initializes the EAL and resets the controller of the device during probing at each startup. By reusing the previous memory layout information, Spool minimizes the EAL initialization time. And, by skipping resetting the device controller, Spool reduces the NVMe probe time.

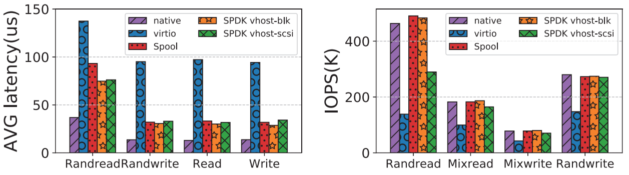
7.5 I/O Performance of Spool

It is crucial to ensure high I/O performance (i.e., high IOPS and low latency) when guaranteeing reliability. In this subsection, we report the I/O performance of NVMe devices with Spool in two cases: an NVMe device is only allocated to a single VM, and an NVMe device is shared by multiple VMs.

7.5.1 Case 1: Single VM Performance

Figure 15 presents the data access latency and IOPS to an SSD when it is virtualized with Virtio, SPDK, and Spool. In the figure, "native" shows the performance of the SSD measured on the host node directly; "SPDK vhost-blk" and "SPDK vhost-scsi" show the performance of the SSD if SPDK is used as the I/O virtualization system and the SSD is treated as a block device or a SCSI device, respectively.

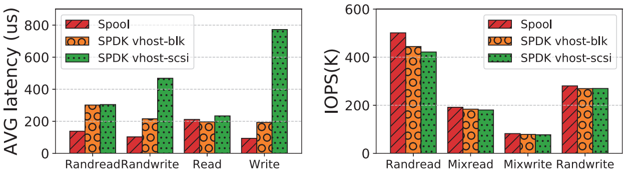
As can be observed from Figure 15, all the I/O virtualization systems result in longer data access latency compared with the native access due to extra layers in the virtualization system. Meanwhile, Spool achieves similar data access latency to SPDK. From the IOPS aspect, the IOPS of *Randread* with Spool is 2.54x higher than Virtio and even slightly better than the native bare metal. As mentioned in Section4, Spool uses polling instead of interrupt to monitor the I/O requests. Polling saves the expense of invoking the kernel interrupt handler and eliminates context switching. These results are consistent with prior work [27].



(a) Average latency

(b) IOPS

Figure 15: Average data access latency and IOPS of an NVMe SSD when it is used by a single VM.



(a) Average latency

(b) IOPS

Figure 16: Average data access latency and IOPS of an NVMe SSD when it is shared by multiple VMs.

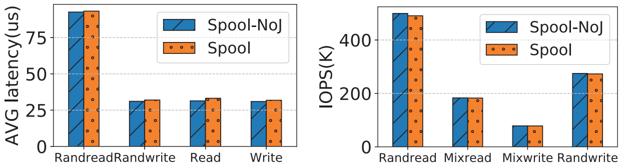
Compared with SPDK vhost-blk, the performance of our implementation is almost the same. Because the SPDK vhost-blk software stack is thinner than SPDK vhost-scsi, the IOPS with SPDK vhost-scsi is lower than that with Spool.

7.5.2 Case 2: Scaling to Multiple VMs

In this experiment, we partition an SSD into three logic disks and assign each logic disk to an individual VM. This experiment tests the effectiveness of Spool in handling multiple VMs on an NVMe device.

Figure 16 shows the IOPS and data access latency when three VMs share an NVMe device, and each result is the sum of those of all VMs. For the latency test, we ran each benchmark 10 times and report the average latency for each benchmark. As can be observed from this figure, Spool does not degrade the I/O performance of all the benchmarks compared with SPDK vhost-blk and SPDK vhost-scsi. Specifically, Spool improves the IOPS of *Randread* by 13% compared with SPDK vhost-blk, which reduces the average data access latency of *Randread* by 54% to 55% compared with SPDK vhost-blk and SPDK vhost-scsi, respectively.

Besides, we can see that the SSD device achieves similar IOPS when the SSD is used by a single VM and three VMs, and we can see the average data access by comparing Figure 15(b) and Figure 16(b). The data access latency of the benchmarks when the SSD is shared by three VMs is three times that of case 1. This is reasonable because the backend I/O load pressure increases linearly with the number of VMs, so the total latency of the three VMs increases. While the I/O load pressure of one VM has reached the throughput limit of the Samsung PM963 specification [10], the total IOPS of three VMs remains unchanged. The I/O performance of Spool is slightly better than that of SPDK because Spool and SPDK use different logical volume management mechanisms. Specifically, Spool uses the buddy system to manage logical volumes, while SPDK uses Blobstore.



(a) Average latency

(b) IOPS

Figure 17: Overhead of the cross-process journal.

7.6 Overhead of the Cross-Process Journal

To measure the overhead of the cross-process journal, we implement a Spool variation, Spool-NoJ that disables the cross-process journal. Figure 17 shows the data access latency and the IOPS of the SSD with Spool and Spool-NoJ.

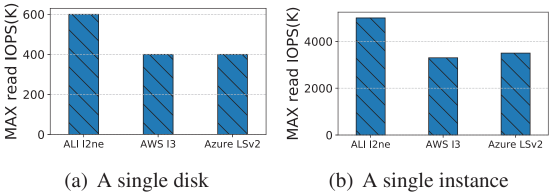
As shown in Figure 17, Spool-NoJ and Spool result in similar data access latency and IOPS. Compared with Spool-NoJ, Spool increases the average data access latency no more than 3%. Meanwhile, Spool reduces the IOPS by less than 0.76% compared with Spool-NoJ. The extra overhead caused by the cross-process journal in terms of average latency and IOPS throughput is negligible.

7.7 Deployment on an In-production Cloud

We currently deploy Spool in 210 clusters with approximately 20,000 physical machines equipped with approximately 200,000 NVMe SSDs.

On the cloud supported by Spool, we built a Platform-as-a-Service cloud(ALI I2 series) that provides low latency, high random IOPS, and high throughput I/O support. The maximum IOPS of single disk is 50% higher than that of competitive products and the maximum IOPS of a largest specification instance is 51% higher than that of the competitive products, as shown in Figure 18. The in-production cloud hosts Cassandra, MongoDB, Cloudera, and Redis. They are ideal for Big Data, SQL, NoSQL databases, data warehousing, and large transactional databases. Recently, the instance resources of local SSD disks have helped OceanBase break the world record for TPC-C benchmark performance test maintained by Oracle for 9 years and becoming an important milestone in the evolution history of global databases.

A holistic fine-grain monitoring system is crucial for clouds. While the monitoring system is able to diagnose media errors and other SSD failures, Spool handles the failures in different ways. Our statistics show that the current hardware failure rate is approximately 1.2% over a whole year. Throughout one year, approximately 2,400 out of 200,000 SSDs suffer from media errors. The media error is due to either media damage or life depletion. From the system upgrade aspect,



(a) A single disk (b) A single instance

Figure 18: Maximum read IOPS compared with AWS and Azure.

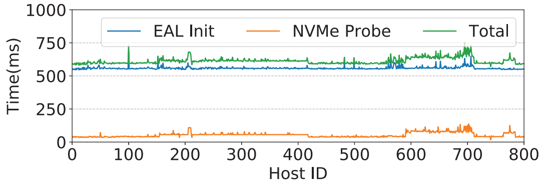


Figure 19: Restart time of Spool during a live upgrade.

we release a new version of Spool every six months. In total, we upgrade Spool on more than 40,000 physical machines every year. The purpose of the new version is to deal with two issues: 1) releasing new features and 2) fixing online stability during the operation and maintenance phase. Most of the new features are related to performance, such as adding support for multiple queues, optimizing memory DMA operation, and optimizing memory pools.

Figure 19 shows the restart time of some selected machines in a live upgrade in production. The *x*-axis is the ID of the physical node. Due to historical reasons, Spool in the production environment is based on the earlier version of the DPDK driver, and the initialization memory requires 1,172 ms, accounting for 70% of the initialization of EAL (1,792 ms in total), which is almost optimized. However, the rest of the initialization of the EAL is still 550 ms, and the total upgrade time for 95% of the machines is within 654 ms. We are working on updating the DPDK driver for Spool.

8 Related Work

There has been a lot of work concentrating on NVMe virtualization and optimizing storage I/O stacks for modern fast storage devices(e.g., NVMe SSDs).

Kim et al. [22] analyzed the overheads of random I/O over storage devices in detail and mainly focused on optimizing the I/O path by eliminating the overhead of user-level threads, bypassing the 4KB aligned I/O routine and enhancing the interrupt delivery delay in QEMU. In QEMU/KVM forum 2017, Zheng et al. [43] implemented a userspace NVMe driver in QEMU through VFIO to accelerate the virtio-blk in a guest OS at the cost of device sharing. Peng et al. [27] discussed the importance of polling for NVMe virtualization and took advantage of polling to achieve extreme I/O performance while each polling thread brings 100% usage of 3 cores.

Virtio [12] is a de facto standard for para-virtualized driver specifications including virtio-blk and virtio-scsi, which defines the common mechanisms for virtual device discovery and layouts. However, each I/O request passes through the I/O stack twice for guest and host, causing great loss of I/O performance. Then, a vhost acceleration method is proposed to accelerate virtio-scsi or virtio-blk provided by the storage performance development kit (SPDK) [38], such as kernel vhost-scsi, userspace vhost-scsi, and vhost-blk.

While local SSDs provide higher data access bandwidth and lower latency, storage disaggregation (e.g., ReFlex [24], NVMe-over-Fabrics [20], [23]) enables flexible scaling and high utilization of Flash capacity and IOPS at the cost of interconnecting latencies over a network. The bandwidth of NIC is the bottleneck to saturate the bandwidth of multiple disks. Two NVMe SSDs may saturate the bandwidth of emerging NIC (100GbE). Meanwhile, the upgrade of cloud services with minimal downtime has also been widely studied. Neamtiu et al. [26] highlighted challenges and opportunities for upgrades to the cloud. Clark et al. [19] proposed a live migration mechanism to temporarily move VMs to a backup server, upgrade the system, and then moves the VMs back. Zhang et al. [41] proposed Orthus to live upgrade the VMM without interrupting customer VMs and significantly reduce the total migration time and downtime. However, Orthus only focuses on KVM and QEMU and ignores the backend services.

9 Conclusion

This paper presented Spool, a holistic virtualized storage system that is capable of handling hardware failure and the NVMe virtualization system upgrades reliably. Spool significantly reduces the restart time by 91% on a Samsung PM963 SSD by reusing the data structures at the restart for system upgrades. Compared with emerging virtualized storage systems such as SPDK, Spool supports live upgrades and guarantees data consistency with a shared memory-based journal at any time. Moreover, Spool diagnoses device failure type instead of hot-plugging directly and eliminates most unnecessary NVMe device replacement.

Abstract

The reliability of a storage system is crucial in large data centers. Hard disks are widely used as primary storage devices in modern data centers, where disk failures constantly happen. Disk failures could lead to a serious system interrupt or even permanent data loss. Many hard disk failure detection approaches have been proposed to solve this problem. However, existing approaches are not generic models for heterogeneous disks in large data centers, e.g, most of the approaches only consider datasets consisting of disks from the same manufacturer (and often of the same disk models). Moreover, some approaches achieve high detection performance in most cases but can not deliver satisfactory results when the datasets of a relatively small amount of disks or have new datasets which have not been seen during training. In this paper, we propose a novel generic disk failure detection approach for heterogeneous disks that can not only deliver a better detective performance but also have good detective adaptability to the disks which have not appeared in training, even when dealing with imbalanced or a relatively small amount of disk datasets. We employ a Long Short-Term Memory (LSTM) based siamese network that can learn the dynamically changed long-term behavior of disk healthy statues. Moreover, this structure can generate a unified and efficient high dimensional disk state embeddings for failure detection of heterogeneous disks. Our evaluation results on two real-world data centers confirm that the proposed system is effective and outperforms several state-of-the-art approaches. Furthermore, we have successfully applied the proposed system to improve the reliability of a data center and exhibit practical long-term availability.

1 Introduction

Device failure is a common problem in large data centers, where hard disks are widely used as the primary storage devices. A disk failure could lead to temporary data loss and thus system breakdown, or even permanent data loss if the lost data cannot be recovered by data protection schemes (eg., replication and erasure codes) due to disk failures exceeding the designed correction capability [1]. About 80% of system breakdowns are caused by hard drive failures in the data center [2]. Therefore, how to ensure the reliability of disks becomes an important issue in a storage system [3]. Although there are a series of passive fault defense mechanisms like EC (Erasure Codes) [4, 5] and RAID (Redundant Arrays of Independent Disks) [6], many researchers have focused on proactive disk failure detection which aims to ensure the reliability and availability of large-scale storage systems in advance [7–9]. Disk failure prediction is an important issue in system researches. Timely and accurate failure prediction can ensure the operational continuity of systems and even avoid data loss. It is because of this common realization among the storage research community, there have recently emerged a decent amount of researches on disk failure prediction.

We observed six classes of approaches of disk failure detection: threshold-based (TB) approaches [10, 11], distance-based anomaly detection (DAD) approaches [12–16], shallow machine learning (SML)-based approaches [17–29], deep neural network (DNN)-based approaches [30–34], one-class classification (OCC) based approaches [35–39] and transfer learning (TL)-based approaches [1, 40–44]. However, these approaches have their limitations as summarized in Table 1.

(1) Limited applicability. Different disk manufacturers have different S.M.A.R.T (Self-Monitoring, Analysis, and Reporting Technology) values or data distribution, even in different disk models of the same manufacturer [1, 43]. This will result in a situation where methods (SML, DNN, OCC, TL) trained on specific parameters only work well for the same manufacturer, and often even for the same models, limiting their scope of applicability in practice.

(2) Lack of adaptability. New disk models enter gradually to replace or augment the storage capacity, leading storage systems to consist of disks from different vendors and/or different models [1, 41, 42]. Facing these different types of heterogeneous disks, the existing prediction models (DAD, SML, DNN, OCC, TL) must be retrained to obtain more reliable predictions in order to adapt to the changes in the data distribution introduced by these new disk models. Such re-

Table 1: Characteristics of different approaches in disk failure detection. $(\star)$ refers to certain conditions that are required, e.g., finding a suitable source domain (i.e., another disk model) for knowledge transfer. All existing methods have certain disadvantages. We use TPR refers to True Positive Rate, FPR refers to False Positive Rate and F-Measure to evaluate these methods (for these evaluation metrics see Section 5.1.3).

	TB	**DAD**	**SML**	**DNN**	**OCC**	**TL**	**HDDse**
Applicability	√	√	×	×	×	×	√
Adaptability	√	√	×	×	×	√$(\star)$	√
Imbalance datasets	√	×	×	×	√	×	√
Minority Disk	√	×	×	×	×	√$(\star)$	√
Performance	TPR: 3%-10%	56%-70%	75%-96%	87%-98%	70%-92%	80%-97%	92%-97%
	FPR: 0%-2%	0%-1%	1%-4%	0%-1%	0%-10%	FPR: 0%-6%	0.2%-0.4%
	F-Measure: 2%-13%	49%-58%	67%-92%	86%-93%	65%-91%	77%-93%	91%-97%

training is tedious and expensive in a large data center.

(3) Imbalanced datasets. Imbalanced data refers to a situation where the number of samples is not the same for all the classes in a classification dataset. Most machine learning (ML) models tend to bias the class with the largest proportion of observations (known as majority class), which may lead to inaccuracies. This may be particularly problematic when we are interested in the correct classification of a "rare" class (also known as minority class). In real world cloud storage systems, the imbalanced ratio of positive (failure) samples and negative (healthy) samples poses a significant threat to the efficiency of machine learning models [2]. The most commonly used technique of existing methods (DAD, SML, DNN, TL) to approach this problem are under-sampling [1, 15, 28] and over-sampling techniques [45]. In under-sampling, the data samples are adjusted based on the class with the lowest sample count to keep the number of samples per class equal. In over-sampling the samples of the sparsely populated class are re-sampled to match the number of data samples in the other classes. Under-sampling discards a large amount of data while oversampling can easily cause overfitting in the model. Moreover, these approaches might increase the training cost.

(4) Minority disk failure detection. In large-scale storage systems, new disks gradually replace failed disks, which results in a situation where the data centers continuously contain small amounts of new disk models. Due to a lack of sufficient training data, some detective approaches (DAD, SML, DNN, OCC) fail to deliver satisfactory detective performance for these models. Although some TL methods (transfer learning is good at transferring knowledge from the source dataset to the target dataset) have been proposed to address this issue, their performance depends on finding a suitable source domain (in the form of another disk model) for knowledge transfer, which might be difficult in a real world data center (detailed in Section 3.1.2).

(5) Detective performance. The True Positive Rate (TPR), False Positive Rate (FPR) and F-Measure (all these evaluation metrics see Section 5.1.3 for details) are the commonly used metrics to measure the capabilities of classification models in disk failure detection [1, 15, 17, 19]. Most methods show unstable performance in practical long-term use and often fail to obtain both high TPR and low FPR.

In this paper, we propose a novel disk failure detection system called "High-Dimensional Disk State Embedding for Generic Failure Detection" (*HDDse*). It is a distance-based anomaly detection approach using deep learning and addresses the discussed shortcomings of the existing methods.

In summary, we provide the following contributions:

- To the best of our knowledge, we propose the first generic disk failure detection system *HDDse* for heterogeneous disks. It is not sensitive to imbalanced datasets, has wider applicability, well detects the minority disks and exhibits high adaptability. (Section 4.1)
- We propose a Long Short-Term Memory (LSTM)-based siamese network to calculate the similarity of disk health states in high-dimension space, which combines distance-based anomaly detection and deep learning to classify disk state in high-dimension. (Section 4.2)
- We experimentally evaluate our method on datasets from two real world data centers. We demonstrate that *HDDse* can effectively detect disk failures in long-term availability that greatly improves the reliability and availability of the storage system and outperforms the state-of-the-art approaches in five adopted metrics (Section 5.2 and 5.3).

2 Related Work

Existing work mostly uses the S.M.A.R.T (Self-Monitoring, Analysis and Reporting Technology) data to build a disk failure detection model. Almost all hard disk drives and flash-based SSDs now support S.M.A.R.T, which monitors the internal attributes of individual drives.

Threshold-based Methods (TB). All disk manufacturers use a thresholding algorithm which triggers a failure alarm when any single S.M.A.R.T attribute exceeds a predefined value [10, 11]. However, this approach provides only an estimated TPR (True Positive Rate, see Section 5.1.3 for details) of 3%-10% with a 0.1% FPR (False Positive Rate, see Section 5.1.3 for details). The reason is that the hard disk manufacturers set the thresholds conservatively to avoid expensive false alarm costs, i.e., they keep the FPR to a minimum at the expense of the TPR.

Distance-based Anomaly Detection Methods (DAD). DAD is the method of finding data objects with behaviors that are very different from expectation based on some similarity metrics. Shen et al. [15] utilize the change in the Euclidean distance [46] between the healthy disk samples and the last sample of a failed drive. Wang et al. [13] propose a model for drive anomaly prediction based on Mahalanobis distance (MD). In their subsequent study [14], they use a generalized likelihood ratio test over the dissimilarity vector to detect disk failures. Huang et al. [16] explore the read/write head failures and bad sector failures using the Euclidean distance to calculate the dissimilarity between each S.M.A.R.T record prior to the failure and the failure record. Gao et al. [12] present an incremental detection model of disk failures based on the Euclidean distance to measure the local anomalies of test points within their isolation regions optimizing the judgment of test point anomalies.

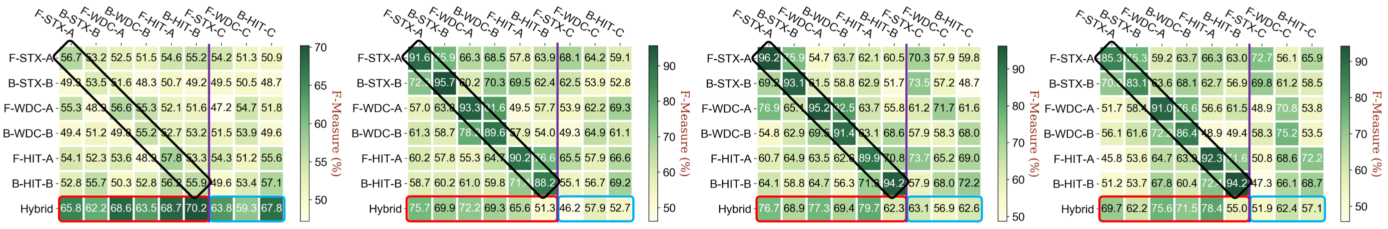
Shallow Machine Learning based Methods (SML). Conventional (shallow) machine learning methods typically require manual extraction and selection of features (eg., Support Vector Machines (SVM [47]), Logistic Regression (LR [48])), a critical step that is dispensed within the deep learning approach, i.e., it is automatic in deep learning approaches. Pitakrat et al. [29] evaluate and compare the performance of 21 machine learning algorithms for proactive disk failure detection. Li et al. [28] propose new drive failure detection models based on classification and regression trees. Yang et al. [27] design a disk failure prediction model based on L1-regularized logistic regression. Ganguly et al. [26] propose a two-stage ensemble predictive model. Chaves et al. [25] design a failure prediction method using a Bayesian Network. Mahdisoltani et al. [23] explore a range of different machine learning techniques (Classification and Regression Trees (CART [49]), Random Forests (RF [50]), SVM, Neural Networks (NN [51]) and LR) and show that sector errors can be predicted ahead of time with high accuracy using RF. Carlos et .al [22] investigate three different machine learning models (Decision Trees, NN, and LR). Xiao et al. [21] introduce a novel disk failure prediction model using Online Random Forests (ORFs). Aussel et al. [24] test several learning methods, SVM, RF and Gradient-Boosted Tree (GBT) and find that RF provides the best performance. Anantharaman et al. [20] experiment with two different types of ML approaches: RF and Long Short-Term Memory (LSTM) recurrent neural networks. Yong et al. [19] develop a cost-sensitive ranking-based ML model that can learn the characteristics of faulty disks from the past and rank the disks based on their error-proneness using the FastTree algorithm [52]. Yi et al. [18] predict the failure order with a LambdaMART [53] model. Xie et al. [17] propose an explanation approach designed for disk failure prediction.

Deep Neural Network based Methods (DNN). DNN method is an artificial neural network (ANN) with multiple layers between the input and output layers. The DNN finds the correct mathematical manipulation to turn the input into the output, whether it be a linear relationship or a nonlinear relationship. Xu et al. [34] introduce a method based on Recurrent Neural Networks (RNN) to assess the health statuses of disks. Pang [33] implement a Combined Bayesian Network (CBN) model to estimate the health degree of disks. Fernando et al. [32] present a remaining useful life estimation approach for disks by leveraging the capabilities of LSTM networks. Basak et al. [31] propose a data-driven framework based on LSTM for detection of whether a disk is going to fail in the next 7 days. Sun et al. [30] propose a temporal Convolutional Neural Network (CNN)-based model to predict failures.

One-Class Classification based Methods (OCC). OCC involves fitting a model on the normal data and predicting whether new data is normal or not. The imbalanced ratio of positive (failure) disk samples and negative (healthy) disk samples poses a significant challenge for efficient learning. Wang et al. [38, 39] present an anomaly detection method, which distinguishes anomalous behaviors from healthy events in each disk. Lucas et al. [37] propose a method for fault detection on hard disks that uses a Gaussian Mixture to model the behavior of only healthy hard disks. They also propose another method named GMFD [36], which applies a semi-parametric model (GMM) to build a statistical model using healthy disks. Francisco et al. [35] evaluate nine one-class classifiers for fault detection in hard disks.

Transfer Learning based Methods (TL). TL is an ML technique where a model trained on one task is re-purposed on a second related task. Transfer learning methods have been proposed to solve the minority disk failure problem. Botezatu et al. [43] apply a transfer learning approach to use a prediction model trained on a specific disk model for a new disk model of the same manufacturer. Francisco et al. [42] evaluate several transfer learning strategies on the task of failure prediction on hard disk drives. Their experiments state that transfer learning methods can provide performance gains in hard disk failure prediction models. Xie et al. [41] employ a simple but effective transfer learning method for disk failure detection which determines the best source from its anterior disk models and builds a transfer learning model with the help of the source domain. Zhang et al. [40,44] integrate both transfer learning and active learning techniques to detect the disk failure called ATAD and show its effective in cross-dataset time series anomaly detection. Zhang et al. [1] propose a minority disk failure prediction model named $TLDFP$ based on a transfer learning approach and use Kullback Leibler Divergence (KLD) as an effective indicator for source domain selection for large heterogeneous datasets.

Shortcomings of existing work. The above mentioned approaches (SML, DNN and OCC) deliver good detective performance only when both training and testing data are drawn from the same distribution [54]. A recent study [22] on heterogeneous disk failure prediction has pointed out that the predictive results are not good enough for adoption in prac-



(a) DAD approach [12]

(b) SML approach [17]

(c) DNN approach [31]

(d) OCC approach [35]

Figure 1: Figure 1(a), 1(b), 1(c) and 1(d) respectively show the overall F-Measure (detailed in Section 5.1.3) of the four state-of-the-art methods using datasets of disk models from two data centers. Although the SML, DNN and OCC achieved better performance than the DAD method in the case of datasets consisting of disks from the same disk models, the DAD approach delivers strong applicability and adaptability.

tice. Therefore, most of the experiments for these methods only consider datasets consisting of disks from the same manufacturer (and often of the same disk models) and thereby have limited applicability. Except for the method DAD, the methods (SML, DNN and OCC) learn the S.M.A.R.T data distribution of the specific disk model but not the unified detection measure, as a result, these approaches have bad predictive performance when dealing with the disk models that have not yet appeared in previously trained models (i.e., poor adaptability). Furthermore, all the methods (especially for DNN and OCC) require a large number of training samples to build robust models, which is difficult to be satisfied for minority disks in data centers. Training models on the minority disks would dramatically increase the risk of overfitting, and the resulting poor generalization will decrease the performance of predictive models [1]. Although TL approaches can handle this situation well, an important premise of this approach is that there is one or more appropriate source majority disk models for knowledge transfer, but we find this to be a tough assumption in practice (see Section 3.1.2). Moreover, most of these approaches increase the training cost to process the imbalanced datasets and could result in discarding a large amount of data or model overfitting (mentioned in Section 1).

3 Preliminary Study and Motivation

In this section, we investigate the performance of existing approaches in three aspects (applicability, adaptability and minority disk failure detection) and describe our motivation for enabling high-dimensional disk state embedding for heterogeneous disk failure detection.

3.1 Preliminary Study

3.1.1 Applicability and Adaptability

We analyzed the overall performance of existing proposed approaches using different disk models from both the publicly available S.M.A.R.T dataset Backblaze[1] and the data center of Tencent (one of the largest social network companies in the world). Figure 1(a), 1(b), 1(c) and 1(d) respectively show the overall detective performance of the state-of-the-art methods (DAD [12], SML [17], DNN [31] and OC [35]) using different datasets of disk models. For convenience, we use `Data Center-Disk Manufacturers-Disk Model` to denote the dataset we use. For example, the disk model C from Seagate in data center BackBlaze can be referred to as `B-STX-C` and the disk model A from WDC in data center Tencent can be referred to as `F-WDC-A`.

In each figure, the vertical and horizontal axes refer to the disk models of training and testing dataset respectively. We use F-Measure (detailed in Section 5.1.3) to evaluate the performance of failure detection models. The higher the value is (the darker in the heatmap), the better the performance is. In the last row of each figure, we use the hybrid datasets (the first 6 disk models contain F-STX-A, B-STX-B, F-WDC-A, B-WDC-B, F-HIT-A and B-HIT-B) for training and then detect on different disk models. Note that the last three disk models F-STX-C, F-WDC-C, B-HIT-C are not included in the hybrid disk models for training. We summarize the findings from these four figures. **(1)** Detection approaches (SML, DNN and OCC) built on a specific disk model only has good results test on the same disk model (i.e., the detective model built on F-STX-A and detect on F-STX-A, as illustrated by the darker diagonal lines). Moreover, DNN-based approach shows the best performance in this case. **(2)** The SML, DNN and OCC approaches built on hybrid disk model datasets decrease the detective performance compared to a model built on the same disk model (we call the model has poor applicability in this case). Moreover, the performance of these approaches further deteriorates when detecting the disk models that have not appeared in the training datasets. **(3)** Although the overall detective results of the DAD method is not good enough to be deployed in practice, it is not sensitive to the different disk models. In other words, the performance of cross-model disk failure detection is very close. Besides, the DAD approach built on hybrid disks increases the performance compared to the model built on a single disk model (good applicability) and shows high adaptability to disk models that have not appeared in training. Note that we also evaluated many other studies on these methods and got similar results and we don't discuss all the results here due to space limitations.

3.1.2 Minority Disk Failure Detection

In order to investigate the detection for minority disks (the number of disks less than 1,500 [1]), for TL approach, we use the majority disk model which has the smallest Kullback Leibler Divergence (KLD) values with the detecting minority

[1] https://www.backblaze.com/b2/hard-drive-test-data.html

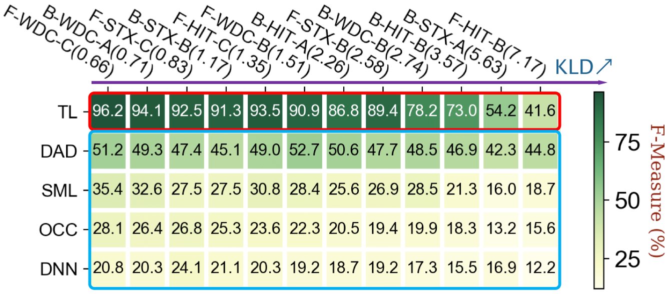


Figure 2: Minority disk failure detection using different approaches. The TL approach achieves the best performance but it depends on the small enough KLD value of the majority disk which is chosen for training.

disk model from the same manufacturer to train the detective models. The detecting minority disk models are listed on the x-axis ordered by the calculated smallest KLD values. For other approaches, they only trained the detective model based on minority disk datasets. Note that KLD is a metric measuring the divergence degree of one probability distribution from another expected probability distribution [55]. It indicates the disparities between two S.M.A.R.T datasets distributions. A zero KLD value means that the distributions of these two disk datasets are the same, while the KLD value increases as the differences between two data distributions widen. In general, the larger a KLD value is, the greater differences between two disk data distributions will be and the more difficult the knowledge transfer between two distributions will be in the transfer learning approach [1]. Figure 2 shows the results. The TL approach delivers the best detective performance on minority disk failure detection especially with the training datasets having smaller KLD values while other candidates are difficult to handle this situation.

Table 2: Distribution characteristics of the smallest KLD value for minority disk model in two data centers

Data Center	KLD(0∼1)	KLD(1∼2)	KLD(2∼3)	KLD(>3)
Tencent	**35%**	25%	23%	17%
Backblaze	**32%**	18%	31%	19%

In order to take an in-depth look at the feasibility of this method in practical large storage systems, we studied the disk quantities by the different KLD values in two data centers. As shown in Table 2, in Tencent data center, only 35% of all minority disk models could find a majority disk model with small KLD value (range from 0 to 1) for training. In other words, most minority disk models only find the majority disk models with a KLD value greater than 1 which might result in poor detection performance. A similar observation has been made in the data center Backblaze. Therefore, even in such large data centers with millions of disks, it is still difficult to find the most suitable majority disk model with small enough KLD value to use TL for minority disk failure detection.

3.2 Motivation

The preliminary study results above show that The DAD approach has better applicability and adaptability than other approaches (SML, DNN, OCC), and DNN approach gives the best detective performance. Before introducing our motivation, we first to answer the following three problems: **(1)** Why the DAD approaches have good applicability and high adaptability while DNN does not? The DAD method learns the distance (similarity) between the normal and abnormal disk samples in a certain space which has a commonality and not sensitive to the disk models. However, the DNN approach learns the distribution of S.M.A.R.T data which varies with disk models, the performance of this approach would decrease when the distribution changes. **(2)** Why the overall detective performance of the DAD method is not as good as other approaches. We think the reason is it performs distance-based transformation and computation in low-dimensional space but does not learn from the dynamically changed long-term behavior in high-dimension. **(3)** Why the DNN approach achieves the best performance among other candidates? DNN is good at mapping the raw low-dimensional S.M.A.R.T attributes to high-dimensional target spaces through complex transformations that perform good expression and fitting ability and thus achieves better performance.

Considering the above advantages of the DAD and DNN approaches, we are motivated to apply the distance-based anomaly detection approach and deep learning to build a general disk failure detection system for heterogeneous disks. In order to learn a unified measure of distance in high-dimension space using deep learning and then easily use the distance-based anomaly detection approach for comparison for two input data, we applied the siamese networks [56] (commonly used in the image recognition technology) which we will describe in detail in the next section.

4 Proposed System *HDDse*

In this section, we first provide an overview of our proposed system *HHDse* in Section 4.1. Then, we introduce the LSTM-based siamese network for disk failure detection in Section 4.2. Finally, we describe the sample pool and decision maker of *HDDse* respectively in Section 4.3 and Section 4.4.

4.1 System Overview

Figure 3 provides an overview of our proposed novel system *HDDse* which combines a sample pool, an LSTM-based siamese network for disk failure detection, and a decision maker. **Sample pool** (see Section 4.3 for details) is used to store the S.M.A.R.T instances collected daily for each disk. These instances are combined to form training and detecting samples for our approach. Note that the sample pool has both the disk S.M.A.R.T instances with ground truth (true labels with the disk states) for training and the unlabeled instances for detecting. **LSTM-based siamese network for disk failure detection** (see Section 4.2 for details) is the core part in *HDDse*, the input of the network is a pair of samples from the sample pool and the output is a binary classification result that indicates the similarity of these two samples. In online

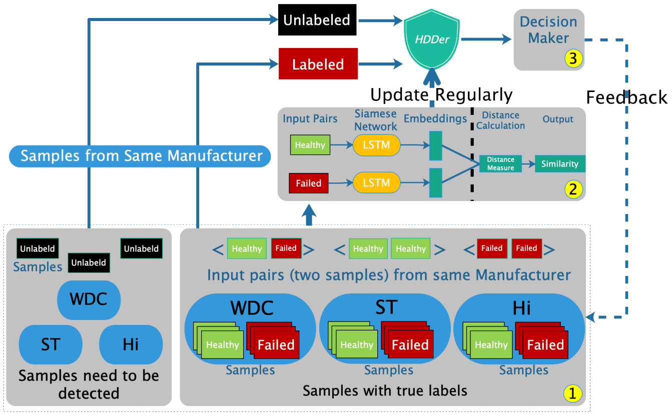

Figure 3: The overview of the proposed *HDDse*. It consists of a sample pool, an LSTM-based siamese network and a Decision Maker marked as 1, 2 and 3 respectively.

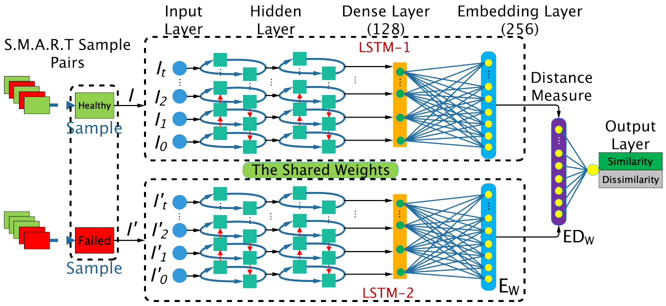

Figure 4: The structure of our proposed LSTM-based Siamese Network for Disk Failure Detection. The input is a pair of detecting samples and output is similarity.

detection, since there are many results of the target detecting samples at a continuous moment compared with other labeled samples, each output detective result indicates for a particular sample at different moments rather than the whole disk health state. Therefore, **Decision Maker** (see Section 4.4 for details) is a module to map these sub-results of samples to the final whole disk healthy state.

4.2 LSTM-based Siamese Network

Many previously proposed machine learning models, such as random forests (RFs), decision trees, SVM and DNN rely on the phenomenon that some key attributes are distinct from others when the disk is going to fail. Therefore, these approaches take a single snapshot of S.M.A.R.T attributes as training data for detection, without considering the sequential dependency between different statuses of a hard disk over time (only rely on features extracted from one day) because they are unable to make use of the time series data (except for converting them to sequential features manually). However, many researches have shown that the S.M.A.R.T of the disk changes dynamically with a certain trend [2, 19, 21, 27, 57], thus the current state of the disk may depend on a long-term historical trend. In contrast to all the aforementioned methods, we apply the LSTM to the parsing of sequential S.M.A.R.T information. LSTMs have been successfully applied to a variety of applications, including text sentiment classification [58] and multi-language text classification [59].

Traditional approaches to solving a classification problem, such as SVM, random forests (RFs) or even DNN, generally require that all the categories be known in advance (some newly disk models entered the data center without enough history information to classify the categories) for training. Moreover, those approaches are not suitable for applications where the number of samples per category is small (minority disk models). Siamese networks are dual-branch networks with tied shared weights, i.e., they consist of the same network copied. This method is proposed for training a similarity metric from data, which can be used for classification tasks (eg., face recognition) in which the categories need to be classified have not appeared during the training process, and can also handle the situation of training samples for a single category which is very small [60]. The symmetry of siamese networks is important and reasonable for learning a unified measure of distance, for example, the distance from disk state S_1 to state S_2 should be equal to the distance from S_2 to S_1.

Therefore, we propose an LSTM-based siamese network for disk failure detection. Figure 4 shows the structure of the network. The training sample pairs we feed to the network are randomly selected from the sample pool which contains two S.M.A.R.T samples (see Section 4.3 for details) from the same disk manufacturer denoted as $< S, S' >$. We design two LSTM networks to receive these two S.M.A.R.T samples respectively which need to be compared for their similarity. Note that these two LSTM networks (BiLSTM [61] refers to bi-direction LSTM layers) shared their weights in order to map the inputs to the same target high-dimension space for comparison. Each LSTM consists of an input layer U, four hidden layers H, one dense (fully connected) layer D with 128-dimensional units and an embedding layer E. In contrast to traditional neural networks, the LSTM operates over sequences of input vectors. This structure is able to capture the historical context of disk healthy statuses and makes LSTMs suitable for tasks related to sequential detection. Note that the dense layer is followed by an embedding layer (a fully connected layer) with 256-dimensional units, and then one more layer computing the distance metric (Euclidean distances [2]) between each siamese twin network. We employ a *Sigmoid* function in the final layer to output a normalized value on the learned high-dimensional feature space and scores the result between the feature vectors of the input sample pair. Note that our proposal is the first to propose an LSTM-based Siamese network based on the peculiar features of disk failures and has shown promising prediction outcomes.

Learning process. Let $E_{\omega}(S)$ and $E_{\omega}(S')$ be the projections of the input pair S and S' in the embedding space computed by the embedding layer (high-dimension space) network function E_{ω}. The output layer is a single unit computed by the induced distance metric between each siamese twin. The detective

[2] It is interesting to explore other sophisticated distance metrics to achieve better results.

vector is given by:

$$ED_\omega(S,S') = f_{sig}(\sum_{i=0}^{N-1} \beta_i |E^i_\omega(S) - E^i_\omega(S')|))$$

where f_{sig} is a *Sigmoid* activation function. β_i are additional parameters that are learned by the model during training, weighting the importance of the component-wise distance. Supposing that N represents the total number of S.M.A.R.T sample pairs over a dataset $D = < S_i, S'_i, Y_i >$, where i indexes the ith training pair and $Y(S^i, S'^i)$ is the corresponding label. We assume $Y(S_i, S'_i) = 1$ whenever S^i and S'_i are the same disk state label and $Y(S_i, S'_i) = 0$ otherwise. The total loss function is given by:

$$L_\omega(D) = \lambda||\omega||_2 + \frac{1}{2N} \sum_{i=0}^{N-1} \ell^i_\omega(S_i, S'_i, Y_i)$$

We use a squared L2-norm regularization (also called ridge regression) in this loss function to improve the ability of model generalization. The ω are the weights of the neural network and λ is the weight decay (this prevents the weights from growing too large and can be seen as gradient descent on a quadratic regularization term to prevent from the model overfitting) set as 0.001 to train our model. The instance loss function ℓ^i_ω comprises of terms including the similar (Y = 1) case (L_s), and the dissimilar (Y = 0) case (L_d):

$$\ell^i_\omega = Y_i \ell_s(S_i, S'_i) + (1 - Y_i)\ell_d(S_i, S'_i)$$

The loss functions for the similar and dissimilar cases are given by:

$$\ell_s(S,S') = (ED_\omega)^2$$

$$\ell_d(S,S') = \begin{cases} (m - ED_\omega)^2, & m < ED_\omega, \\ 0, & otherwise. \end{cases}$$

m is a margin which defines how far away the dissimilarities should be. These settings were chosen during cross validation, grid searching over possible margin settings. Suitable margin helps us distinguish the two input S.M.A.R.T samples better. Therefore, the instance loss function can also be given by:

$$\ell^i_\omega = Y_i(ED_\omega)^2 + (1 - Y_i)\{max(m - ED_\omega, 0)\}^2$$

It is interesting to investigate the proposed loss function. When the two samples are similar/dissimilar (Y = 1/ Y=0), if the ED_ω is wrongly calculated large/small by our model, the value of this loss function will become larger. Our goal is to minimize it.

The parameters of our model are optimized using the Adam optimizer [62] with a decreased decaying learning rate. The training process was run for 150,000 epochs with learning rate (lr) starting at 0.1 and decrease it by a factor of 2 every 50 training epochs. We use the dropout technique [63] (a dropout of 0.5) used on the recurrent units and between layers to prevent overfitting. For the hyper parameter (margin m, weight decay λ, learning rate, the unit number of fully-connected layers) optimization, we use the grid searching to perform hyper parameter selection.

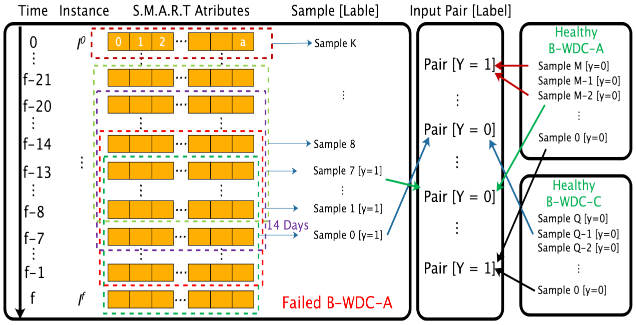

Figure 5: The relationship between S.M.A.R.T instances, samples and the input pairs in our approach. Each sample consists of 14 continuous instances and the continuous samples in a period of seven days before actual failures are labeled as failed.

4.3 Sample Pool for Imbalanced Datasets

Our sample pool consists of the collected S.M.A.R.T instances with their corresponding confirmed labels and some instances that need to be detected. We collect all the instances of each disk in the data center every day. All the time data have been discretely sampled at an interval of one day. If the data collection starts at day T_0 and a disk can fail in any day T_f after that, a disk can have data for all such time indices t where t varies from T_0 to T_f. We can formulate this instance as a multivariate sequential vector $I^t = \{I^t_0, I^t_1, I^t_2, ..., I^t_a\}$ that contain length-a attributes of S.M.A.R.T data at time t for each disk. More specific information about the attributes we use in our evaluation is given in Table 3. Besides, each input of the LSTM consists of a fixed length (we set 14 days in our system to learn the long-term disk state behavior) continuous instances (referred to one sample) with its corresponding label. The first day recorded in a disk failed sample is not the day when the disk fails, but the latest day when the collected attribute stops changing [2, 21, 23]. We use change-point detection to decide how many days samples of failed disks preserve for training. Change-point detection can find an abrupt change during a period. We observe that most attributes have a significant change around 7 days before failures. Therefore, for a failed disk, continuous samples in a period of 7 days (our method has the ability to predict the failure 1-7 days in advance) before actual failure (T_f) are labeled as failed ($y = 1$). For healthy disks, we label the total continuous samples as healthy ($y = 0$). Note that Y = 1 (Y = 0) means the label of the generated input pairs which is a combination of two same (different) labeled samples. The relationship between S.M.A.R.T instances, samples and the input training pairs is shown in the Figure 5. RAID arrays will not affect the operations in the sample pool and the decision maker in Section 4.4.

As mentioned in Section 4.2, the inputs of our proposed network are two S.M.A.R.T samples $< S, S' >$ in pairs. Therefore, we can freely combine and label a pair of samples from the same disk manufacturer. There are two benefits for generating this form of training datasets compared to existing approaches which treat each S.M.A.R.T sample as a snapshot in the training process.

Better with imbalanced datasets. It reduces the degree of data imbalance by the simplest free combination. We use the imbalance degree (*IDe*) [64] to indicate the dataset imbalance which is defined as the ratio between the majority and minority samples (the larger value the *IDe* is when *IDe* is larger than 1, the more imbalanced the dataset is). For an imbalanced dataset containing a minority class sample with size A and the IDe is α, the majority class sample size is αA. The number of pairs with labels $Y = 1$ ($Y = 0$) n_1 (n_0) after combining the input samples can be expressed as: $\begin{cases} n_1 = C_A^2 + C_{\alpha A}^2, \\ n_0 = C_A^1 \times C_{\alpha A}^1. \end{cases}$ where the C_A^2 ($C_{\alpha A}^2$) is the number of "similar" sample pairs generated by the minority class samples (majority class samples). The new imbalance degree IDe' of the input pairs is given by: $IDe' = \frac{n_1}{n_0} = \frac{\alpha}{2} - \frac{1+\alpha-A}{2A\alpha}$ since $A, \alpha > 1$, the value of IDe' will be around $\frac{\alpha}{2}$, which effectively alleviates the original data imbalance by a factor of two. Note that we directly arrange all labeled samples to form the input training pairs without losing large amounts of information (instances) in the sample pool compared to the Under-sampling method which is commonly used in recent researches. Although our method can alleviate imbalanced datasets, it is difficult to eliminate. Fortunately, extensive experimental results in Section 5 demonstrate that the siamese network is insensitive to imbalanced datasets, which is the same as many existing research results [65, 66].

Better with minority disk models. It forms large training samples even with the minority disk models. The number of training pairs with the minority disk models in existing methods is $P = A(1+\alpha)$. However, in our method the number of training pairs is: $\frac{P!}{2!(P-2)!} = \frac{P(P-1)}{2}$ which is extremely large compared to existing methods. Therefore, our model can increases the number of samples greatly and make better use of deep learning algorithms to detect the failure and avoid model overfitting (the experimental results are discussed in Section 5.2.2).

4.4 Decision Maker in *HDDse*

In this section, we aim to seek answers to the following two problems: **(1) Which** training samples need to be arranged to form the input pairs with the detecting sample and how to make a decision (same state or not) for these pairs in the online detection process. **(2) How** to make a disk healthy state decision for a target disk based on the results of these detecting samples at continuous moments?

When a sample of a target detecting disk needs to be detected, we let all the labeled training samples from the same disk manufacturer to be arranged to form the input pairs. For accelerating the process of making a decision for each sample, we follow four detecting steps:

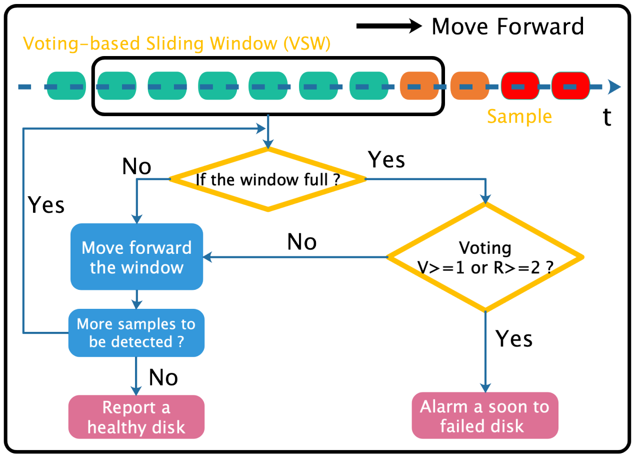

Figure 6: The flowchart of the voting-based sliding window. Moving forward until the disk health statue is reported.

Step 1. We arrange all the samples labeled as failed ($y = 1$) from the same disk model (all majority and minority disks) to form the input pairs with the target detecting sample respectively. If any of these pairs are detected as similar ($Y = 1$), we will mark this detecting sample as failed ($y = 1$), otherwise, proceed to the next step.

Step 2. Considering the sparsity of the state of healthy disk samples, we first randomly select 10% healthy disks of the same disk model and arrange the samples ($y = 0$) collected randomly in one-month intervals to form the input pairs with the detecting sample. If all these pairs are detected as similar ($Y = 1$), we will mark this sample as healthy ($y = 0$). Otherwise, follow the third step.

Step 3. We compare with the samples labeled as failed ($y = 1$) from the different disk models but the same manufacturer with the detecting sample. If more than half of the results are detected as similar ($Y = 1$), we will mark this sample as failed ($y = 1$).

Step 4. Similar to step 2, the only difference is we arrange the different disk models from the same manufacturer. Note that when the disk model of the detecting sample did not exist in the sample pool, we will start from step 3.

Each target detecting disk consists of several results of detecting samples at continuous moments, each output result indicates the detection for a particular sample at one moment rather than the whole disk health state in a period. Therefore, to improve the robustness of the detection method against noise, we propose a voting-based sliding window (VSW) method to make a disk healthy state decision for the final disk state. Figure 6 shows the architecture of VSW. According to the results of the detecting samples stored in the Decision Maker, we define the VSW method for failure detection in the following manner: Define a length-W time sliding window and move it forward everyday. A failure alarm will be reported, if the window consists of V (R) consecutive results from step 1 (step 3), otherwise, there is no failure alarm. These parameters (W, V, R) will be optimized as hyper parameters of the model to determine its optimal value and were chosen during cross validation, grid searching over possible settings. The configuration of our real-world large scale storage system is $W = 7, V = 1, R = 2$. Note that some other decision solutions can be explored to improve the robustness of our method further (eg., a weighted k-nearest neighbors approach).

5 Experimental Evaluation

In this section, we evaluate the detective performance of *HDDse*. We first describe the methodology, followed by the experimental results of effectiveness and efficiency and compare *HDDse* against the state-of-the-art approaches with respect to the evaluation metrics.

5.1 Methodology

We describe the characteristics of two real world S.M.A.R.T datasets and the attributes selection in our experiments. Then we introduce the experiment setup and some evaluation metrics used in our experiments.

5.1.1 Datasets and Attribute Selections.

Datasets. We use S.M.A.R.T datasets from two real world data centers for evaluation. One is the publicly available data set from "Backblaze"[3], which spans a period of 58 months consisting of 146,203 healthy disks and 8,256 failed disks. The second proprietary dataset has been collected by Tencent and spans 29 months consisting of 70,192 healthy disks and 2,971 failed disks. All disks in these datasets were labeled to be either failed or healthy. Note that the data from these two data centers are extremely imbalanced. We tried to impute the missing S.M.A.R.T values or disks by replacing them with the median value.

Attribute Selections. Each S.M.A.R.T instance contains many meaningful attributes. We first select all the common attributes of the disk manufacturers. However, we find some attributes are irrelevant to disk failure events because they are immutable or have not experienced noticeable abnormal changes. Therefore, we use correlation coefficients and select nine attributes that correlate most with disk failure. The selected attributes are listed in Table 3. Each SMART attribute entry consists of many elements. In our paper, we focus on the three elements $(ID, Normalized\,value, Raw\,value)$ in our collected datasets. Since different attributes have different output ranges, (which might lead to different impacts on the detection model), we normalize the range of all S.M.A.R.T attributes using min-max normalization, a common preprocessing technology in machine learning: $x_{norm} = \frac{x - x_{min}}{x_{max} - x_{min}}$ where x is the original value of a S.M.A.R.T attribute, x_{max} and x_{min} are the maximum and minimum value of the attribute in the training data set, respectively. Note that we tried other normalization methods (e.g., z-score), but achieved the best results using min-max normalization. The hyper parameters and attribute selections were done over the entire datasets.

Table 3: The S.M.A.R.T Attributes for Our Evaluations

#ID	S.M.A.R.T Attribute Name	Attribute type
001	Raw Read Error Rate	Normalized
004	Start/Stop Count	Raw
005	Reallocated Sectors Count	Raw
012	Power Cycle Count	Raw
187	Reported Uncorrectable Errors	Normalized
193	Load Cycle Count	Normalized
196	Reallocation Event Count	Raw
197	Current Pending Sector Count	Raw
198	Offline Uncorrectable Sector Count	Raw

5.1.2 Experiment Setup.

To simulate the detecting process of disk failure in the real world, we use the following method to build the experimental datasets. All disks are randomly divided into a training set and a testing set at a ratio of 7 to 3, as in most researches [1,35,67, 68] which guarantees that the failed disks in the training set and the testing set are completely independent. Note that the deterioration of a failed disk is a gradual process from healthy to failure, and not all samples of failed disks need to be used in the training set; otherwise, those healthy samples of failed disks which are far from the actual failure would disturb the training of the detection model. Therefore, only the last seven continuous samples (we detailed it in Section 4.3) before the moment of failure of the training disks can be regarded as failed samples and need to be added to the training dataset. Furthermore, we obtain all results via cross-validation [69] to decrease the variability of the detections (analogous to many methods [1,41,70]). For the configurations and parameters of our system *HDDse*, the maximum number of training epochs is set to 1000; the learning rate is initially set to 0.1, and we decrease it by a factor of 2 every 50 training epochs; the coefficient of weight decay λ is set to 10^{-8}. We train and evaluate our method on a Linux server with 12-core 4.0GHz CPU, 64GB RAM and 200GB HDD.

5.1.3 Evaluation Metrics.

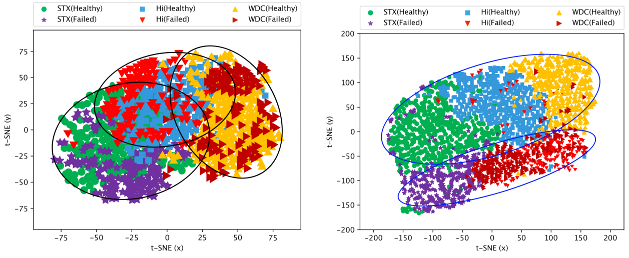
We use the following five metrics to report the detective performance in our experiments which are commonly used for evaluating the capability of disk failure detection approaches.

TPR. True Positive Rate (also called recall) is the proportion of failed disks that are correctly predicted. The higher the TPR is, the better the model is.

FPR. False Positive Rate (also called false alarm rate) is the proportion of healthy disks that are falsely predicted as failed. The lower the FPR is, the better the model is.

AUC. We use the AUC (Area under the receiver operating characteristic curve) value under the ROC curve (receiver operating characteristic) to evaluate the binary classification performance of our detection model in imbalanced datasets. ROC is a curve plotting the TPR against the FPR where TPR is on the y-axis and FPR is on the x-axis. Therefore, the larger the AUC value, the higher the TPR and the lower the FPR. AUC is the area under this curve. A higher AUC means the model is better at distinguishing failed and healthy disks.

[3] https://www.backblaze.com/b2/hard-drive-test-data.html



(a) Before embedding. (b) After embedding.

Figure 7: The t-SNE of the S.M.A.R.T data before and after embedding using our approach. After the disk state embedding, the healthy and failed disks are nearly clustered together and easily separated.

F-Measure. F-Measure is a balance between the two metrics TPR and Prediction Precision (PP). PP is the proportion of detected failed disks that are correctly detected. The higher the F-Measure is, the better the model is.

C-MTTDL. We use Cost-based MTTDL (Mean Time To Data Loss) to evaluate the reliability and availability of the storage system. MTTDL [71] was proposed to approximate the mean time to data loss with failure detection model which is given by: $MTTDL \approx \frac{MTTF}{1-\frac{k\mu}{\mu+\gamma}}$ where $MTTF$ is the Mean Time To Failure of a disk. k is the TPR and γ is the inverse of how far in advance the model can detect the impending failures. μ is the inverse value of Mean Time To Repair (MTTR, replace a new disk or transfer the data of the failing disk to a new one). However, this metric only demonstrates the relationship between the MTTDL and the TPR (correctly detected) but neglects the cost of misclassification by the approach. Too many misclassifications will result in unavailability of the storage system. Therefore, we propose an end-to-end economic analysis metric called the Cost-based MTTDL ($C-MMTDL$) which considers not only the reliability but also the misclassifications cost (considering the false positive rate and cost of replacing disks). We will give the detailed definition of $C-MTTDL$ in Section 5.2.5. Although we propose the $C-MTTDL$, it is interesting to explore other end-to-end evaluation metrics (benefit in customer-perceived latency or throughput from accurate prediction).

5.2 Effectiveness Comparison

In this section, we first analyze the disk state embeddings learned by our LSTM-based Siamese Network. Then we show the results of *HDDse* compared to several state-of-the-art approaches in aspects of the ability of the minority disk detection, model applicability and adaptability respectively.

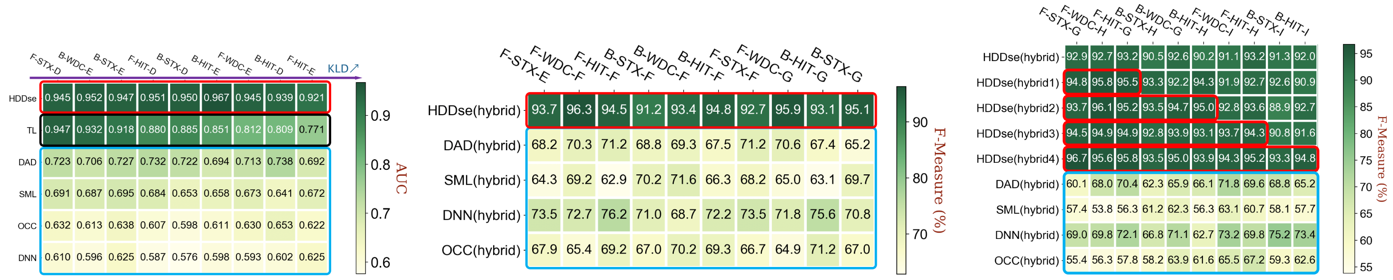
5.2.1 Analysis of Disk State Embeddings

To visualize the high-dimension embedded disk statues of the embedding layers in our approach (See Figure 4), we use the t-Distributed Stochastic Neighbor Embedding (t-SNE) [72] technique which can project high-dimensional embedding spaces into 2D spaces for visualization while striving to keep data clustered together in the high dimensional space clustered together in the low-dimensional space as well.

For comparison, Figure 7 shows the t-SNE of the S.M.A.R.T data attributes in low and high dimensionality respectively (before and after embedding using *HDDse*) based on the collected data from three disk manufacturers. In our case, the low dimensionality is the original S.M.A.R.T attributes most of the recently proposed methods (DAD, SML, DNN, OCC and TL) leveraged (the specific attributes are listed in Table 3). Note that the x and y axes of a particular point have no meaning on their own and the t-SNE only attempts to preserve clusters in higher dimensional space. The data points have been colored and shaped based on disk statues and their manufacturers. It is observed the data points of these three disk manufacturers cluster relatively closely and the relationship between the healthy and failed disks is hard to distinguish with a unified method shown in Figure 7(a). This highlights the challenges in failure detection of disks based on S.M.A.R.T attributes in heterogeneous populations. This result is consistent with the findings of the research [70] and results in most of the related works only considered population consisting of the same disk models in their experiments. As can be seen from Figure 7(b), the healthy and failed disks are easily separated (the healthy state is above the failed state for all the disks from different manufacturers) after the embedding using our proposed approach. This experiment demonstrates that our *HDDse* can generate a unified and efficient high-dimensional disk state embeddings for generic disk failure detection of heterogeneous disks.

5.2.2 *HHDse* only Trained on Minority Disk Datasets.

As mentioned in Section 4.3, the input training pairs generated by our method is extremely large compared to the original samples of existing approaches. It is interesting to investigate the detective performance of *HHDse* when only trained on minority disk datasets. We compare our approach with the other five state-of-the-art approaches: DAD [12], SML [17], OCC [35], DNN [31] and TL [1]. For a fair comparison, the TL approach uses the majority disk model which has the smallest KLD value with the detecting minority disk model from the same manufacturer to train the detective models. Minority disk models from different data centers and manufacturers are listed in the x-axis ordered by these calculated the smallest KLD values. For other approaches, they only trained the detective model based on minority disk datasets. As can be seen from Figure 8(a), none of the four approaches (DAD, SML, OCC and DNN) can deliver a high AUC value. The poor detective performance is due to overfitting caused by using small homogeneous datasets [1]. In particular, DNN achieved the worst results because the neural network required a huge number of samples to fit a large number of weights. Besides, the results of the TL method imply it largely depends on whether you can find the smallest KLD value majority disk training dataset for modeling as discussed in Section 3.1.2. It is worthy to note that our *HDDse* achieves the best performance in all cases. The reason is two-fold. On the one hand, the training pairs generated by our method are extremely large which makes our model not easy to get overfitting. On the other



(a) (b) (c)

Figure 8: (a) Performance comparison for minority disk failure detection of different approaches. *HDDse* delivers the highest AUC in most cases. (b) Performance comparison for disk failure detection using hybrid disk datasets. *HDDse* achieves the best detection results in all cases which shows good applicability. (c) Performance comparison for disk failure detection using different hybrid disk datasets. *HDDse* achieves the best detection results even the disk models have not appeared for training which shows good adaptability.

hand, the disk state embeddings in high-dimension learned by our designed LSTM-based Siamese Network is effective for model classification.

5.2.3 The Applicability of *HHDse*

In order to investigate the model applicability of our *HDDse*, we use the imbalanced datasets of ten disk models from three disk manufacturers in two data centers to conduct this experiment. We compare our approach with the other four approaches: DAD, SML, OCC and DNN. Considering the generality, those ten detecting disk models consist of three from the data center Tencent (F-STX-E, F-WDC-F and F-Hi-F), three from data center BackBlaze (B-STX-F, B-WDC-F, B-HIT-F) and four minority disk models from two data centers (F-STX-F, F-WDC-G, B-HIT-G, B-STX-G). We use all these hybrid disk datasets to train and detect these models respectively, and the detective results are shown in Figure 8(b). When dealing with the disks from different manufacturers, data centers and even minority disk models, *HDDse* achieves higher F-Measure values compared to other candidates. The main reason is that our model maps low-dimensional attributes (disk status) to a general high-dimensional space that is not sensitive to the differences in disk models, which leads to the detection to be performed well using a unified distance calculation. This experiment demonstrates that *HDDse* has good applicability for disk failure detection in a heterogeneous environment.

5.2.4 The Adaptability of *HHDse*

We evaluate the adaptability of our *HHDse*, e.g., how an approach can adapt to a disk model that has not appeared in the training dataset. We use another ten disk models (note that they are different from the ten disk models showed in Figure 8(b)) from three disk manufacturers in two data centers to conduct this experiment. As can be seen from Figure 8(c). Data set “Hybrid” contains the same ten disk models for training described in Figure 8(b). “Hybrid1” contains another three disk models from data center Tencent (F-STX-G, F-WDC-H and F-Hi-G) compared to “Hybrid”, dataset “Hybrid2” add another three from data center BackBlaze (B-STX-H, B-WDC-G, B-Hi-H), “Hybrid3” has two more minority disk models from data center Tencent (F-WDC-I , F-HIT-H) than “Hybrid2” and “Hybrid4” includes all 10 disk models in the x-axis compared to the dataset “Hybrid”. For a fair comparison, we use the dataset “Hybrid” to train the DAD, SML, DNN, OCC approaches. The results are shown in Figure 8(c). Our method using different hybrid datasets all achieved better detective performance than other candidates. It is worthy to note that the datasets of the detecting disk models have not appeared for training delivers comparable performance as those disk models contained (framed by red lines) in training data sets in the first five rows of Figure 8(c). It indicates that our *HDDse* does not need to establish or maintain a new model and owns strong adaptability that can completely adapt to a new disk model regardless of disk manufacturers, disk models, data centers, and minority disks. Note that we also verified the HDDse’s performance on NVMe SSD and obtained promising results, which are not included due to the space limit.

5.2.5 Improvement of Storage System Reliability

As the above comprehensive analysis of detective results described, we achieved better AUC and F-Measure compared to other approaches. In this section, we will first give the definition of the economic analysis metric $C-MTTDL$ and then quantitatively evaluate the reliability and availability of the system based on different approaches. $C-MTTDL$ can be expressed as: $C-MTTDL = \frac{MTTDL}{Cost} \approx \frac{MTTF}{(1-\frac{k\mu}{\mu+\gamma})(C_aFP+C_bFN)}$ where MTTDL was defined in Section 5.1.3 and FP (FN) is the number of true healthy (failed) disks that are falsely predicted as failed (healthy). C_a and C_b are the corresponding cost of these misclassifications. These two factors can be set differently and obtain different results according to the model maintenance requirement (cost sensitivity) in the real world. C_a and C_b are set to 200 and 100 (dollars) respectively in our evaluation which were estimated in Tencent data center. $C-MTTDL$ denotes the MTTDL per dollar cost and the larger the better. The larger the $C-MMTDL$ is, the better is the reliability and availability the storage. We investigate the $C-MTTDL$ in based on the datasets from data center Tencent. We assume all models can detect the impending failures seven days in advance ($\gamma = 1/(7*24hours)$, the inverse value of $MTTR$ $\mu = 1/10hours$ and $MTTF$ = 1,390,000 hours. All these parameters come from data center Tencent and our experiments. We list the results in Table 4, which shows our approach improves the $C-MTTDL$ by about 2 orders of magnitudes than the other four candidates. In other words, in addition to ensuring the detective performance of our approach *HDDse*, we have greatly improved the reliability of the storage system at a lower cost.

Table 4: Improvement of C-MTTDL

Method	$k(TPR)$	**FP**	**FN**	**Cost**	**MTTDL (years)**	**C-MTTDL (hours/dollar)**
OCC	**62.6%**	8212	1062	1,748,600	397.6	1.94
DAD	**45.2%**	3422	1537	838,100	276.7	2.89
SML	**72.6%**	6159	783	1,310,100	504.10	3.37
DNN	**85.3%**	4791	419	1,000,100	814.13	7.13
HDDse	**95.8%**	103	140	34,600	1656.3	419.35

5.3 Efficiency Comparison

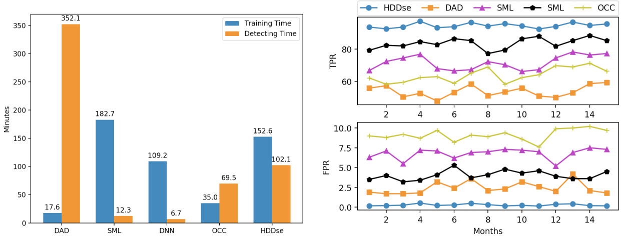
In this section, we evaluate the effect on training/detecting time and the practical long-term availability of our approach *HDDse* compared to the state-of-the-art approaches.

5.3.1 Training and Detecting Time

We train and evaluate all the approaches on a Linux server with 12-core 4.0GHz CPU, 64GB RAM and 200GB HDD. All the approaches record the total training (from start until convergence is achieved, i.e. little changes in the performance) and online detecting time (it is for the entire testing set). Figure 9(a) provides further time statistics for each approach. DAD has the lowest training time and the highest detecting due to its easy training method and large computation of calculating distances. Our approach *HDDse* takes the second-highest training time followed by the SML method (Random Forests) and the second-highest detecting time followed by the DAD method. This is attributed to our method generating large training pairs compared to the original datasets that need more time to converge. Moreover, it needs more time compared to other training samples to determine the disk statue in the detecting process (we use some sampling methods to accelerate the process of detecting mentioned in Section 4.4). Considering the training task in a data center and sometimes, the detective models are updated weekly or monthly (we perform once a week), so the time cost of *HDDse* is acceptable. Note that the time cost can be further shortened if GPU and many model compression and acceleration technologies [73] are used. We leave in our future work to explore other solutions for optimizing the efficiency of our approach.

5.3.2 Evaluating Practical Long-Term Availability

We last simulate practical long-term availability in data centers Tencent. As we mentioned in section 4.2, S.M.A.R.T data of the disk changes dynamically with a certain trend, thus the distribution of S.M.A.R.T attributes changes over time, resulting in unstable detective performance for many approaches. However, it is important to design a stable detection approach for large data centers without additional manual model tuning. To fairly evaluate the detective performance of different approaches in the long term, we employ the same accumulation strategy to update the model periodically e.g., once a week, using all the training data collected from the beginning. Figure 9(b) shows the TPRs and FPRs of the different detective approaches in the following 15 months. As can be seen, *HDDse* shows higher TPR and lower FPR compared to other state-of-the-art methods. It is worthy to note that *HDDse* exhibits stable detective performance than other candidates. We attribute this to the LSTM-based network which is well learned from the dynamically changed long-term behavior of disk statues. Similar to most of related works, we are focused on the predictive accuracy, because designing an accurate approach is the first critical step toward building a robust, highly reliable, and readily available operational storage system. With a high-accuracy failure prediction approach in place, we will have a high level of confidence in integrating it into the system, which is more of a mechanism rather than a policy. For instance, a direct application is to use the prediction results to perform data backups and replace disks that are about to fail to prevent data loss. Moreover, we can use the predictive results to analyze the mechanism of disk sector error and build a sector error predictive model to accelerate the scrubbing rate of disks to find the sector errors in advance and improve the reliability of the storage system.



(a) (b)

Figure 9: (a) Training and detecting time comparison for different approaches. (b) TPR and FPR of different approaches. *HDDse* delivers higher TPR and lower FPR in a stable manner which shows long-term availability.

6 Conclusion

Disk failures have become one prevailing reason for unexpected system unavailability. In this paper, we propose *HDDse*, an LSTM-based siamese network that can learn the dynamically changed long-term behavior of disk healthy statues and generate a unified and efficient high dimensional disk state embeddings from low dimensional S.M.A.R.T attributes for disk failure detection. We evaluate our approach using two real-world datasets to demonstrate that *HDDse* is effective and outperforms several state-of-the-art approaches. Specifically, *HDDse* has good detective adaptability to the disks which have not appeared in training and deliver good performance for the imbalance or minority disk datasets, thus improving storage system availability. Furthermore, the proposed approach improves the reliability of a data center and exhibits long-term availability.

Adaptive Placement for In-memory Storage Functions

Ankit Bhardwaj Chinmay Kulkarni Ryan Stutsman
University of Utah

Abstract

Fast networks and the desire for high resource utilization in data centers and the cloud have driven disaggregation. Application compute is separated from storage, but this leads to high overheads when data must move over the network for simple operations on it. Alternatively, systems could allow applications to run application logic within storage via user-defined functions. Unfortunately, this ties provisioning and utilization of storage and compute resources together again.

We present a new approach to executing storage-level functions in an in-memory key-value store that avoids this problem by dynamically deciding where to execute functions over data. Users write storage functions that are *logically* decoupled from storage, but storage servers choose where to run invocations of these functions *physically*. By using a server-internal cost model and observing function execution, servers choose to directly run inexpensive functions, while preferring to execute functions with high CPU-cost at client machines.

We show that with this approach storage servers can reduce network request processing costs, avoid server compute bottlenecks, *and* improve aggregate storage system throughput. We realize our approach on an in-memory key-value store that executes 3.2 million strict serializable user-defined storage functions per second with 100 µs response times. When running a mix of logic from different applications, it provides throughput better than running that logic purely at storage servers (85% more) or purely at clients (10% more). For our workloads, it also reduces latency (up to 2×) and transactional aborts (up to 33%) over pure client-side execution.

1 Introduction

Today, in data centers and the cloud, compute is disaggregated from storage. Separating compute and storage eases provisioning and keeps utilization high by decoupling their allocation. Fast networks have made this practical, but moving all data to compute comes at a cost.

Beyond conventional, higher-level approaches like SQL, many systems have evolved to embed more functionality within storage servers to make storage operations more expressive and to reduce inefficient data movement. For example, some databases allow compile-time extensions [38,47], user-defined functions [34], and stored-procedures [19,22,33,38,48]. Among key-value and object stores, some stores offer a fixed set of extra operators [2,43], while others allow runtime extension with just-in-time [14,26,45] or ahead-of-time compiled user-supplied operations [26]. All of these approaches move user operations closer to the data that they operate on.

The downside is that these approaches fix the ratio of compute to storage, so compute at storage servers can quickly become a bottleneck. The result is that the state-of-practice is to prefer easy provisioning and high utilization while keeping a hard network boundary between compute and storage.

However, the steady decrease in the granularity of compute allocation and scheduling in the cloud (from virtual machines, to containers, to serverless functions) has raised a possibility: application compute need not be statically embedded within storage; nor must it be the case that it is always run separately. Storage servers that support running granular user-supplied functions at low cost create the opportunity to dynamically adapt where functions on stored data are executed. By shifting processing of storage functions back to storage client machines, a storage server can avoid CPU-intensive operations when under load to avoid becoming bottlenecked, choosing instead to send data back to clients for processing. By shifting processing onto itself, a server can eliminate data movement, lend its spare CPU capacity to clients, and reduce its own request processing load. Since moving user-logic into the server reduces the number of requests clients make for data, counter-intuitively, a server can improve its own throughput by taking on more of client applications' compute work.

To show the benefits of such an approach, we developed a new scheme for executing storage functions on top of Splinter [26], which is an extensible in-memory key-value store. Beyond fast `get()`/`put()` key-value operations, applications can push compiled, binary-code extensions containing storage functions to Splinter. These functions can be invoked over the network by clients with low overhead such that even operations that only perform a few microseconds of compute are practical and efficient. Our new approach builds on Splinter to imbue it with a profiler that tracks storage function execution. Clients attempt to invoke their functions at servers. Servers use an internal cost model that weighs the CPU cost to the server if the function were to continue to run at the server against the CPU cost to the server if the function were to run at the client (which would result in extra remote requests to the server for data). Functions invocations that compute over large amounts of data are deemed beneficial and are run at the server, since running them at the client would require transferring large amounts of data. Functions invocations that are compute-intensive but access little data are *pushed back* to the client, where the client must perform the computation.

Beyond the server side, the framework includes a smart storage client library that makes "pushback" cases transparent to applications. The server and the storage client library both provide a binary compatible runtime, so functions are unaware of whether they are run at a storage server (where data access is local) or at a client (where data access is remote). Applications attempt to invoke their storage functions, and the client library transparently executes any client function invocation requests that are pushed back by the storage server before returning the result to the application.

In our model, invocations may execute on the server, at the client, or partially on both, so ensuring consistency is a challenge. Our approach adapts techniques from distributed optimistic concurrency control protocols (OCC) [3, 27, 51] to solve this. All storage functions run within strict serializable transactions, which ensure that clients observe the same strong consistency regardless of where functions execute. These transactions play a key role in the function execution model itself; when a function's execution is transferred from a server to a client, its transaction's read/write set is shipped along with it, avoiding extra requests back to the server for data.

We demonstrate adaptive storage function placement (or *ASFP*) with functions drawn from different domains including aggregation, graph traversal, machine learning classifiers, and authentication. We show these workloads have heterogeneous compute demands, often with compute-to-storage-access ratios varying within one application's functions. Even so, ASFP provides throughput better than running functions purely at storage servers (85% more) or purely at clients (10% more), and it automatically adjusts, optimizing throughput as workloads and server network costs vary and change.

2 Background and Motivation

Today, cloud and data center applications keep data in one set of servers and compute over it on another. This "client-side" function execution model serves as a baseline. Our question is, can a system consistently beat the performance of this client-side approach without creating server bottlenecks?

To do this, one needs a way to embed application logic within storage to compute on data. Our approach relies on the Splinter multi-tenant in-memory key-value store (KVS) [26]. Similar to other low-latency in-memory stores like RAMCloud [40] and FaRM [12], remote clients issue `get()`, `put()`, `multiget()`, and `multiput()` operations to a Splinter server. Unlike most other systems, clients also send compiled *extensions* with custom *storage functions* to it at runtime, which they *invoke* remotely to perform operations over their data. Invoking a storage function only incurs 1,400 cycles of overhead and adds no other no runtime overheads. Splinter achieves low-latency and high-throughput via kernel-bypass networking; one server handles 6.5 million `get()` or 13.5 million no-op `invoke()` requests per second over the network with tens of microseconds of delay. It supports thousands of inter-isolated tenants per server; each application and its storage functions can only access and modify data that it owns.

Extensions reduce requests to storage. With them, a single request could fetch a "user profile" object along with the profiles of friends listed within that profile. Another application could make recursive k-hop queries by traversing edge lists stored in values or make classification requests to stored models. Storage functions access multiple values, reducing server request processing costs, but they are most effective for inter-dependent data accesses since these accesses would otherwise require multiple requests separated by a round-trip.

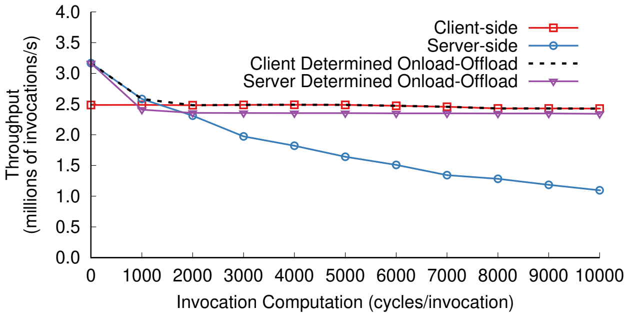

Figure 1: Server-side vs client-side throughput when CPU cost varies. Throughput is inversely related to the compute applied to two accessed values per invocation when run server-side. When the logic is run client-side, the server must process more requests (2 `get()` vs 1 `invoke()` request), but computation is offloaded to clients.

2.1 Understanding the Impact of Placement

Storage functions can lower server overhead, but if functions perform too much computation, then the benefits of eliminating requests are offset as the server CPU becomes a bottleneck. Figure 1 shows this effect. When functions are run server-side (circles), a server performs 3.2 million invocations/second if the functions perform no computation, but its throughput is inversely proportional to the CPU cycles spent computing on the values (x-axis). When run client-side (squares), the server only processes the two `get()` operations for each function; the extra computation is run at clients, which have sufficient idle CPU to perform the work. (Later, we show that if clients do not have idle CPU capacity, our approach shifts work to the server still so long as it is not overloaded. In either case, a global bottleneck is avoided.) When functions perform no computation on values, the two `get()` requests incur higher server-side overhead than sending one `invoke()` request, so server CPU becomes a bottleneck when servicing the equivalent of 2.5 million invocations/second.

Sometimes pure server-side execution provides better system throughput and other times pure client-side execution does. The key insight of this paper is that with lightweight performance tracking, the server can determine this cross-over point, and it can separate invocations into those that should be kept at the server from those that are better run at clients.

2.2 Challenges in Execution Placement

Ideally, a server could get the best of both worlds if it could perfectly determine where to execute an invocation. We simulate this by manually controlling where invocations run based on how much computation they do on data

(`Client Determined Onload-Offload`, dashed line). Here, clients never issue compute-heavy invocations to the server – so, performance matches pure server-side execution for data-intensive invocations and pure client-side execution for compute-intensive invocations.

However, real clients (and real servers) do not know how much computation an invocation will use a priori; different functions vary, and even invocations of the same function could access values and use the CPU in different ratios. Statically determining how much data or how much computation an invocation will use is undecidable in general. Static analysis or modeling might help make good guesses, but the analysis could be fragile and have pathologies.

Our approach is to measure rather than guess; rather than using history, another option is to optimistically assume invocations should run at the server and then try to minimize the cost of correcting mistakes. Figure 1 shows the cost of this conservative, "black box" approach (`Server Determined Onload-Offload`, triangles). Here, clients always invoke functions at the server, but the server quickly sheds invocations that consume CPU without accessing many values. This adds overhead for compute-intensive functions, since the server wastes a small amount of compute before realizing the mistake, but these results show this only hurts throughput 3% for compute-intensive invocations (all other invocations benefit).

Simple enhancements to this scheme are likely to work in practice. Tracking the history of the costs of a particular function's last few invocations can help. If a function's invocations are determined better to be run client-side a few times in a row, then running the next several invocations client-side makes sense. This would work for many applications, but we intentionally avoided such tweaks in this paper. Our approach never relies on the history of invocations (neither across nor within a function); optimizations that make better predictions are likely limited to only recovering that 3% of performance.

In summary, ASFP based on optimistic onloading of application compute to storage with pushback to clients achieves the best of both worlds. For storage functions that access a great deal of data, ASFP avoids data movement costs; for functions that are compute-costly it avoids server bottlenecks.

3 ASFP Design

Applications vary in how they work with data they hold in remote storage. Compute-bound applications may access little data, so moving data to computation is efficient; for data-intensive applications moving computation is more efficient. Multi-tenant stores take this to an extreme: they see a diverse set of applications with a wide variety of compute and data needs. The key idea of ASFP is to exploit this diversity by optimistically colocating functions with the data they access and then profiling storage function execution costs to dynamically relocate invocations that would create a bottleneck.

ASFP relies on *mechanisms* for running storage functions at servers, at clients, or split between both and *policies* to control the mechanisms and decide placement. The four main mechanisms are needed for ASFP are:

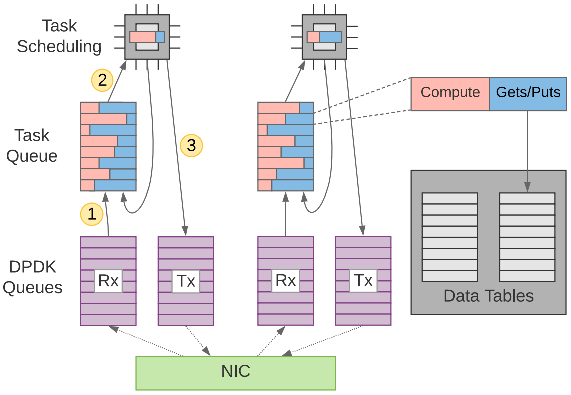

Figure 2: Splinter Request Execution. Each server core has a dedicated network receive queue where clients steer requests. Each core polls this queue and creates a task for each incoming request. Tasks are run round-robin; storage functions can access key-value pairs and perform custom computation on them within the server.

- **Server-side Storage Functions (§3.1.1).** Tenant-provided storage functions reduce data movement. They are key for improving server performance for data-intensive functions. This functionality already pre-exists in Splinter.
- **Server-to-client Pushback (§3.1.2).** ASFP uses a *pushback* scheme that relocates costly function invocations back to clients to avoid server-side bottlenecks.
- **Concurrency Control (§3.1.3).** Since a single function invocation could run partly server-side and partly client-side, consistency becomes an issue. ASFP ensures that this does not cause repeated effects or inconsistencies. It uses OCC to ensure strict serializability of invocation operations, and it integrates with OCC read/write set tracking to preserve work for invocations that are pushed back to clients.
- **Client-side Runtime (§3.1.4).** Clients locally execute invocations that are pushed back from the server, and the ASFP client library makes this transparent. Applications wait for invocations to complete; the client library runs pushed back invocations, fetching data from the server as needed.

The server's primary objective in ASFP is to minimize the CPU usage per function invocation and to optimize its own throughput, which, indirectly optimizes the throughput of the entire system. The ASFP policy relies on three key components to do this:

- **Invocation Profiling.** Each server tracks each function invocation as it runs to account for its CPU time.
- **Request/Response Cost Modeling (§3.2.1).** Similarly, each server dynamically profiles networking CPU costs to determine a CPU cost model for data movement. This projects how much server CPU is being saved by running each invocation at the server. If an invocation has consumed substantially more CPU cycles at the server than the request/response cost model projects have been saved by running it at the server, then it is pushed back to the client.

Overload Trigger (§3.2.2). Even compute-bound functions run more efficiently at the server than they do at clients since they can avoid data movement. All invocations run at the server if there is spare CPU capacity available, so long as they don't create a bottleneck at the server. Hence, pushback is only triggered when our server deems itself overloaded.

First, we describe ASFP's mechanisms to show how storage functions, pushback, and concurrency control work; then, we explain how its measurements and policies drive its mechanisms. Overall, ASFP constitutes about 7,500 lines of code split across additions to the Splinter server and a the new client library, which shares much of its code with the server (available at `https://github.com/utah-scs/splinter/`).

3.1 ASFP Mechanisms

3.1.1 Server-side Storage Functions

ASFP is built on top of the Splinter in-memory KVS. Splinter supports typical KVS remote `get()` and `put()` operations. It is a good starting point because it also supports installation of client-supplied native-code extensions. These extensions add storage functions to the server that can be called remotely via `invoke()` requests. ASFP uses `invoke()` requests to move computation to data, and it extends Splinter with new profiling, policy, and function invocation relocation functionality.

Internally, Splinter multitasks between `get()`, `put()`, and (possibly longer-running) `invoke()` requests, so each incoming request is converted into a *task*. The server runs these cooperative tasks round-robin until they complete or yield; this prevents head-of-line blocking when functions take awhile to execute. Tasks handling `invoke()` operations maintain state for the running storage function as a coroutine stored in the task. Figure 2 illustrates request processing. Each server core polls a CPU-core-specific network receive queue and creates a task for each incoming request (①), each of which is added to a per-core task queue. Each queued task is run once (②), then the core polls its receive queue again. The core transmits a response (③) when a task completes and then destroys it.

Invocations run interleaved due to cooperative scheduling, but they can also run in parallel too. Clients steer requests to specific CPU cores to reduce overhead, but server cores steal work from each others' receive queues to keep throughput high under load imbalance. Hence, pipelined invocations from a client can run in parallel at the server.

3.1.2 Pushing `invoke()`s Back to Clients

ASFP lets Splinter servers selectively shed load. When a storage server's cores are overloaded, it *may* perform a *pushback* on tasks. These tasks are terminated at the server and restarted client-side. Figure 4 shows the state transition diagram of the lifecycle of an `invoke()` request at a server. ASFP adds a new `Offload` state to server-side tasks to support pushback.

For each incoming `invoke()` request, a server creates a task and tries to run it to completion, sending a `Result` response (top of Figure 3). However, if a server is past an *overload trigger point* (§3.2.2), then it chooses some `Ready` `invoke()` tasks that are good candidates for client-side execution based on a *threshold function* (§3.2.1), and it moves them to `Offload`.

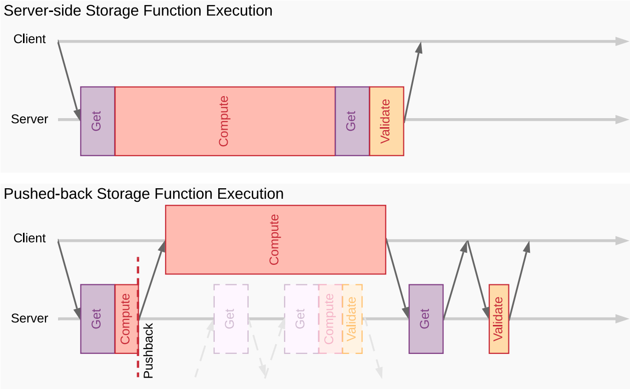

Figure 3: Timeline of a function invocation request when run server-side (top) and when pushed back to the client side (bottom). In this case, offloading this relatively long-running function to the client gives the server extra CPU resources to service other requests.

When tasks in the `Offload` state are scheduled, a `Pushback` response is generated that informs the client that it should run the function client-side. The client runs the function, falling back to making `get()` requests to the server to fetch needed values (`put()`s are cached locally and installed atomically when the invocation completes, §3.1.3). Figure 5 shows this. If the client receives a `Result` response, the work of the requested invocation has been done, and there is nothing left to do. If the client receives a `Pushback` response, the client begins to execute the function logic itself in a fashion similar to the server. The bottom of Figure 3 shows the interactions between the server and the client when an invocation is pushed back to the client; as shown, this avoids a bottleneck in this case, freeing the server to process other requests at the server.

3.1.3 Consistency and Concurrency Control

Storage functions and pushback create interrelated challenges, especially for consistency. First, `invoke()` tasks run concurrently at the server; this can happen because tasks run interleaved at the server and because server cores perform work stealing. Pushed back requests also create concurrency, since those functions run at the client in parallel with server tasks. Second, when tasks are pushed back, the client restarts execution of that function from the beginning – pushback has no means to preserve the running state of a function to resume it at the client. This means that without care, clients might repeat operations, which would affect the concurrent behavior of functions and make it hard to reason about consistency.

To solve these consistency issues, invocations are run as strict serializable transactions. This makes it easy to reason about consistency regardless of where an invocation is run. ASFP adds OCC transactions to Splinter. When a server receives an `invoke()`, it creates an empty read/write set. The server tracks the version of each value that a task sees and the values that the tasks wishes to install in storage. If the task

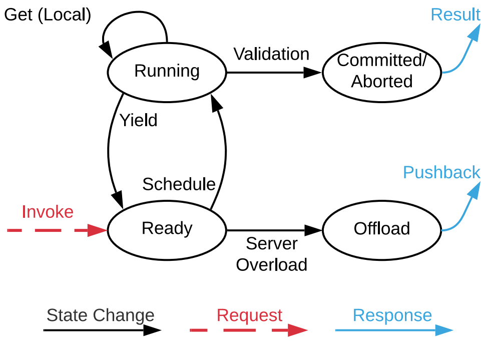

Figure 4: Server-side task states for an `invoke()`.

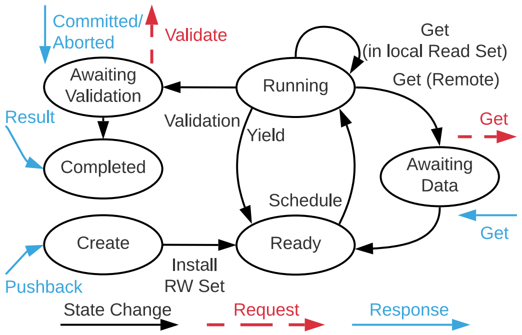

Figure 5: Client-side task states for a pushed-back `invoke()`.

completes on the server, validation is performed by latching the invocation's read/write set. For each key in the read set, if the associated value versions remain unchanged, then its write set is installed and the client is informed of commitment; otherwise, the server indicates abort.

The server's read/write set has a second purpose: by tracking what values an invocation has read, the server can save work by returning those values immediately on pushback. The client installs this read/write set locally before restarting the function. This way, the server will never have to repeat any work for a pushed back task: all of the values the task needs have already been delivered to it up to the point that it was terminated at the server. This is key: pushed back requests never generate extra work for the server. This bears similarities to reconnaissance queries in deterministic databases [50].

On completion of a pushed back task, the client sends the write set and version metadata for the values it read to the server where validation is performed the same as if the task has completed server-side. This is another advantage of OCC: the server need not keep any state about an invocation once it is pushed back. For example, the server retains no metadata or locks on behalf of a pushed back task. This makes any recovery or state reclamation unnecessary on client failures.

3.1.4 Client Runtime for `invoke()`s

Splinter client requests consist of basic `get()/put()` requests and `invoke()` requests that attempt to invoke a storage function within the store. Clients register *extensions* at the server before invoking the functions they contain. ASFP requires that the same extensions are registered at the client library as well, so that they can handle pushed back `invoke()` requests.

On each `invoke()` response from the server, the client checks a `Pushback` response flag. If it is set, the client performs logic similar to request dispatching on the server: it creates a task and coroutine similar to the ones used on the server, and it places the task in a client-local task queue (Figure 5). The main difference is that the read/write set returned from the server is used to pre-populate the read/write set of the invocation before it starts at the client side.

Clients put `Ready` tasks in their task queue and run tasks round-robin, just like the server. This lets clients make progress on invocations while continuing to issue new operations to the server.

The ASFP client library provides a binary-compatible interface with the server, so identical versions of storage functions work whether they run at the client or at the server. Splinter extensions have a restricted `get()/put()` interface for interacting with storage, and they have a restricted set of whitelisted library functions they can run beyond that. Extensions on the client-side have the same restrictions, so that pushed back invocations will run the same way in both places.

Client-side execution does run different from server-side in one important regard: the client must access key-value pairs remotely. This is solved by passing in handles into storage functions through which they request access to data. On the server-side the handles call `get()/put()` functions to access data directly; on the client-side the handles issue remote `get()/put()` requests. Requests to the store take about 10 µs to service, and task context switch time is just 24 cycles, so tasks waiting for responses from the server enter an `Awaiting Data` state. Each invocation has a unique client-side id; whenever the client library receives a response to a particular extension invocation, it adds the record to the local read/write set for that invocation. Clients read through their read set; after a "hit" in their read set or upon the completion of a remote access, the task is returned to the `Ready` state.

3.2 ASFP Policies

3.2.1 `invoke()`s Profiling and Classification

Splinter is both multi-tenant and extensible. Together, these mean that it must deal with different access patterns and functions with varying compute-to-storage-access ratios. This also means a server will be able to find many suitable functions to run that can reduce its load. When overloaded, it must determine which `Ready` tasks should be pushed back; however, pushing back the wrong tasks can *hurt* its throughput.

Whether a task is beneficial to server throughput when run server-side is determined by two things: the amount of CPU time it uses computing on the values it accesses (which hurts throughput) and the number of values it interacts with (which benefits throughput, since each access run at the server eliminates a network request that it otherwise would have had to process). Effectively, each time a task accesses a stored value it should be credited for the amount of server CPU it saved by having run that operation locally. Likewise, whenever it performs other computation that does not save server CPU work it should be debited, since this slows request processing.

This results in a natural threshold for when tasks would be pushed back to clients, which we call the *pushback threshold*. It is defined by

$$c < nD - (D+I)$$

where c is the amount of computation done by an invocation so far, n is the number of values accessed by the invocation so far, D is the request processing CPU cost, I represents the cost to perform an invocation (beyond request processing cost). Effectively, nD is the work the server would have done if the client issued n `get()` requests. $(D+I)$ represents CPU cost at the server of an `invoke()` request. Hence, so long as $c < nD - (D+I)$, server-side work is saved by letting the invocation remain at the server.

This inequality divides all tasks into two classes, $\mathcal{S}$ and $\mathcal{C}$. Tasks in $\mathcal{S}$ are beneficial to run at the server, and tasks in $\mathcal{C}$ improve server throughput when run at clients. The inequality does not hold when an invocation accesses zero or one values; these invocations save the server less work than the cost of an `invoke()` request. It never makes sense to run them at the server, and it would also be unusual for a client to try to do so. The model is simple and linear, so the server can calibrate it inexpensively at runtime. Just by profiling the cost of an `invoke()` operation and a `get()` operation, it can accurately assess which invocations should be pushed back.

As discussed in Section 2.2, it is undecidable in general to determine the class of an invocation. The input parameters to an `invoke()`, the data its accesses, the server hardware, and its cache policies/pollution all influence performance. Our approach simply assumes all invocations should be initially attempted server-side. Exploiting history or domain knowledge would improve performance in cases where functions are pushed back. However, we explicitly avoid relying on such information since its effectiveness is workload dependent, and it can only provide a few percent performance improvement for invocations in $\mathcal{C}$ (and would only hurt functions in $\mathcal{S}$).

3.2.2 Server Overload

The final piece of ASFP is overload detection. Functions should always run at the server when it has idle CPU; this still eliminates data movement costs, and it frees client CPUs to do other work. However, when overloaded, the server must shed load to improve throughput and control response times.

Algorithm 1 shows how the server detects overload (others use similar approaches [39]). The server is under high load when it receives new tasks and the requests from previous scheduling passes have not completed. At the beginning of a server's round-robin pass through its set of tasks, it polls its receive queues and creates up to B tasks, one for each incoming request (where B is the maximum receive batch size, which we fix at 32). Then, it compares the amount of time spent dispatching requests in that round of scheduling (time spent polling network queues and creating tasks) with the time spent executing invocation tasks in that scheduling pass. If invocation task execution time is the dominating factor, the scheduler checks the task queue length. If it contains at least B/k tasks and processing incoming requests would create at least another B/k tasks, then the scheduler sets a flag indicating the server is overloaded. Higher values of k trigger overload more easily; $k = 2$ works well, and we keep it fixed in our experiments. This guarantees that the scheduler:

1. only pushes back work if load is mainly from `invoke()`s;
2. keeps at least B/k tasks in the queue after pushback; and
3. only pushes back when $\geq 2B/k$ requests await service.

On overload, the server tests the threshold inequality (§3.2.1) on all old `Ready` tasks, triggering pushback on some of them.

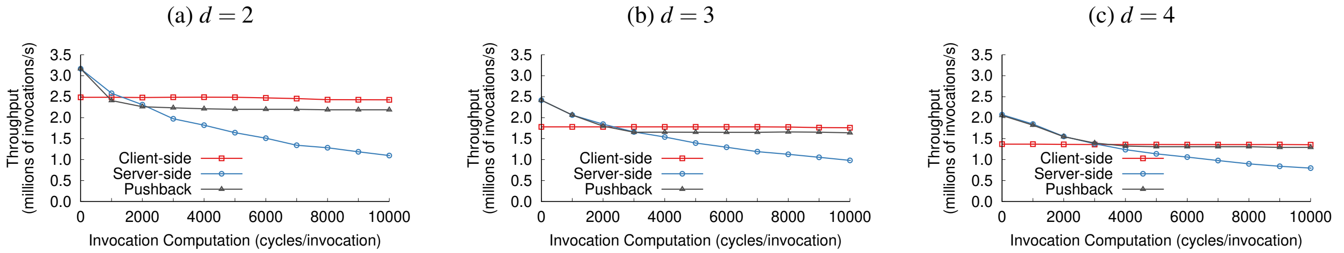
Algorithm 1: Server Overload Detection

```
Function Scheduler()
    totalTime ← 0;
    while true do
        t ← taskQueue.Dequeue();
        if t = DispatchTask then
            newTasks, dispatchTime ← PollRecvQueue();
            if totalTime ≫ dispatchTime then
                if taskQueue.length ≥ B/k and
                  newTasks.length ≥ B/k then
                    taskQueue.ClassifyAndPushback();
                    taskQueue.Enqueue(newTasks);
                end
                taskQueue.Enqueue(t);
                totalTime ← 0;
            end
        else if t = RequestTask then
            t.getPutTime, t.computeTime, t.state = t.Run();
            totalTime += (t.getPutTime + t.computeTime);
            if t.state ∉ {Committed, Aborted} then
                taskQueue.Enqueue(t);
            end
        end
    end
```

4 Evaluation

We compare three models for storage functions. *Client-side* runs them on clients and issues `get()` requests to the server. This is state-of-practice and the baseline. *Server-side* runs functions on the server and represents Splinter's approach. *Pushback* is our approach, which runs functions on the server, pushing some back to clients. We focused on these questions:

Does ASFP improve storage server throughput? For an application mix consisting of machine learning classification and graph-based storage functions, ASFP can improve throughput by 10% (§4.5.3). For functions with dependent data accesses, ASFP improves throughput by 42% (§4.2).



(a) $d = 2$

(b) $d = 3$

(c) $d = 4$

Figure 6: A function with 2, 3, or 4 dependent `get()`s followed by varied computation lengths. ASFP improves throughput by 42% over client-side execution. For compute-intensive invocations, ASFP throughput is within 15% of pure client-side in the worst case.

What is the cost of using ASFP? For invocations that improve server throughput (those in class $\mathcal{S}$), ASFP gives the full performance benefit of server-side execution with no measurable overhead. For compute-intensive invocations that access little data, classification and client-side re-execution delivers performance within 15% (§4.2) of pure client-side execution in the worst case.

How effective is the ASFP classifier? For a mix of predominantly $\mathcal{C}$-class invocations with significant compute variance, 87% of all $\mathcal{C}$-class invocations are offloaded to clients (§4.3). The remaining are accurately classified but retained by the server because it has idle compute to execute them, improving overall system throughput.

How does ASFP impact latency? For invocations in class $\mathcal{S}$, ASFP saves on round trips to the server, which reduces latency by as much as 2× (§4.4). For invocations in class $\mathcal{C}$, ASFP's read/write set and server overload-based optimizations can help reduce latency by 15% compared to executing client-side. For extremely compute-intensive invocations, ASFP matches client-side execution.

How do ASFP and OCC interact? Beyond providing consistency, OCC lets the server send back read/write sets on pushback, improving throughput by 33% (§4.6). ASFP also exploits idle compute at both servers and clients speeding up transactions and reducing abort rates (§4.6.1).

4.1 Experimental Setup

Evaluation is on five machines; four as clients and one server (unless otherwise noted) on CloudLab [13] (Table 1). All use DPDK [11] over Ethernet. Eight of ten server cores process requests; Splinter uses two cores for task management. Clients also use eight cores; each core pipelines `invoke()` requests up to a depth of 32 and receives responses in a closed-loop.

Using a closed-loop is helpful. ASFP demands complex, heterogeneous workloads; an open-loop load requires careful manual pacing of the request rate for each storage function type. To ensure we always measure the server at saturation (unless otherwise noted), we control client thread count instead of manually tuning per-storage-function request rates.

The server held 15 GB as 120 M records (30 B keys, 100 B values) unless otherwise noted. On pushback, clients transparently ran functions locally, issuing remote record requests.

CPU	Ten-core Intel E5-2640v4 at 2.4 GHz
RAM	64GB Memory (4x 16 GB DDR4-2400 DIMMs)
NIC	Mellanox CX-4, 25 Gbps Ethernet
Switch	Mellanox SN2410 48-port, 25 Gbps per port
OS	Ubuntu 16.04, Linux 4.4.0-138, DPDK 17.08 Rust 1.29.0-nightly, 16×1 GB Hugepages

Table 1: Experimental setup. Evaluation used one machine as a server and four as clients. All experiments were run on CloudLab.

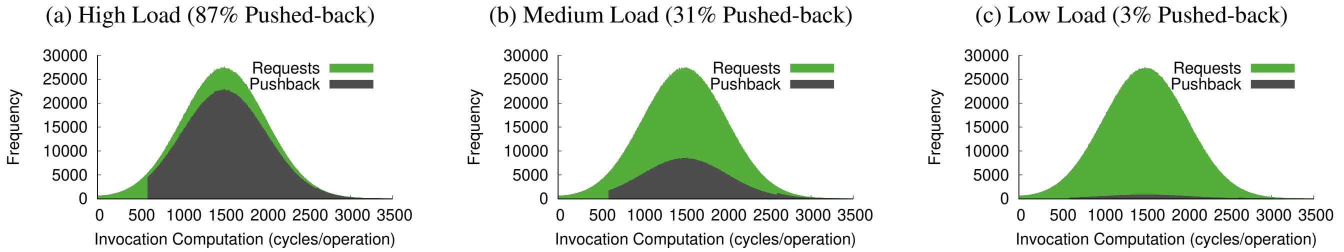
4.2 ASFP Throughput Benefits & Costs

Benefits. ASFP combines the benefits of server- and client-side execution; invocations with low compute-to-data access ratios run on overloaded servers, otherwise they are offloaded to clients. To show this, we run a microbenchmark that varies the number of records accessed and the amount of compute performed within an invocation.

Clients issue `invoke()`s that do d data-dependent `get()`s followed by x cycles of compute. Figure 6 shows server throughput when the function is run purely client-side, purely server-side, and with adaptive pushback for d from 2 to 4. With a small x, server-side execution prevents clients from stalling on remote `get()`s. With a large x, client-side execution with remote value access avoids a server CPU bottleneck.

Here, ASFP's simple model works well. In Figure 6 (a), invocations that perform little compute over values stay at the server, improving throughput over client-side execution by 27%. Invocations using more CPU are pushed back, and throughput tracks the client-side approach. For increasingly CPU-intensive invocations ($x >$ 6,000), the throughput of pure server-side execution tends toward zero, so the benefits of pushback over server-side execution grow (until all client CPUs saturate, but realistic servers will service many clients).

These results show that the more data an invocation accesses, the more savings pushback provides; increasing d to 3 and 4 gives savings of up to 33% and 42%, respectively (Figure 6 (b), (c)). The area between pushback and client-side can be large for CPU-inexpensive functions (left side of graphs), but the area between pushback and server-side for CPU-expensive functions (right side) is also large since real functions will vary even more in how much CPU they use.



(a) High Load (87% Pushed-back) (b) Medium Load (31% Pushed-back) (c) Low Load (3% Pushed-back)

Figure 7: Distribution of invocations generated overlaid with those pushed back to one client under different loads. ASFP can use idle server compute to run some of the invocations classified as $\mathcal{C}$. This is why the distributions do not completely overlap.

Costs. These graphs also show ASFP's costs. On a pushback, there are two costs: the first is the cost of having the server process an extra request for `invoke()` and validation; the second is the computation the invocation did before it was terminated. Most of the first cost is eliminated by shipping all accessed values back to the client on pushback. An `invoke()` only costs 9% more than a `get()`, and all practical functions receive some values when they are pushed back. Hence, the cost of the `invoke()` is offset by the fact that it eliminates the need for the client to issue at least one `get()`.

The second cost explains the gap between the client-side and the pushback approach. This experiment is a pessimistic case: the function first accesses all of its values, then it performs compute over those values. For compute-intensive functions, this means the server runs them longer before it pushes them back; for functions where data access and computation are intermingled, pushback would achieve performance closer to the client-side case. Even so, in all cases where client-side execution would outperform server-side, pushback is only 13 to 15% slower than running everything at clients.

Cost Breakdown. This 15% overhead for ASFP for $\mathcal{C}$-class functions in Figure 6 (a) has two components. The first is the cost of suspending an invocation and sending its read/write set back to the client, but this only accounts for 3% of the 15%. Figure 1 shows this; in it, the performance difference between (omniscient) client-determined placement and server-determined placement that observes each invocation is only 3% even when invocations are in $\mathcal{C}$. The second component of the overhead (12%) comes from an interplay between overload detection and $\mathcal{C}$-class invocations. In Figure 1, the server never executes an invocation in $\mathcal{C}$ to completion, even if the server is idle, but ASFP completes invocations server-side, regardless of class, if the server is underloaded. However, a server's load can shift rapidly at fine timescales. Leaving $\mathcal{C}$-class invocations onloaded is a form of speculation about whether invocations will arrive in the near-term that will overload the server. This 12% is due to cases where the server performed some $\mathcal{C}$ work, and it became overloaded during that work. This effect can be seen in §4.3 Figure 7 (a) as well; even at high load some $\mathcal{C}$-class functions are run at the server. This can be controlled; making overload detection more aggressive reduces this overhead (down to 3%, if desired); the trade-off is that the server may sit idle in more cases to ensure it has capacity when $\mathcal{S}$-class tasks arrive.

4.3 Invocation Heterogeneity

Real invocations are likely to be heterogeneous in two ways: first, the total compute performed might vary across invocations (*inter-invocation heterogeneity*), and second, compute might be clustered at points of execution instead of being evenly distributed across data accesses (*intra-invocation heterogeneity*). To be effective, ASFP must be able to accurately classify invocations (as $\mathcal{S}$ or $\mathcal{C}$), as well as efficiently use both server and client CPU under such forms of heterogeneity.

Inter-Invocation Heterogeneity. To demonstrate ASFP's efficiency under inter-invocation heterogeneity, we configured one client to generate `invoke()`s where the number of cycles of extra compute performed (after two dependent `get()`s) is drawn from a normal distribution, $\mathcal{N}(1500, 500)$. Figure 7 (a) plots the distribution of the generated requests overlaid with the distribution of those that were pushed back and completed on the client. This figure shows two things; first, no requests that perform less than 600 cycles of work are pushed back, so inexpensive functions are executed at the server; second, the two distributions do not completely overlap, so many compute-intensive invocations still complete at the server. With just one client, the server has some idle CPU capacity; as a result, many of invocations in $\mathcal{C}$ run server-side. As the load on the server decreases, this spare capacity increases, allowing more $\mathcal{C}$ invocations to run server-side (Figure 7 (b), (c)). This shows that ASFP can be efficiently split work between the server and client(s); any idle compute at storage can accelerate clients and improve throughput.

Intra-invocation Heterogeneity. Figure 6 presented the benefits and costs of ASFP when compute is performed after all records are accessed by an invocation. Under this scenario, pushed back invocations benefit from the shipped back read/write set. However, real function invocations are likely to perform compute at different points of execution (between record accesses for example). Figure 8 explores such scenarios. 'Pushback-*y*' represents a run where invocations perform compute after issuing *y* `get()`s (out of a total of 4 per

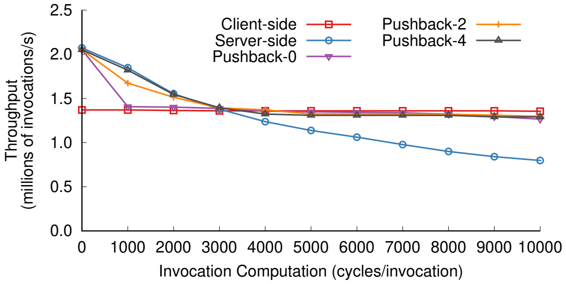


Figure 8: Throughput when the position of compute within an invocation varies. 'Pushback-*y*' is when invocations perform compute after issuing *y* `get()`s. ASFP is never worse than pure client-side.

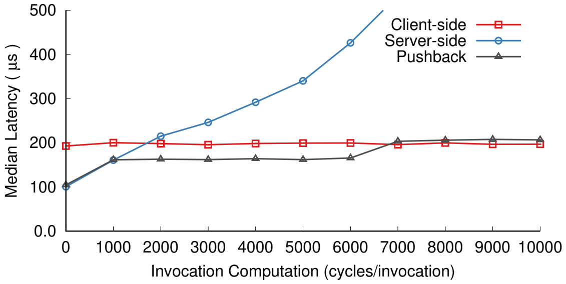

Figure 9: Effect of ASFP on median latency. ASFP improves latency between 15% to 2× compared to pure client-side.

`invoke()`). ASFP throughput is always better than or equal to pure client-side execution; for cases where compute is performed early on (Pushback-0), compute inexpensive invocations (left side of the graph) get pushed back earlier, resulting in lower gains over pure client-side execution.

4.4 ASFP Impact on Latency

Figure 9 shows median latency for an experimental setup similar to Figure 6 (a). When compute is less than 600 cycles, ASFP reduces round trips by running invocations on the server, improving latency over pure client-side execution by as much as 2×. As compute increases, invocations get pushed back; ASFP's latency is still better (15%) because these invocations receive their read/write set, resulting in one less RPC compared to client-side execution. The pure server-side approach bottlenecks, causing its response times to spike. As compute increases beyond 6,000 cycles, pushed-back invocations cause clients to saturate, reducing server load. This makes ASFP's overload detection loop retain more invocations on the server, increasing median latency to track that of pure client-side execution. Since, ASFP restarts pushed-back invocations at clients, it can increase the latency by up to 2× in the worst case. However, the only invocations that could experience this worst case are ones that never access values, since invocations that access values always execute more quickly on the client-side after pushback due to read/write set shipping. These functions should be rare and should not be attempted at storage servers; clients have little reason to send them to the server since they never access data.

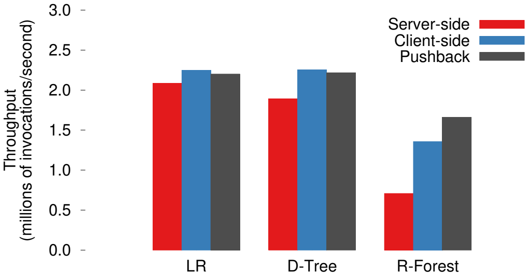

Figure 10: Machine learning classifiers. LR and D-Tree are within 2% of pure client-side. For R-Forest, ASFP leverages idle server compute, improving performance by 22% over pure client-side.

4.5 Realistic Applications

Beyond microbenchmarks, we applied ASFP to more realistic functions. We use three types of functions from different domains that we believe would be a possible fit for low-latency in-memory storage services. The first is an application barely in class $\mathcal{S}$ that accesses little data and performs little compute per invocation: Facebook's TAO social graph database [5]. The second is an application barely in class $\mathcal{C}$ that accesses little data with compute requirements slightly higher than the $\mathcal{S}/\mathcal{C}$ threshold: a machine-learning based disk failure prediction. The last is an application well in class $\mathcal{C}$ that accesses little data and uses significant CPU: authentication [42]. To be effective, ASFP must classify (as $\mathcal{S}$ or $\mathcal{C}$) and place invocations (on the server or the client) and improve overall throughput. We show ASFP can do so for these functions and for mixes of both $\mathcal{S}$ and $\mathcal{C}$ invocations.

4.5.1 Machine Learning

We use disk failure prediction [17, 28, 41, 44] for our first application. This application consults a classifier to predict whether a disk in a data center is about to fail. We chose classifiers because they benefit from Splinter's model that supports complex but native functions; they are a realistic and expected use; and their compute requirements vary.

We evaluated three classifiers: logistic regression (LR), a decision tree (D-Tree) and a random forest (R-Forest) (an ensemble of decision trees). Classifiers are trained offline from a data set with 25 features [37]. The server holds data points to be classified (loaded/streamed in a priori). Two clients generate `invoke()`s that classify two data points each.

Figure 10 shows how the classifiers perform. All three are in $\mathcal{C}$, so client-side execution outperforms server-side. R-Forest is the most CPU-intensive. ASFP outperforms both pure client-side (22%) and pure server-side (2.3×) execution because invocations are placed on both the server and the client. LR and D-Tree are harder cases; they are nearer to the $\mathcal{S}/\mathcal{C}$ split; the extra overhead of initially running them server-side before pushing them to the client cuts into ASFP's benefits. As a result, for these two classifiers, pure client-side execution marginally outperforms ASFP (by $<2\%$) even considering the extra compute capacity that the server provides.

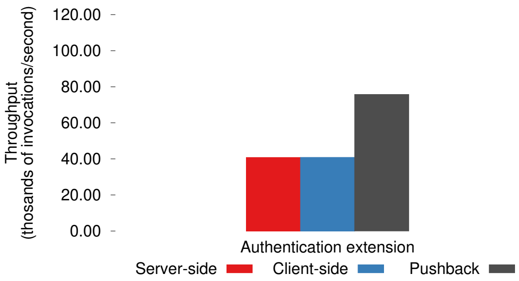

Figure 11: Authentication application. Compared to running server-side or client-side, ASFP can exploit idle cycles anywhere among the machines, improving throughput by nearly 2×.

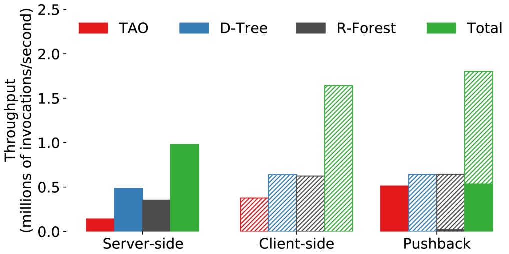

Figure 12: TAO/D-Tree/R-Forest Mix. ASFP correctly places invocations, improving overall throughput by 10%. Solid-colored regions of the bars show throughput due to invocations that ran server-side; hashed regions show throughput due to those that ran client-side.

4.5.2 Authentication

Authentication is another application; it uses bcrypt [42] to verify user identity. It uses few values, and it is computationally costly (well in class $\mathcal{C}$). Even so, it can still benefit from ASFP. We ran an experiment over 128,000 records, each containing a 30 B username and a 40 B salted hash (16 B salt, 24 B hash). One client issues `invoke()`s with a username and a 72 B AES-encrypted password. The salted hash is applied to the password. If the result matches the stored salted hash, then the invocation returns success, otherwise it returns failure.

Figure 11 shows throughput. Purely server- and client-side execution perform about 40,000 authentications/s. Both are CPU bottlenecked; bcrypt takes about 450,000 cycles per request. With pushback, throughput is nearly doubled over both approaches, as expected; with ASFP, CPUs on both the server and the client can be used to perform authentication.

4.5.3 Application Mix

Splinter is expected to run multi-tenant workloads, and pushback is primarily beneficial in a setting where there are a wide and heterogeneous set of `invoke()` requests. To create such a scenario, we ran a mixed workload comprised of an R-Forest classifier (class $\mathcal{C}$), a D-Tree classifier (class $\mathcal{C}$ by a small margin), and an implementation of Facebook's TAO [5, 26] data model which consists of dependent data accesses (class $\mathcal{S}$). Three client machines generated requests to the server.

Figure 12 shows how ASFP improves throughput for this mix. The solid-colored regions of the bars show throughput achieved from running invocations server-side. The hashed regions of bars show throughput achieved from running invocations client-side. The final bar in each group shows the aggregate throughput of the three applications (both at clients and the server). R-Forest requests are CPU-intensive; so, they are bottlenecked by server CPU in pure server-side execution, *and* they hurt the throughput of the other applications sharing the server. Running functions client-side avoids this bottleneck and interference, raising the throughput of the other applications. However, this runs TAO at clients as well, which creates extra server load since it is in class $\mathcal{S}$. Hence, ASFP provides the best results. R-Forest and D-Tree are classified as $\mathcal{C}$ and run (almost completely) at clients. TAO is classified as $\mathcal{S}$ and runs at the server improving server throughput. Hence, ASFP provides 10% better throughput than a conventional, disaggregated approach. Interestingly, onloading TAO creates CPU headroom at the server that R-Forest is able to exploit.

This workload is a challenging one for ASFP; a majority of the TAO requests only access one data item per invocation (60%); hence, all of the applications perform fairly well when executed client-side. As a result, the system only experiences modest gains when TAO is run at the server.

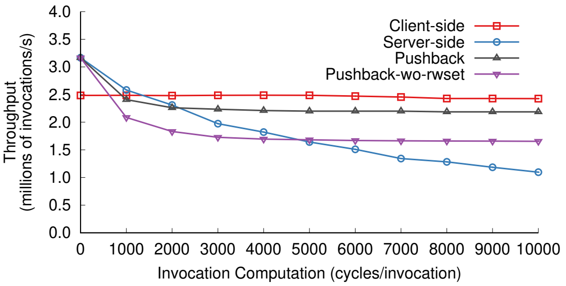

Figure 13: Impact of read/write set shipping on ASFP. When turned off, throughput suffers by 33% since pushed-back invocations load the server by reissuing remote `get()` requests.

4.6 Concurrency Control and ASFP

Beyond providing consistency, OCC improves ASFP's throughput; instead of reissuing `get()` requests to the server and increasing its request processing load, pushed-back requests reuse their read/write set. We explore this optimization with a setup similar to Figure 6 (a). Figure 13 shows that disabling read/write set shipping for pushed back invocations hurts throughput by 33% (Pushback-wo-rwset). Note, this workload only accesses two records per invocation; invocations that access more records would benefit more.

4.6.1 ASFP Impact on Abort Rate

Moving execution between servers and clients affects transaction commit latency and abort rates. To study this, we used YCSB+T's *Closed Economy Workload* [9] with four clients generating a request distribution where 50% of the requests are read-only and the remaining are read-modify-writes. We added a parameter to the read-modify-write transactions to control how much compute each one performs.

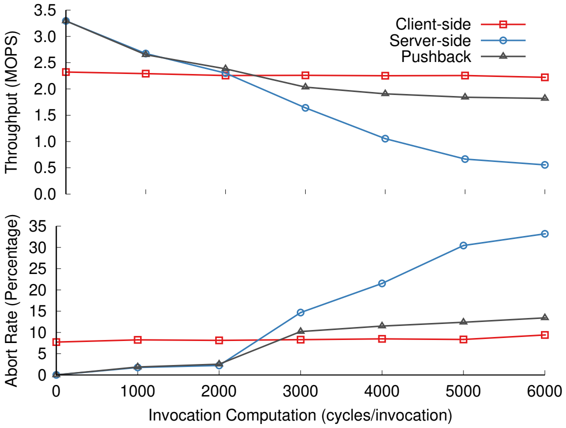

Figure 14: Impact on abort rate. ASFP leverages idle compute to speed up transactions, reducing read/write conflicts and abort rates.

Figure 14 shows trends similar to §4.2. ASFP speeds transactions/invocations in $\mathcal{S}$ by placing them on the server, reducing read/write conflicts and aborts. Server-side execution would bottleneck and slow transactions/invocations in $\mathcal{C}$, increasing conflicts. Here, ASFP uses clients to speed invocations, reducing aborts. The conflict window of each transaction is mainly determined by its latency. This relationship can be clearly seen when comparing these results to those in Figure 9. ASFP avoids bottlenecks, controls latency, and reduces aborts regardless of how much compute invocations use. We omitted results for a 90-10 read/write ratio; aborts are always negligible (0.02%), even for invocations in $\mathcal{C}$.

5 Discussion

Security. ASFP builds on Splinter's unique function isolation model that uses Rust's type system. This software-based scheme has a broad attack surface including Splinter's code; Rust (its type system, compiler, and standard library comprising millions of lines of code); and underlying libraries including libc and DPDK. This model is also complicated by micro-architectural side channels and speculative execution attacks, which continue to surface. For example, Splinter does not include the micro-architectural state flushes needed on protection domain switches to protect against information leaking via Spectre v2 and other similar vulnerabilities [6, 23].

ASFP is independent of Splinter's isolation and trust model, but there two ways that its isolation costs affect ASFP's applicability to other systems. First, its software-based isolation has extremely low protection domain/context switch costs. Tenant function invocations cause neither page table nor stack switches; hence, `invoke()`s are only 9% more expensive than `get()`s. With stronger isolation schemes, like conventional page table switching, each `invoke()` would need to make up for these costs, which can add up to several microseconds of CPU. With Splinter, some functions that only access two records improve efficiency when run server-side; if a page table switch were needed per invocation, invocations that accessed less than tens of records would be inefficient server-side. The second impact of Splinter's model is that it supports thousands of tenants per machine with low overhead, increasing the heterogeneity of operations it would be offered by tenants. Overall, this means using stronger isolation primitives would result in providers dedicating at least one server core to each tenant to avoid protection domain switch costs; this would limit the diversity of functions each server handles.

Larger-than-DRAM data & distribution. ASFP targets low-latency in-memory storage where only small, hot records are economical to store, which simplifies its cost model. Records are so small that the CPU cost of copying them (in/out of network buffers) is negligible, and neither I/O CPU cost nor storage throughput limits need to be considered. Addressing more complex systems is an interesting problem.

ASFP is focused on one server and its clients. As-is it can work in a sharded store where data is partitioned (e.g. by key). In the future, we plan to extend its OCC model for distributed transactions while factoring in data movement costs and abort rates in deciding placement of operations.

Idle client-side CPU assumptions. ASFP assumes clients have sufficient idle CPU to run pushed back invocations. This relies on provisioning client capacity according to state-of-practice: as if all invocations run client-side. When invocations are shifted server-side, this can only produce extra idle capacity at clients and servers.

State migration. A full system would need sharding, load balancing (similar to Slicer [4]), state migration to consolidate load [25], and a means to deprovision idle CPUs. ASFP is complementary; load and state must be rebalanced in any cluster with or without ASFP. For the heterogeneous invocations offered to servers, ASFP optimizes server CPU regardless of how state is sharded across the cluster.

Restart vs. resume. Process/function migration [10, 32, 35] is costly and complex. Resumed functions would need to send intermediate state to clients; that additional state capture, transmission, and restoration would need to be incorporated into ASFP's cost model. Further, restarted, pushed back functions take no more client-side CPU than they would in today's client-side approaches. Worst case, a function could be (nearly) computed at the server and repeated at a client. In the cases we have looked at redundant work is small, so it would be hard to offset function shipping/resuming costs.

Predicting placement. Speculatively onloading a function only adds 3% server load even when it is always pushed back (Figure 1). Pathological cases could access many records after pushback. These would perform nearly the same as today's pure client-side approach, but history/prediction could help. Simple approaches that track recent invocation misclassifications could be used to bias a function's future invocations to stay server-side. Pushback only happens on overload, so some misclassification has little impact; the server need only classify enough tasks correctly to mitigate overload.

Other key-value stores. ASFP can work in any extensible store, like Redis [43]. Splinter's kernel-bypass networking simplifies cost modeling; modeling kernel TCP costs would add complexity but would increase potential savings over our implementation. ASFP is also targeted toward diverse, multi-tenant workloads with heterogeneous operations that it can place. Single-application functions added to a single-tenant store could likely be statically classified as server- or client-side, eliminating some benefits of dynamic profiling.

Network congestion. Congestion isn't a problem in our high-bandwidth setup. However, exposing transport layer information (window sizes) to ASFP could let it choose placement to minimize network traffic under congestion. If an invocation accesses little data and enqueues many bytes for transmission while the network is congested, the server could return the data instead, forcing the client to compute the result.

6 Related Work

Adaptive pushback for Splinter builds on many ideas.

Storage Procedures, UDFs, and Database Extensions. There are several common approaches for pushing computation to databases and data stores. SQL is ubiquitous, though it is a poor fit for specialized computation, especially for microsecond timescales. SQL stored procedures [34] and UDFs [19, 22, 33, 38, 48] allow more specialized, procedural logic to be added to stores, and they can often be compiled for performance. Some databases also allow dynamic libraries to be loaded as well for specialized operations [49]. Some key-value stores and object stores support similar user-provided functions or extensions provided either at server-start time [43] or at runtime [14, 26, 45, 53], some relying on just-in-time compilation and some ahead-of-time compiled.

All of these approaches can ship computation to storage, but they do not address the question of whether doing so is beneficial for storage servers or its clients. Our approach could be applied to stored procedures and UDFs.

Thread and Process Migration. In the 1990s, both process and thread migration were pursued as ways to move computation at a fine-grain, often to place computation near data [10, 32, 35]. These approaches are often complex and highly runtime-specific, since moving in-progress computation requires precise reasoning about the state it closes over. We take a much simpler approach; rather than moving running functions, we preserve some of the work they have done through their read/write sets and restart functions from the beginning at clients. This assumes that invocations tend to be short, which is true for the small timescales that we target.

Fast, Disaggregated Storage. Fast networks have led to disaggregated storage and even disaggregated memory [16, 30, 31]. Many works focus on building scalable in-memory stores that move data efficiently [29], and many more have used techniques like kernel-bypass and RDMA (both one-sided and two-sided) to minimize the CPU cost of request processing for fast storage [20, 21, 29, 52]. These approaches reduce server-side CPU consumption and improve throughput for the simple operations that these stores provide, but they provide no way to move computation into storage when it would improve server efficiency. FaRM [12] is an exception. Clients can do this manually since each node in FaRM is both a client and a server; functions can be compiled into the storage server for custom request handlers. However, FaRM lacks an adaptive mechanism to move invocations of these functions between clients and remote servers.

Cell [36] is a distributed in-memory B-tree that uses RDMA. Cell uses a similar idea to pushback. In Cell, when clients lookup keys in the B-tree they can use one-sided RDMA reads to fetch nodes from the B-tree and perform the tree traversal client-side, or clients can send a request to a server to have it do the traversal. Clients track round-trip times to estimate queuing delay to determine whether the server network card or server CPU is under pressure. This lets them intelligently choose between the two approaches to improve server throughput. Our approach is similar, but ASFP is black box; it assumes no visibility into the functions that clients want to run. As a result, it must track and predict the relative client-side versus server-side cost of operations.

Offloading and migrating code has also been pursued in other contexts like edge computing and mobile devices where there is a large imbalance between the capabilities of devices and where moving data over edge links incurs high cost [8,15, 18,24,46]. Our approach and Splinter are also similar to Active Disks [1, 7] that allow application code to be downloaded to and executed on disk- and flash-based storage devices.

7 Conclusion

Today, data center and cloud storage systems disaggregate compute; clients must fetch data to compute on it, resulting in wasted work. When clients can send computation to storage, both clients and storage servers can benefit; however, to be practical, storage servers need a means to avoid becoming a bottleneck. ASFP does this by keeping client functions logically decoupled from storage and deciding physical placement of their invocations at runtime. By profiling invocations and observing both the CPU costs and savings they create at the server, storage servers can dynamically determine when invocations should be forced back for client-side execution.

We show ASFP's promise; servers and smart clients adapt function placement at microsecond timescales, improving throughput even when storage function CPU cost varies. We show it works when running a mix of different applications' logic, providing better throughput than running that logic purely at storage servers (85% more) or clients (10% more).

Abstract

This paper presents a system called NetKernel that decouples the network stack from the guest virtual machine and offers it as an independent module. NetKernel represents a new paradigm where network stack can be managed as part of the virtualized infrastructure. It provides important efficiency benefits: By gaining control and visibility of the network stack, operator can perform network management more directly and flexibly, such as multiplexing VMs running different applications to the same network stack module to save CPU. Users also benefit from the simplified stack deployment and better performance. For example mTCP can be deployed without API change to support nginx natively, and shared memory networking can be readily enabled to improve performance of colocated VMs. Testbed evaluation using 100G NICs shows that NetKernel preserves the performance and scalability of both kernel and userspace network stacks, and provides the same isolation as the current architecture.

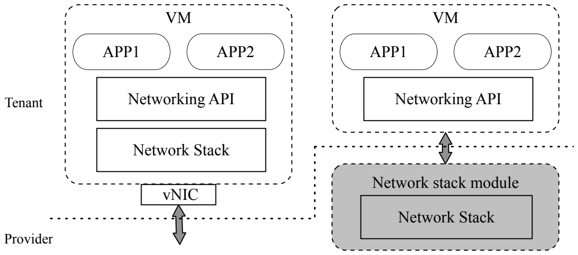
1 Introduction

Virtual machine (VM) is the predominant virtualization form in today's cloud due to its strong isolation guarantees. VMs allow customers to run applications in a wide variety of operating systems (OSes) and configurations. VMs are also heavily used by cloud operators to deploy internal services, such as load balancing, proxy, VPN, etc., both in a public cloud for tenants and in a private cloud for various business units of an organization.

VM based virtualization largely follows traditional OS design. In particular, the TCP/IP network stack is encapsulated inside the VM as part of the guest OS as shown in Figure 1(a). Applications own the network stack, which is separated from the network infrastructure that operators own; they interface using the virtual NIC abstraction. This architecture preserves the familiar hardware and OS abstractions so a vast array of workloads can be easily moved into the cloud. It also provides high flexibility to applications to customize the entire network stack.

We argue that the current division of labor between application and network infrastructure is becoming increasingly inadequate, especially in a private cloud setting. The central issue is that the network stack is controlled solely by individual guest VM; the operator has almost zero visibility or control. This leads to efficiency problems that manifest in various aspects of running the cloud network. Firstly, the operator is unable to orchestrate resource allocation at the end-points of the network fabric, resulting in low resource utilization. It remains difficult today for the operator to meet or define performance SLAs despite much prior work [17,28,35,41,56,57], as she cannot precisely provision resources just for the network stack or control how the stack consumes these resources. Further, resources (e.g. CPU) have to be provisioned on a per-VM basis based on the peak traffic; it is impossible to coordinate across VM boundaries. This degrades the overall utilization of the network stack since in practice traffic to individual VMs is extremely bursty. Also, many network management tasks like monitoring, diagnosis, and troubleshooting have to be performed in an extra layer outside the guest VMs, which requires significant efforts in design and implementation [23, 59, 60]. They can be done more efficiently if the network stack is opened up to the operator.

Even the simple task of maintaining or deploying a network stack suffers from much inefficiency today. Numerous new stack designs and optimizations ranging from congestion control [14, 19, 50], scalability [34, 42], zerocopy datapath [4, 34, 55, 64, 65], NIC multiqueue scheduling [63], etc. have been proposed in our community. Yet the operator, with sufficient expertise and resources, could not easily deploy these solutions in a virtualized cloud to improve performance and reduce overheads because it does not own or control the network stack. As a result, our community is still finding ways to deploy DCTCP in the public cloud [20, 31, 36]. On the other hand, applications without much knowledge of the underlying network or expertise on networking are forced to juggle the deployment and maintenance details. For example if one wants to deploy a new stack like mTCP [34], he faces a host of problems such as setting up kernel bypass, testing



(a). Existing architecture (b). Decoupling network stack from the guest

Figure 1: Decoupling network stack from the guest, and making it part of the virtualized infrastructure.

with kernel versions and NIC drivers, and porting applications to the new APIs. Given the intricacy of implementation and the velocity of development, it is a daunting task for individual users, whether tenants in a public cloud or first-party services in a private cloud, to maintain the network stack all by themselves.

To address these limitations, we advocate the *separation* of network stack from the guest OS as a new paradigm, in which the network stack is managed as part of the virtualized infrastructure by the operator. As the heavy-lifting is taken care of, applications can just use network stack as a basic service of the infrastructure and focus on their business logic.

More concretely, as shown in Figure 1(b), we propose to decouple the VM network stack from the guest OS. We keep the network APIs such as BSD sockets intact, and use them (instead of vNIC) as the abstraction boundary between application and infrastructure. Each VM is served by an external network stack module (NSM) that runs the network stack chosen by the user , *e.g.,* the kernel-bypass stack mTCP or the improved kernel stack FastSocket [42] . Application data are handled in the NSM, whose design and implementation are managed by the operator. Various network stacks can be provided as different NSMs to ensure applications with diverse requirements can work. This new paradigm does not necessarily enforce a single transport design, or trade off such flexibility of the existing architecture.

We make three specific contributions in this paper.

- We design and implement NetKernel that demonstrates our new approach is feasible on existing KVM virtualization platforms (§3–§5). NetKernel provides transparent BSD socket redirection so existing applications can run directly.
- We present NetKernel's benefits by showcasing novel use cases that are difficult to realize today (§6). For example, we show that NetKernel enables multiplexing: one NSM can serve multiple VMs at the same time and save over 40% CPU cores without degrading performance using traces from a production cloud.
- We conduct comprehensive testbed evaluation with commodity 100G NICs to show that NetKernel achieves the same scalability and isolation as the current architecture (§7). For example, the kernel stack NSM achieves 100G send throughput with 3 cores; the mTCP NSM achieves 979Krps with 8 cores.

NetKernel's official website is https://netkernel.net.

2 Motivation

Decoupling the network stack from the guest OS and making it part of the infrastructure marks a clear departure from the way networking is provided to VMs nowadays. In this section we elaborate why this is a better architectural design by presenting its benefits and tradeoffs, and contrasting it with alternative solutions.

2.1 Benefits and Tradeoffs

We highlight the key benefits of our vision with several new use cases that we experimentally realize with NetKernel in §6.

Better efficiency in management for the operator. Gaining control over the network stack, the operator can now perform network management more efficiently. For example it can orchestrate the resource provisioning strategies more flexibly: For mission-critical workloads, it can dedicate CPU resources to their NSMs to offer performance SLAs in terms of throughput and rps (requests per second) guarantees. For elastic workloads, on the other hand, it can consolidate their VMs to the same NSM (if they use the same network stack) to improve its resource utilization. The operator can also directly implement management functions as an integral part of user's network stack, compared to doing them in an extra layer outside the guest OS.

Use case 1: Multiplexing (§6.1). Utilization of network stack in VMs is very low most of the time in practice. Using a real trace from a large cloud, we show that NetKernel enables multiple VMs to be multiplexed onto one NSM to serve the aggregated traffic and saves over 40% CPU cores for the operator without performance degradation.

Deployment and performance gains for users. Making network stack part of the virtualized infrastructure is also beneficial for users in both public and private clouds. Various kernel stack optimizations [42, 64], high-performance userspace stacks [11, 18, 34, 55], and even designs using advanced hardware [6, 8, 9, 43] can now be deployed and maintained transparently without user involvement or application code change. For instance, DCTCP can now be deployed across the board easily in a public cloud. Since the BSD socket is the only abstraction exposed to the applications, it is now feasible to adopt new stack designs independent of the guest kernel or the network API. Our vision also opens up new design space by allowing the network stack to exploit visibility of the infrastructure for performance benefits.

Use case 2: Deploying mTCP without API change (§6.2). We show that NetKernel enables unmodified applications in the VM to use mTCP [34] in the NSM, and improves

Paradigm	Scenario	Multiplexing	New Stack Deployment	Performance Opt. with Infrastructure
Guest-based	VM	✗	Require user effort	✗
Host-based	Container	✓	Limited by host OS	✓
Application-based	Library OS	✗	Require user effort	✗
NetKernel	VM + NSM	✓	✓	✓

Table 1: Comparison of different network stack architectures depending on where the stack is. The current architecture is a guest-based paradigm where the network stack is part of the guest OS of a VM.

performance greatly due to mTCP's kernel bypass design. mTCP is a userspace stack with new APIs (including modified `epoll`/`kqueue`). During the process, we also find and fix a compatibility issue between mTCP and our NIC driver, and save significant maintenance time and effort for users.

Use case 3: Shared memory networking (§6.3). When two VMs of the same user are colocated on the same host, NetKernel can directly detect this and copy their data via shared memory to bypass TCP stack processing and improve throughput. This is difficult to achieve today as VMs have no knowledge about the underlying infrastructure [40, 66].

Tradeoffs. We are conscientious of the tradeoffs our approach brings about. For example, due to the removal of vNIC and redirection from the VM's own network stack, some networking tools like netfilter are affected. This is acceptable since most users wish to focus on their applications instead of tuning a network stack. If they wish to gain maximum control over the network stack they can still use VMs without NetKernel. Also, additional fate-sharing may be introduced by our approach say when multiple VMs share the same NSM. We believe this is not serious because cloud users already have fate-sharing with the vSwitch, hypervisor, and the complete virtual infrastructure. The efficiency benefits of our approach as demonstrated outweigh the marginal increase of fate-sharing; the success of cloud computing these years is another strong testament to this tradeoff. NetKernel enforces another level of indirection in order to achieve flexibility which does not cause performance degradation in most cases as we will show in §7, and part of it can run on hardware for more efficiency (see §8). Lastly, one may have security concerns with using the NSM to handle tenant traffic. Most of the security protocols such as HTTPS/TLS work at the application layer and are not affected. One exception is IPSec. Due to the certificate exchange issue, IPSec does not work in our approach. However, in practice IPSec is implemented at dedicated gateways instead of end-hosts [62]. Thus we believe the impact is not serious. More discussion on security can be found in §8.

2.2 Alternative Solutions

We now discuss several alternative architectures depending on where the network stack resides, and why they are inadequate compared to NetKernel as summarized in Table 1. Note that none of them provides all four key benefits as NetKernel does.

Host-based. The first alternative is a host-based paradigm where the network stack runs on the host machine. This corresponds to the container scenario in the cloud. A container is essentially a process with namespace isolation: it shares the host's network stack in the hypervisor. Therefore containers can achieve some of NetKernel's benefits, i.e multiplexing and performance optimization with infrastructure, since the operator can access the hypervisor. However, container has tight coupling with the host OS which makes the stack deployment difficult. A Windows application in a container cannot use the Linux-based mTCP, unless the operator ports mTCP to Windows. With NetKernel no such porting is needed: mTCP can run in a Linux-based NSM and serve a Windows user because the only coupling is the BSD socket APIs.

We also note that currently containers have performance isolation problems [38] and as a result are usually constrained to be deployed inside VMs in production settings. In fact we find that all major public clouds [1, 2, 5] require users to launch containers inside VMs. Thus, our work is centered around VMs that cover the majority of usage scenarios in a cloud. NetKernel readily benefits containers running inside VMs as well.

Application-based. Another alternative is to move the network stack upwards by taking an application-based paradigm. A representative scenario is library OS including unikernels [22, 44] and microkernels [26], where many OS services including the network stack are packaged as libraries and compiled with the application in userspace. Similar to the guest-based paradigm, users have to deploy the network stack by themselves though the I/O performance can be improved with unikernels [46] and microkernels. In addition, application-based paradigm is a clean-slate approach and requires radical changes to both the virtualization software and user applications. NetKernel can flexibly decouple the network stack from the guest without re-writing existing applications or hypervisor.

3 Design Philosophy

NetKernel imposes three fundamental design questions around the separation of network stack from the guest OS:

1. How to transparently redirect socket API calls without changing applications?
2. How to transmit the socket semantics between the VM and NSM whose implementation of the stack may vary?

3. How to ensure high performance with semantics transmission (e.g., 100 Gbps)?

These questions touch upon a largely uncharted territory in the design space. Thus our main objective in this paper is to demonstrate feasibility of our approach on existing virtualization platforms and showcase its potential. Performance and overhead are not our primary goals. It is also not our goal to improve any particular network stack design.

In answering the questions above, NetKernel's design has the following highlights.

Transparent socket API redirection. NetKernel needs to redirect BSD socket calls to the NSM instead of the tenant network stack. This is done by inserting into the guest a library called GuestLib. The GuestLib provides a new socket type called NetKernel socket with a complete implementation of BSD socket APIs. It replaces all TCP and UDP sockets when they are created with NetKernel sockets, effectively redirecting them without changing applications.

A lightweight semantics channel. Different network stacks may run as different NSMs, so NetKernel needs to ensure socket semantics from the VM work properly with the actual NSM stack implementation. For this purpose NetKernel builds a lightweight socket semantics channel between VM and its NSM. The channel relies on small fix-sized queue elements as intermediate representations of socket semantics: each socket API call in the VM is encapsulated into a queue element and sent to the NSM, who would effectively translate the queue element into the corresponding API call of its network stack.

Scalable lockless queues. As NIC speed in cloud evolves from 40G/50G to 100G [24] and higher, the NSM has to use multiple cores for the network stack to achieve line rate. NetKernel thus adopts scalable lockless queues to ensure VM-NSM socket semantics transmission is not a bottleneck. Each core services a dedicated set of queues so performance is scalable with number of cores. More importantly, each queue is memory shared with a software switch, so it can be lockless with only a single producer and a single consumer to avoid expensive lock contention [33, 34, 42].

Switching the queue elements offers important benefits beyond lockless queues. It facilitates a flexible mapping between VM and NSM: a NSM can support multiple VMs without adding more queues compared to binding the queues directly between VM and NSM. In addition, it allows dynamic resource management: cores can be readily added to or removed from a NSM, and a user can switch her NSM on the fly. The CPU overhead of software switching can be addressed by hardware offloading [24, 27], which we discuss in §7.4 in more detail.

VM based NSM. Lastly we discuss an important design choice regarding the NSM. The NSM can take various forms. It may be a full-fledged VM with a monolithic kernel. Or it can be a container or module running on the hypervisor, which is appealing because it consumes less resource and offers better performance. Yet it entails porting a complete TCP/IP stack to the hypervisor. Achieving memory isolation among containers or modules are also difficult [52]. More importantly, it introduces another coupling between the network stack and the hypervisor, which defeats the purpose of NetKernel. Thus we choose to use a VM for NSM. VM based NSM readily supports existing kernel and userspace stacks from various OSes. VMs also provide good isolation and we can dedicate resources to a NSM to guarantee performance. VM based NSM is the most flexible: we can run stacks independent of the hypervisor.

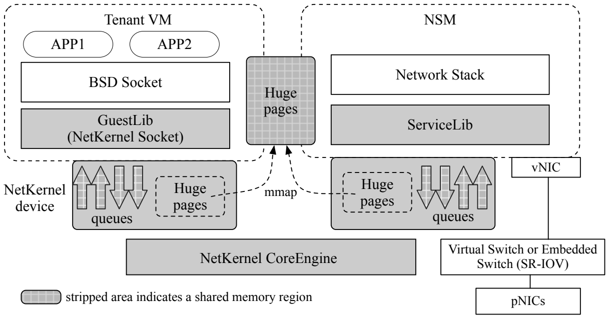


Figure 2: NetKernel design overview.

4 Design

Figure 2 depicts NetKernel's architecture. The BSD socket APIs are transparently redirected to a complete NetKernel socket implementation in GuestLib in the guest kernel (§4.1). The GuestLib can be deployed as a kernel patch and is the only change we make to the user VM. Network stacks are implemented by the operator on the same host as Network Stack Modules (NSMs), which are individual VMs in our current design. Inside the NSM, a ServiceLib interfaces with the network stack. The NSM connects to the vSwitch, be it a software or a hardware switch, and then the pNICs. Thus our design also supports SR-IOV.

All socket operations and their results are translated into NetKernel Queue Elements (NQEs) by GuestLib and ServiceLib (§4.2). For NQE transmission, GuestLib and ServiceLib each has a NetKernel device, or NK device in the following, consisting of one or more sets of lockless queues. Each queue set has a *send queue* and *receive queue* for operations with data transfer (e.g. `send()`), and a *job queue* and *completion queue* for control operations without data transfer (e.g. `setsockopt()`). Each NK device connects to a software switch called CoreEngine, which runs on the hypervisor and performs actual NQE switching (§4.3). The CoreEngine is also responsible for various management tasks such as setting up the NK devices, ensuring isolation among VMs, etc. (§4.4) A unique set of hugepages are shared between each VM-NSM tuple for application data exchange. A NK device also maintains a hugepage region that is memory mapped to the corresponding application hugepages as in Figure 2

(§4.5). Note that as the socket API that copies data is preserved, misbehaving applications cannot pose security risks on NetKernel, this is the same as original kernel design. We discuss additional security implications of NetKernel in §8.

For ease of presentation, we assume both the user VM and NSM run Linux, and the NSM uses the kernel stack.

4.1 Transparent Socket API Redirection

We first describe how NetKernel's GuestLib interacts with applications to support BSD socket semantics transparently.

Kernel space API redirection. There are essentially two approaches to redirect BSD socket calls to NSM, each with its unique tradeoffs. One is to implement it in userspace using `LD_PRELOAD` for example. The advantages are: (1) It is efficient without syscall overheads and performance is high [34]; (2) It is easy to deploy without kernel modification. However, this implies each application needs to have its own redirection service, which limits the usage scenarios. Another way is kernel space redirection, which naturally supports multiple applications without IPC. The flip side is that performance may be lower due to context switching and syscall overheads.

We opt for kernel space API redirection to support most of the usage scenarios, and leave userspace redirection as future work. GuestLib is a kernel module deployed in the guest. This is feasible by distributing images of para-virtualizated guest kernels to users, a practice operators are already doing nowadays. Note that kernel space redirection follows the asynchronous syscall model [61] to get better performance.

NetKernel socket API. GuestLib creates a new type of sockets—`SOCK_NETKERNEL`, in addition to TCP (`SOCK_STREAM`) and UDP (`SOCK_DGRAM`) sockets. It registers a complete implementation of BSD socket APIs to the guest kernel. When the guest kernel receives a `socket()` call to create a new TCP socket say, it replaces the socket type with `SOCK_NETKERNEL`, creates a new NetKernel socket, and initializes the socket data structure with function pointers to NetKernel socket implementation in GuestLib. The `sendmsg()` for example now points to `nk_sendmsg()` in GuestLib instead of `tcp_sendmsg()`.

4.2 A Lightweight Semantics Channel

Socket semantics are contained in NQEs and carried around between GuestLib and ServiceLib via their respective NK devices.

1B	1B	1B	4B	8B	8B	4B	5B
op type	VM ID	Queue set ID	VM socket ID	op_data	data pointer	size	rsved

Figure 3: Structure of a NQE. Here socket ID denotes a pointer to the `sock` struct in the user VM or NSM, and is used for NQE transmission with VM ID and queue set ID in §4.3; `op_data` contains data necessary for socket operations, such as ip address for bind; `data pointer` is a pointer to application data in hugepages; and `size` is the size of pointed data in hugepages.

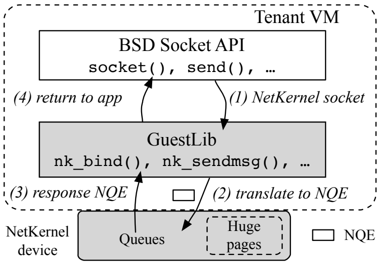

Figure 4: NetKernel socket implementation in GuestLib redirects socket API calls. GuestLib translates socket API calls to NQEs and ServiceLib translates results into NQEs as well (not shown here).

NQE and socket semantics translation. Figure 3 shows the structure of a NQE with a fixed size of 32 bytes. Translation happens at both ends of the semantics channel: GuestLib encapsulates the socket semantics into NQEs and sends to ServiceLib, which then invokes the corresponding API of its network stack to execute the operation; the execution result is again turned into a NQE in ServiceLib first, and then translated by GuestLib back into the corresponding response of socket APIs.

For example in Figure 4, to handle the `socket()` call in the VM, GuestLib creates a new NQE with the operation type and information such as its VM ID for NQE transmission. The NQE is transmitted by GuestLib's NK device. The `socket()` call now blocks until a response NQE is received. After receiving the NQE, ServiceLib parses the NQE from its NK device, invokes the `socket()` of the kernel stack to create a new TCP socket, prepares a new NQE with the execution result, and enqueues it to the NK device. GuestLib then receives and parses the response NQE and wakes up the `socket()` call. The `socket()` call now returns to application with the NetKernel socket file descriptor (fd) if a TCP socket is created at the NSM, or with an error number consistent with the execution result of the NSM.

We defer the handling of application data to §4.5.

Queues for NQE transmission. NQEs are transmitted via one or more sets of queues in the NK devices. A queue set has four independent queues: a *job queue* for NQEs representing socket operations issued by the VM without data transfer, a *completion queue* for NQEs with execution results of control operations from the NSM, a *send queue* for NQEs representing operations issued by VM with data transfer; and a *receive queue* for NQEs representing events of newly received data from NSM. Queues of different NK devices have strict correspondence: the NQE for `socket()` for example is put in the job queue of GuestLib's NK device, and sent to the job queue of ServiceLib's NK device.

We now present the working of I/O event notification mechanisms like epoll with the receive queue. Figure 5 depicts the details. Suppose an application issues `epoll_wait()` to monitor some sockets. Since all sockets are now NetKernel sockets, the `nk_poll()` is invoked by `epoll_wait()` and checks the receive queue to see if there is any NQE

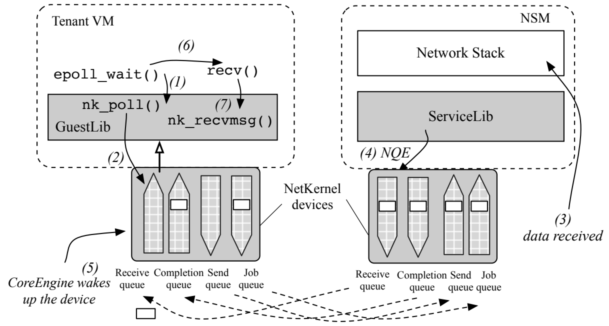

Figure 5: The socket semantics channel with epoll as an example. GuestLib and ServiceLib translate semantics to NQEs, and queues in the NK devices perform NQE transmission. Job and completion queues are for socket operations and execution results, send queues are for socket operations with data, and receive queues are for events of newly received data. Application data processing is not shown.

for this socket. If yes, this means there are new data received, `epoll_wait()` then returns and the application issues a `recv()` call with the NetKernel socket fd of the event. This points to `nk_recvmsg()` which parses the NQE from receive queue for the data pointer, copies data from the hugepage directly to the userspace, and returns.

If `nk_poll()` does not find any relevant NQE, it sleeps until CoreEngine wakes up the NK device when new NQEs arrive to its receive queue. GuestLib then parses the NQEs to check if any sockets are in the epoll instances, and wakes up the epoll to return to application. An `epoll_wait()`can also be returned by a timeout.

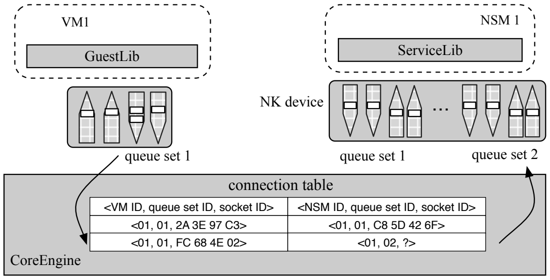
4.3 NQE Switching across Lockless Queues

We now elaborate how NQEs are switched by CoreEngine and how the NK devices interact with CoreEngine.

Scalable queue design. The queues in a NK device is scalable: there are one dedicated queue set per vCPU for both VM and NSM, so NetKernel performance scales with CPU resources. Each queue set is shared memory with the CoreEngine, essentially making it a single producer single consumer queue without lock contention. VM and NSM may have different numbers of queue sets.

Switching NQEs in CoreEngine. NQEs are load balanced across multiple queue sets with the CoreEngine acting as a switch. CoreEngine maintains a connection table as shown in Figure 6, which maps the tuple ⟨VM ID, queue set ID, socket ID⟩ to the corresponding ⟨NSM ID, queue set ID, socket ID⟩ and vice versa. Here a socket ID corresponds to a pointer to the `sock` struct in the user VM or NSM. We call them VM tuple and NSM tuple respectively. NQEs only contain VM tuple information.

Using the running example of the `socket()` call, we can see how CoreEngine uses the connection table. The process is also shown in Figure 6. (1) When CoreEngine processes the socket NQE from VM1's queue set 1, it realizes this is a new connection, and inserts a new entry to the table with the VM tuple from the NQE. (2) It checks which NSM should handle it,[1] performs hashing based on the three tuple to determine which queue set (say 2) to switch to if there are multiple queue sets, and copies the NQE to the NSM's corresponding job queue. CoreEngine adds the NSM ID and queue set ID to the new entry. (3) ServiceLib gets the NQE and copies the VM tuple to its response NQE, and adds the newly created connection ID in the NSM to the `op_data` field of response NQE. (4) CoreEngine parses the response NQE, matches the VM tuple to the entry and adds the NSM socket ID to complete it, and copies the response NQE to the completion queue 1 of VM1 as instructed in the NQE. Later NQEs for this VM connection can be processed by the correct NSM connection and vice versa. ServiceLib pins its connections to its vCPUs and queue sets, so processing the NQE and sending the response NQE are done on the same CPU.



<VM ID, queue set ID, socket ID>	<NSM ID, queue set ID, socket ID>
<01, 01, 2A 3E 97 C3>	<01, 01, C8 5D 42 6F>
<01, 01, FC 68 4E 02>	<01, 02, ?>

Figure 6: NQE switching with CoreEngine.

The connection table allows flexible multiplexing and demultiplexing with the socket ID information. For example one NSM can serve multiple VMs using different sockets. CoreEngine polls all queue sets to maximize performance.

4.4 Management with CoreEngine

CoreEngine acts as the control plane of NetKernel and carries out many control tasks beyond NQE switching.

NK device and queue setup. CoreEngine allocates shared memory for the queue sets and sets up the NK devices accordingly when a VM or NSM starts up, and de-allocates when they shut down. Queues can also be dynamically added or removed with the number of vCPUs.

Isolation. CoreEngine sits in an ideal position to carry out isolation among VMs. In our design CoreEngine polls each queue set in a round-robin fashion to ensure the basic fair sharing. Operator can implement other isolation mechanisms to rate limit a VM in terms of bandwidth or the number of NQEs (i.e. operations) per second, which we show in §7.3. Note that CoreEngine isolation happens for egress; ingress isolation at the NSM is more challenging and may have to use physical NIC queues [21].

Busy-polling. The busy-polling design of CoreEngine requires a dedicated core per machine which is an inherent

[1] A user VM to NSM mapping is determined either by the users/operator offline or some load balancing scheme dynamically by CoreEngine.

overhead of our design. We resort to this simple design as we focus on showing feasibility and potential of NetKernel in this work, and prior work also used dedicated cores for software polling [40]. One can explore hardware offloading using FPGAs for example to eliminate this overhead [23, 24].

4.5 Processing Application Data

We now discuss the last missing piece of NetKernel design: how application data are actually processed in the system.

Sending data. Data is transmitted by hugepages shared between the VM and NSM. Their NK devices maintain a hugepage region that is mmaped to the application hugepages. For sending data with `send()`, GuestLib copies data from userspace directly to the hugepage, and adds a data pointer to the send NQE. It also increases the send buffer usage for this socket similar to the send buffer size maintained by the kernel. The `send()` now returns to application. ServiceLib invokes `tcp_sendmsg()` provided by the kernel stack upon receiving the send NQE. Data are obtained from hugepages, processed by the network stack, and sent to the vNIC. A new NQE is generated with the result of send by the NSM and sent to GuestLib, who then decreases the send buffer usage.

Receiving data. Now for receiving packets in the NSM, a normal network stack would send received data to userspace applications. In order to send received data to the user VM, ServiceLib then copies the data chunk to hugepages and create a new NQE to the receive queue, which is then sent to the VM. It also increases the receive buffer usage for this connection, similar to the send buffer maintained by GuestLib described above. The rest of the receive process is already explained in §4.2. Note that application uses `recv()` to copy data from hugepages to their own buffer.

ServiceLib. As discussed ServiceLib deals with much of data processing at the NSM side so the network stack works in concert with the rest of NetKernel. One thing to note is that unlike the kernel space GuestLib, ServiceLib should live in the same space as the network stack to ensure best performance. We have focused on a Linux kernel stack with a kernel space ServiceLib here. The design of a userspace ServiceLib for a userspace stack is similar in principle. ServiceLib busy-polls its queues for maximum performance.

4.6 Optimization

We present several optimizations employed in NetKernel.

Pipelining. NetKernel applies pipelining between VM and NSM for performance. For example on the VM side, a `send()` returns immediately after putting data to the hugepages, instead of waiting for the actual send result from the NSM. Similarly the NSM would handle `accept()` by accepting a new connection and returning immediately, before the corresponding NQE is sent to GuestLib and then application to process. Doing so does not break BSD socket semantics. Take `send()` for example. A successful `send()` does not guarantee delivery of the message [13]; it merely indicates the message is written to socket buffer successfully. In NetKernel a successful `send()` indicates the message is written to buffer in the hugepages successfully. As explained in §4.5 the NSM sends the result of send back to the VM to indicate if the socket buffer usage can be decreased or not.

Interrupt-driven polling. We adopt an interrupt-driven polling design for NQE event notification to GuestLib's NK device. This is to reduce the overhead of GuestLib and user VM. When an application is waiting for events e.g. the result of the `socket()` call or receive data for epoll, the device will first poll its completion queue and receive queue. If no new NQE comes after a short time period (20µs in our experiments), the device sends an interrupt to CoreEngine, notifying that it is expecting NQE, and stops polling. CoreEngine later wakes up the device, which goes back to polling mode to process new NQEs from the completion queue. This is similar in spirit to busy-polling sockets in Linux kernel [3, 10]. Interrupt-driven polling presents a favorable trade-off between overhead and performance compared to pure polling based or interrupt based design. It saves precious CPU cycles when load is low and ensures the overhead of NetKernel is very small to the user VM. Performance on the other hand is competent since the response NQE is received within the polling period in most cases for blocking calls, and when the load is high polling automatically drives the notification mechanism. As explained before CoreEngine and ServiceLib use busy polling to maximize performance.

Batching. Batching is used in many parts of NetKernel for better throughput. CoreEngine uses batching whenever possible for polling from and copying into the queues. The NK devices also receive NQEs in a batch.

5 Implementation

Our implementation is based on QEMU KVM 2.5.0 and Linux kernel 4.9 for both host and guest, with over 11K LoC.

GuestLib. We add the `SOCK_NETKERNEL` socket to the kernel (`net.h`), and modify `socket.c` to rewrite the `SOCK_STREAM` to `SOCK_NETKERNEL` during socket creation. We implement GuestLib as a kernel module with two components: Guestlib_core and nk_driver. Guestlib_core is mainly for Netkernel sockets and NQE translation, and nk_driver is for NQE communications via queues. Guestlib_core and nk_driver communicate with each other using function calls.

ServiceLib and NSM. We also implement ServiceLib as two components: Servicelib_core and nk_driver. Servicelib_core translates NQEs to network stack APIs, and the nk_driver is identical to the one in GuestLib. For the kernel stack NSM, Servicelib_core calls the kernel APIs directly to handle socket operations without entering userspace. We create an independent `kthread` to poll the job queue and send queue for NQEs to avoid kernel stuck. Some BSD socket APIs can not be invoked in kernel space directly. We use `EXPORT_SYMBOLS` to export the functions for ServiceLib. Meanwhile, the boundary check between kernel space and userspace is disabled. We use per-core `epoll_wait()` to obtain incoming events from the kernel stack.

We also port mTCP [12] as a userspace stack NSM. It uses DPDK 17.08 for packet I/O. For simplicity, we maintain its two-thread model and per-core data structure. We implement the NSM in mTCP's application thread at each core. The ServiceLib is essentially an mTCP application: once receiving a NQE from its send queue, it accesses data from the shared hugepage by the data pointer in the NQE and sends it using mTCP with DPDK. For receiving, the received data is copied into the hugepage, and ServiceLib encapsulates the data pointer into a NQE of the receive queue. The per-core application thread (1) translates NQEs polled from the NK device to mTCP socket APIs, and (2) responds NQEs to the tenant VM based on the network events collected by `mtcp_epoll_wait()`. Since mTCP works in non-blocking mode for performance, we buffer send operations at each core and set the `timeout` parameter to 1ms in `mtcp_epoll_wait()` to avoid starvation when polling NQE requests.

Queues and hugepages. The hugepages are implemented based on QEMU's IVSHMEM. The page size is 2 MB and we use 128 pages. The queues are ring buffers implemented as much smaller IVSHMEM devices. Together they form a NK device which is a virtual device to the VM and NSM.

CoreEngine. The CoreEngine is a daemon with two threads on the KVM hypervisor. One thread listens on a pre-defined port to handle NK device (de)allocation requests, namely 8-byte network messages of the tuples ⟨ce_op, ce_data⟩. When a VM (or NSM) starts (or terminates), it sends a request to CoreEngine for registering (or deregistering) a NK device. If the request is successfully handled, CoreEngine responds in the same message format. Otherwise, an error code is returned. The other thread polls NQEs in batches from all NK devices and switches them as described in §4.3.

6 Evaluation: New Use Cases

In the first part of evaluation, we present some new use cases that are realized using our prototype to demonstrate the potential of NetKernel. Details of the performance and overhead microbenchmarks are presented in §7.

6.1 Multiplexing

Here we describe a new use case where the operator can optimize resource utilization by serving multiple bursty VMs with one NSM.

To make things concrete we draw upon a user traffic trace collected from a large cloud in September 2018. The trace contains statistics of tens of thousands of application gateways (AGs) that handle tenant (web) traffic in order to provide load balancing, proxy, and other services. The AGs are internally deployed as VMs by the operator. We find that the AG's average utilization is very low most of the time. Figure 7 shows normalized traffic processed by three most utilized AGs (in the same datacenter) in our trace with 1-minute intervals for a 1-hour period. We can clearly see the bursty nature of the traffic. Yet it is very difficult to consolidate their workloads in current cloud because they serve different customers using different configurations (proxy settings, LB strategies, etc.), and there is no way to separate the application logic with the underlying network stack. The operator has to deploy AGs as independent VMs, reserve resources for them, and charge customers accordingly.

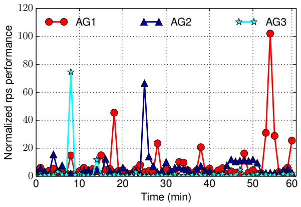


Figure 7: Traffic of three most utilized application gateways (AGs) in our trace. They are deployed as VMs.

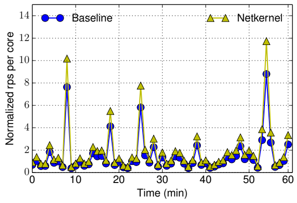

Figure 8: Per-core rps comparison. Baseline uses 12 cores for 3 AGs, while NetKernel with multiplexing only needs 9 cores.

NetKernel enables multiplexing across AGs running distinct services, since the common TCP stack processing is now separated into the NSM. Using the three most utilized AGs which have the least benefit from multiplexing as an example, without NetKernel each needs 4 cores in our testbed to handle their peak traffic, and the total per-core requests per second (rps) of the system is depicted in Figure 8 as Baseline. Then in NetKernel, we deploy 3 VMs each with 1 core to replay the trace as the AGs, and use a kernel stack NSM with 5 cores which is sufficient to handle the aggregate traffic. Totally 9 cores are used including CoreEngine, representing a saving of 3 cores in this case. The per core rps is thus improved by 33% as shown in Figure 8. Each AG has exactly the same rps performance without any packet loss.

In the general case multiplexing these AGs brings even more gains since their peak traffic is far from their capacity. For ease of exposition we assume the operator reserves 2 cores for each AG. A 32-core machine can host 16 AGs. If we use NetKernel with 1 core for CoreEngine and a 2-core NSM, we find that we can always pack 29 AGs each with 1 core for the application logic as depicted in Table 2, and the maximum utilization of the NSM would be well under 60% in the worst case for ∼97% of the AGs in the trace. Thus one machine can run 13 or 81.25% more AGs now, which means the operator can save over 40% cores for supporting this workload. This implies salient financial gains for the operator: according to [24] one physical core has a maximum potential revenue of $900/yr.

	Total Cores	NSM	CoreEngine	AGs
Baseline	32	0	0	**16**
NetKernel	32	2	1	**29**

Table 2: NetKernel multiplexes more AGs and saves over 40% cores.

6.2 Deploying mTCP without API Change

We now focus on use cases of deployment and performance benefits for users.

Most userspace stacks use their own APIs and require applications to be ported [4, 11, 34]. For example, in mTCP an application has to use `mtcp_epoll_wait()` to fetch events [34]. The semantics of these APIs are also different from socket APIs [34]. These factors lead to expensive code changes and make it difficult to use the stack in practice. The lack of modern APIs also makes it difficult to support complex web servers like nginx. mTCP also lacks some modern kernel TCP features such as advanced loss recovery, small queue, DSACK, *etc.*

With NetKernel, applications can directly take advantage of userspace stacks without any code change. To show this, we deploy unmodified nginx in the VM with the mTCP NSM we implement, and benchmark its performance using `ab`. Both VM and NSM use the same number of vCPUs. Table 3 depicts that mTCP provides 1.4x–1.9x improvements over the kernel stack NSM across various vCPU setting.

# vCPUs	1	2	4
Kernel stack NSM	71.9K	133.6K	200.1K
mTCP NSM	98.1K	183.6K	379.2K

Table 3: Performance of nginx using `ab` with 64B html files, a concurrency of 100, and 10M requests in total. The NSM and VM use the same number of vCPUs.

NetKernel also mitigates the maintenance efforts required from users. We provide another piece of evidence with mTCP here. When compiling DPDK required by mTCP on our testbed, we could not set the RSS (receive side scaling) key properly to the mlx5_core driver for our NIC and mTCP performance was very low. After discussing with mTCP developers, we were able to attribute this to the asymmetric RSS key used in the NIC, and fixed the problem by modifying the code in the DPDK mlx5 driver. We have submitted our fix to mTCP community. Without NetKernel users would have to deal with such technical complication by themselves. Now they are taken care of transparently, saving much time and effort for many users.

6.3 Shared Memory Networking

Inter-VM communication is well-known to suffer from high overheads [58]. A VM's traffic goes through its network stack, then the vNIC and the vSwitch, even when the other VM is on the same host. It is difficult for users and operator to optimize for this case, because a VM has no information about where the other endpoint is. The hypervisor cannot help either as the data has already been processed by the TCP/IP stack. With NetKernel the NSM is part of the infrastructure, the operator can easily detect the on-host traffic and use shared memory to copy data for the two VMs. We build a prototype NSM to demonstrate this idea: When a socket pair is detected as an internal socket pair by the GuestLib, and the two VMs belong to the same user, a shared memory NSM takes over their traffic. This NSM simply copies the message chunks between their hugepages and bypasses the TCP stack processing. As shown in Figure 9, with 7 cores in total, NetKernel with shared memory NSM can achieve 100Gbps, which is ~2x of Baseline using TCP Cubic and same number of cores.

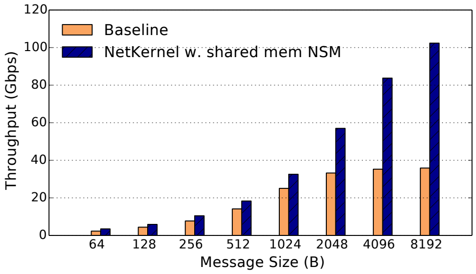

Figure 9: Using shared memory NSM for NetKernel for traffic between two colocated VMs of the same user. NetKernel uses 2 cores for each VM, 2 cores for the NSM, and 1 core for CoreEngine. Baseline uses 2 core for the sending VM, 5 cores for receiving VM, and runs TCP Cubic. Both schemes use 8 TCP connections.

7 Evaluation: Microbenchmarks

We now present microbenchmarks of crucial aspects of NetKernel: performance and multicore scalability in §7.2; isolation of multiple VMs in §7.3; and system overhead in §7.4.

7.1 Setup

Each of our testbed servers has two Xeon E5-2698 v3 16-core CPUs clocked at 2.3 GHz, 256 GB memory at 2133 MHz, and a Mellanox ConnectX-4 single port 100G NIC. Hyperthreading is disabled. We compare to the status quo where an application uses the kernel TCP stack in its VM, referred to as Baseline in the following. We designate NetKernel to refer to the common setting where we use the kernel stack NSM in our implementation. When mTCP NSM is used we explicitly mark the setting in the results. The same TCP parameter settings are used for both systems. The NSM uses the same number of vCPUs as Baseline since CPU is used almost entirely by the network stack in Baseline. NetKernel allocates 1 more vCPU for the VM to run the application and ServiceLib throughout the evaluation. Its CPU utilization is usually low: we report the actual CPU overheads of NetKernel in §7.4. The throughput results are measured by `iperf` and the rps results are measured by `ab`, unless stated otherwise. The throughput results are averaged over 5 runs each lasting 30 seconds.

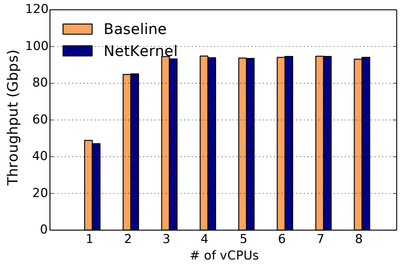

Figure 10: Send throughput of 8 TCP streams with varying numbers of vCPUs, 8KB messages.

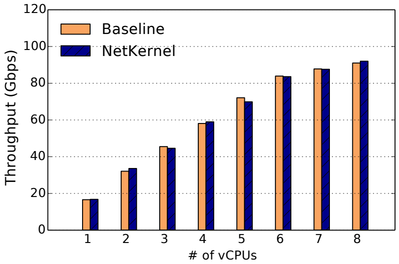

Figure 11: Recv throughput of 8 TCP streams with varying numbers of vCPUs, 8KB messages.

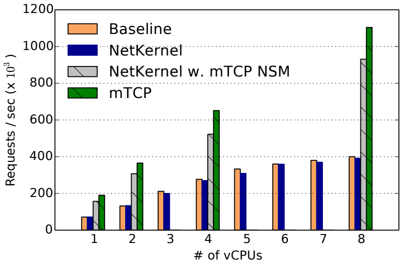

Figure 12: Performance of TCP short connections with multiple vCPUs. Message size 64B.

7.2 Performance and Scalability

We now look at NetKernel's basic performance.

NQE switching and memory copy. NQEs are transmitted by CoreEngine as a software switch. It is important that CoreEngine offers enough horsepower to ensure performance at 100G and higher. We measure CoreEngine throughput which is defined as the number of 32-byte NQEs copied from GuestLib's NK device queues to the ServiceLib's NK device queues. Table 4 shows the results with varying batch sizes. CoreEngine achieves ~8M NQEs/s without batching. With a small batch size of 4 or 8 throughput reaches 41.4M NQEs/s and 65.9M NQEs/s, respectively, which is sufficient for most applications.

We also measure the memory copy throughput between GuestLib and ServiceLib via hugepages. A memory copy in this experiment includes the following: (1) application in the VM issues a `send()` with data; (2) GuestLib gets a pointer from the hugepages; (3) copies the message to hugepages; (4) prepares a NQE with the data pointer; (5) CoreEngine copies the NQE to ServiceLib; and (6) ServiceLib obtains the data pointer and puts it back to the hugepages. Thus it measures the effective application-level throughput using NetKernel (including NQE transmission) without network stack processing.

We observe from Table 5 that NetKernel delivers over 100G throughput with messages larger than 4KB: with 8KB messages 144G is achievable. Thus NetKernel provides enough raw performance to the network stack and is not a bottleneck to the 100G deployment in production.

Batch Size (B)	1	2	4	8	16	32	64	128	256
NQEs per second ($\times 10^6$)	8.0	14.4	22.3	41.4	65.9	100.2	119.6	178.2	198.5

Table 4: CoreEngine switching throughput using a single core with different batch sizes.

Message Size (B)	64	128	256	512	1024	2048	4096	8192
Throughput (Gbps)	4.9	8.3	14.7	25.8	45.9	80.3	118.0	144.2

Table 5: Message copy throughput via hugepages with different message sizes.

Throughput. We examine throughput performance using the kernel stack NSM and 8 TCP streams with 8KB messages. Figures 10 and 11 show respectively the send and receive throughput with varying number of vCPUs. NetKernel achieves the same throughput performance and scalability with Baseline. The single-core send and receive throughput reaches 48Gbps and 17Gbps, respectively. Receive throughput is much lower because the kernel stack's RX processing is much more CPU-intensive with interrupts. Note that if the other cores of the NUMA node are not disabled, soft interrupts (softirq) may be sent to those cores instead of the one assigned to the NSM (or VM), thereby inflating the receive throughput. Both systems achieve the line rate of 100G using at least 3 vCPUs for send throughput as in Figure 10. For receive, both achieve 91Gbps using 8 vCPUs as in Figure 11.

Short TCP connections. We also benchmark NetKernel's performance in handling short TCP connections using a custom server sending a short message as a response. The server runs multiple worker threads that share the same listening port. Each thread runs an epoll event loop. Our workload generates 10 million requests in total with a concurrency of 1000. The connections are non-keepalive. The message size is 64B. Socket option `SO_REUSEPORT` is always used for the kernel stack. Figure 12 shows that NetKernel has the same multicore scalability as Baseline: performance increases from ~71Krps with 1 vCPU to ~400Krps with 8 vCPUs, i.e. 5.6x the single core performance. To demonstrate NetKernel's full capability, we also run the mTCP NSM with 1, 2, 4, and 8 vCPUs.[2] NetKernel with mTCP offers 167Krps, 313Krps, 562Krps, and 979Krps respectively, and shows better scalability than the kernel stack.

The results here show that NetKernel preserves the performance and scalability of network stacks, including high performance stacks like mTCP since our scalable queue design can ensure NetKernel is not the bottleneck and the contention is not severe in this situation.

7.3 Isolation

Isolation is important to ensure co-located users do not interfere with each other, especially in a public cloud. It is different from fair sharing: Isolation ensures a VM's performance guarantee is met despite network dynamics, while fairness ensures a VM obtains a fair share of the bottleneck capacity which varies dynamically. We conduct an experiment to verify NetKernel's isolation guarantees. As discussed in §4.4, CoreEngine

[2] Using other numbers of vCPUs for mTCP causes stability problems even without NetKernel.

uses round-robin to poll each VM's NK device for basic fairness. In addition, to achieve isolation we implement token buckets in CoreEngine to limit the bandwidth of each VM, taking into account varying message sizes. There are 3 VMs now: VM1 is rated limited at 1Gbps, VM2 at 500Mbps, and VM3 has unlimited bandwidth. They arrive and depart at different times. They are colocated on the same host running a kernel stack NSM using 1 vCPU. The NSM is given a 10G VF for simplicity of showing work conservation.

Figure 13 shows the time series of each VM's throughput, measured by our epoll server at 100ms intervals. VM1 joins the system at time 0 and leaves at 25s. VM2 comes later at 4.5s and leaves at 21s. VM3 joins last and stays until 30s. We can observe that NetKernel throttles VM1's and VM2's throughput at their respective limits correctly despite the dynamics. VM3 is also able to use all the remaining capacity of the 10G NSM: it obtains 9Gbps after VM2 leaves and 10Gbps after VM1 leaves at 25s. Therefore, NetKernel is able to achieve the same isolation in today's clouds with bandwidth caps.

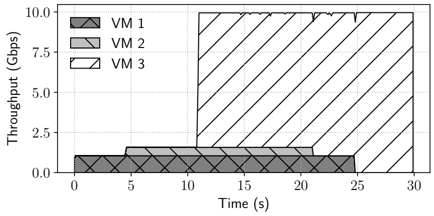

Figure 13: VM 1 is capped at 1Gbps, VM2 at 500Mbps, and VM3 uncapped. All VMs use the same kernel stack NSM. The NSM is assigned 10Gbps bandwidth. NetKernel isolates VM1 and VM2 successfully while allowing VM3 to obtain the remaining capacity.

7.4 Overhead

Latency. One may wonder if NetKernel with the NQE transmission would add delay to TCP processing, especially in handling short connections. Table 6 shows the latency statistics when we run `ab` to generate 1K concurrent connections to our epoll server for 64B messages. A total of 5 million requests are used. NetKernel achieves the same latency as Baseline. Even for the mTCP NSM, NetKernel preserves its low latency due to the much simpler TCP stack processing and various optimization [34]. The standard deviation of mTCP latency is much smaller, implying that NetKernel itself provides stable performance to the network stacks. We also investigate the latency without the effect of connection concurrency. To measure microsecond granularity latency, we use a custom HTTP client instead of `ab`, which reports application-level latency from the transmission of a request to the reception of the response. The experiments show the latency of Baseline and the NetKernel is 61.14μs and 89.53μs, respectively. The latency overhead is mostly introduced by CoreEngine in NetKernel.

CPU. Now to quantify NetKernel's CPU overhead, we use the epoll server at the VM side, and run clients from a different machine with fixed throughput or requests per second for both NetKernel and Baseline with kernel TCP stack. We disable all unnecessary background system services in both the VM and NSM, and ensure the CPU usage is almost zero without running epoll servers. During the experiments, we measure the total number of cycles spent by the VM in Baseline, and that spent by the VM and NSM together in NetKernel. We then report NetKernel's CPU usage normalized over Baseline's for the same performance level in Tables 7 and 8.

	Min	Mean	Stddev	Median	Max
Baseline	0	16	105.6	2	7019
NetKernel	0	16	105.9	2	7019
NetKernel, mTCP NSM	3	4	0.23	4	11

Table 6: Distribution of response times (ms) for 64B messages with 5 million requests and 1K concurrency.

Throughput	20Gbps	40Gbps	60Gbps	80Gbps	100Gbps
Normalized CPU usage	1.14	1.28	1.42	1.56	1.70

Table 7: Overhead for throughput. The NSM runs the Linux kernel TCP stack. We use 8 TCP streams with 8KB messages. NetKernel's CPU usage is normalized over that of Baseline.

Requests per second (rps)	100K	200K	300K	400K	500K
Normalized CPU usage	1.06	1.05	1.08	1.08	1.09

Table 8: Overhead for short TCP connections. The NSM runs the kernel TCP stack. We use 64B messages with a concurrency of 100.

We can see that to achieve the same throughput, NetKernel incurs relatively high overhead especially as throughput increases. To put things into perspective, we also measure CPU usage when the client runs in a docker container with the bridge networking mode. Docker incurs 13% CPU overhead compared to Baseline to achieve 40 Gbps throughout whereas NetKernel's is 28%. The overhead here is due to the extra memory copy from the hugepages to the NSM. It can be optimized away by implementing zerocopy between the hugepages and the NSM, which we are working on currently.

Table 8 shows NetKernel's overhead with short TCP connections. We can observe that the overhead ranges from 5% to 9% in all cases and is mild. As the message is only 64B here, the results verify that the NQE transmission overhead in NK devices is small.

8 Discussion

How can I do netfilter now? Due to the removal of vNIC and redirection from the VM's own TCP stack, some networking tools like netfilter are affected. Though our current design does not address them, they may be supported by adding additional callback functions to the network stack in the NSM. When the NSM serves multiple VMs, it then becomes challenging to apply netfilter just for packets of a specific VM. We argue that this is acceptable since most users wish to focus on their applications instead of tuning a network stack. NetKernel does not aim to completely replace the current architecture. Tenants may still use the VMs without NetKernel if they wish to gain maximum flexibility on the network stack implementation.

What about troubleshooting performance issues? In current virtualized environment, operators cannot easily determine whether a performance issue is caused by the guest network stack or the underlying infrastructure. With NetKernel operators gain much visibility of the guest network stack, which potentially facilitates debugging the performance issues. For example operators can closely monitor their NSMs to detect problems with the network stack; they can also deploy additional mechanisms in the NSMs to monitor their datacenter network [29, 49], all without disrupting users at all.

Does NetKernel increase the attack surface? It is well-known that shared memory design might suffer from side-channel attacks where malicious tenants could temper with other tenants' data on the hugepages. In this regard, NetKernel limits the visibility of NK devices into the hugepage for guest VMs: each device can only access its own address space. This is guaranteed by enforcing the address allocation and isolation control at CoreEngine.

How about supporting stacks with non-socket API? There are many fast network stacks with non-socket API such as PASTE [32], Seastar [11], and IX [18]. As NetKernel keeps the socket API, the central challenge to support these stacks (as NSMs) is how to resolve the semantic differences. While this requires case-by-case porting efforts, in general the ServiceLib should take care of the semantic transformation between the APIs.

Future directions. We outline a few future directions that require immediate attention with high potential: (1) Performance isolation. When multiple guest VMs share the same NSM, fine-grained performance isolation is imperative. In addition, it is necessary and interesting to design charging policies that promote fair use of the NSM and CoreEngine; (2) Resource efficiency. Various aspects of NetKernel's design can be optimized for efficiency and practicality. The CPU overhead of CoreEngine, mostly to poll the shared memory queues for NQE transmission, can be optimized by offloading to hardware like FPGA and SoC.

9 Related Work

We discuss related work besides those mentioned in §2.2.

There are many novel network stack designs to improve performance. The kernel stack continues to receive optimization in various aspects [42, 53, 64]. Userspace stacks based on fast packet I/O are also gaining momentum [7, 11, 34, 40, 45, 48, 55, 65]. Beyond transport layer, novel flow scheduling [16] and end-host based load balancing schemes [30, 37] are developed to reduce flow completion times. These proposals are targeting specific problems of the stack, and can be potentially deployed as NSMs in NetKernel. This paper takes on a broader and more fundamental issue: how can we properly re-factor the network stack, so that new designs can be easily deployed, and operating them in cloud can be more efficient?

Snap [47] is a microkernel networking framework that implements a range of network functions in userspace motivated by the need of rapid development and high performance packet processing in a private cloud. As NetKernel's design space and design choice are significantly different, it achieves many advantages that Snap does not target, such as multiplexing, porting a network stack across OSes or from kernel to user space, enforcing different network stack for different VMs, etc.

Lastly, our earlier position paper [51] presents the vision of network stack as a service. Here we provide the complete design, implementation, and evaluation of a working system in addition to several new use cases compared to [51].

10 Conclusion

We have presented NetKernel, a system that decouples the network stack from the guest, therefore making it part of the virtualized infrastructure in the cloud. NetKernel improves network management efficiency for operator, and provides deployment and performance gains for users. We experimentally demonstrated new use cases enabled by NetKernel that are otherwise difficult to realize in the current architecture. Through testbed evaluation with 100G NICs, we showed that NetKernel achieves the same performance and isolation as today's cloud.

We focused on efficiency benefits of NetKernel in this paper since they seem most immediate. The idea of separating network stack from the guest VM applies to public and private clouds as well, and brings additional benefits that are more far-reaching. For example, it facilitates innovation by allowing new protocols in different layers of the stack to be rapidly prototyped and experimented. It provides a direct path for enforcing centralized control, so network functions like failure detection [29] and monitoring [39, 49] can be integrated into the network stack implementation. It opens up new design space to more freely exploit end-point coordination [25, 54], software-hardware co-design, and programmable data planes [15, 43]. We encourage the community to fully explore these opportunities in the future.

Acknowledgment

Abstract

The service-oriented architecture decomposes a monolithic service into single-purpose services for better modularity and reliability. The interactive nature, plus the fact of running inside a managed runtime, makes garbage collection a key to the reduction of tail latency of such services. However, prior concurrent garbage collectors reduce stop-the-world (STW) pauses by consuming more CPU resources, which can affect the application performance, especially under heavy workload.

Based on an in-depth analysis of representative latency-sensitive workloads, this paper proposes *Platinum*, a new concurrent garbage collector to reduce the tail latency with moderate CPU consumption. The key idea is to construct an isolated execution environment for concurrent mutators to improve application latency without interfering with the execution of GC threads. *Platinum* further leverages a new hardware feature (i.e., memory protection keys) to eliminate software overhead in previous concurrent collectors. An evaluation against state-of-the-art concurrent garbage collectors shows that *Platinum* can significantly reduce the tail latency of real-world interactive services (by as much as 79.3%) while inducing moderate CPU consumption.

1 Introduction

Today's cloud environment is an enormous beast with quantities of interconnected machines. To tame the beast, developers (1) break the traditional monolithic applications into small and interactive *services* and (2) implement services atop managed languages (such as Java, C#, and Go) to build reliable, elastic and efficient systems. Unfortunately, a tension exists between those services and managed languages. Services are designed as single-purpose and interactive applications to achieve low latency. It typically takes several milliseconds and even sub-millisecond to complete a request in interactive services. Meanwhile, managed languages like Java introduce garbage collections (GC) to manage memory resources automatically. However, mainstream garbage collectors used in interactive services will introduce stop-the-world (STW) events, where all application threads (known as *mutators*) are forced to pause so that GC threads can scan the heap for memory reclamation. The pause time is tens to hundreds of milliseconds, which are usually one to two magnitudes of the execution time for a single request in interactive services. Therefore, STW pauses will affect the latency of services and cause the long tail problem. Prior work has observed that STW pauses have significant effects on tail latency in latency-sensitive scenarios [19, 40].

There are mainly two ways to reduce the STW pause time. *Partially-concurrent collectors*, such as G1 [11] and CMS, suggests reducing STW pauses by restricting the size of *collection set* in which objects need to be collected. However, this solution will introduce more frequent collections and larger accumulated STW pause time. *Mostly-concurrent collectors*, such as Shenandoah [13] and ZGC [33], allow mutators to run in nearly all GC phases. Those collectors are quite effective in reducing the duration of STW pauses, but it requires GC threads to run constantly and spend more computing resources coordinating with mutators. In summary, both kinds of collectors achieve shorter STW pauses by occupying more CPU slices and thereby put more pressure on mutators. When the workload becomes stressful, spending more computing resources in GC may end up with even worse application latency.

In this paper, we present a new garbage collector which (1) reduces the tail latency of interactive services and (2) induces moderate CPU consumption. To achieve this, we first study the effect of GC on various latency-sensitive interactive service scenarios, including production traces in Alibaba, whose business applications rely heavily on JVM. We further analyze state-of-the-art collectors and uncover their problems respectively: *idle computing resources* in stop-the-world pauses of partially-concurrent collectors and *considerable runtime overhead* in mostly-concurrent collectors. We then describe the *skewed memory write* behaviors of interactive service applications. We also discuss the development of hardware to show opportunities for a brand-new design.

According to the analysis, this paper proposes *Platinum*, which finds a sweet-spot in the design of concurrent collectors. It leverages idle cores in STW pauses and grants them to mutators to solve the idle computing resources problem. It then provides an isolated execution model to minimize the synchronizations between GC threads and mutators to reduce the runtime overhead in prior mostly-concurrent collectors. It further exploits recently-released hardware features (MPK) to eliminate *barriers*, the primary source of software overhead in traditional mostly-concurrent collectors. With *Platinum*, GC threads and mutators can run together with little interference with each other, so the latency and CPU utilization are both satisfying.

Platinum is implemented atop the Parallel Scavenge Garbage Collector (PSGC), a STW and throughput-oriented collector used by default in the HotSpot JVM of OpenJDK 8. Evaluation of various interactive service benchmarks show that *Platinum* significantly improves the tail latency of applications (by up to 79.3% for 99th percentile latency) compared with other concurrent collectors while preserving moderate CPU utilization.

The contributions of this paper include:

- A comprehensive analysis of latency-sensitive interactive services, including simulated industrial workload with production traces, to understand the effect of GC (Section 2).
- *Platinum*, a concurrent garbage collector that can reduce the tail latency for interactive services while preserving moderate CPU consumption (Section 4).
- Experiments on different latency-sensitive scenarios to confirm that *Platinum* can outperform other garbage collectors on tail latency and CPU utilization for interactive services (Section 5).

2 Analysis: when interactive services meet GC

In this section, we will analyze the effect of GC in interactive services with production traces in Alibaba.

2.1 A page is multiple services

Alibaba has one of the world's largest e-commerce platforms. To serve an ocean of concurrent requests from a vast number of clients at any time, Alibaba has deployed its platform atop a large scale of machines. Traditional monolithic applications are too cumbersome and thus not suitable to be distributed to many machines due to the prohibitive cost of development and maintenance, so the developers from Alibaba have split them into smaller, simple-purpose, and interactive units, namely *services*. A service is much smaller to simplify the deployment process, and it can also be replicated to enhance the availability of the overall platform.

Due to the complex business logic in Alibaba, every operation from users require the collaboration of various services. For example (shown in Figure 1), when a user wants to check out, she will request for the check-out page, where all items in the shopping cart (cart service) will be combined together so that the most cost-effective way to purchase them with available coupons will be automatically computed (coupon service). In addition, the check-out page also recommends other items according to those in the cart and the user's prior purchase behaviors (recommendation service). Those services also interact with each other, and they may communicate with the cache service for high-speed data fetching.

Since those services are mostly written in Java for reliability, productivity, and compatibility, all of them will be affected by GC. Alibaba has provided some workarounds to mitigate the effect of GC. For example, when the recommendation service is not responsive, the page render is capable of generating a simplified web page without any recommendation information for users. Unfortunately, not all services can benefit from those optimizations. For example, as for the coupon service, the latest-available coupons must be included for computation. Otherwise, the users will fail to purchase in the most cost-effective way. We have conducted a series of tests to understand the role GC plays in those latency-critical services. Note that a garbage collector usually includes *minor GC* and *major GC*. The minor GC collects a part of the heap while the major GC collects the whole heap. Since major GC rarely happens in the scenario of interactive services, this work will focus on the effect of minor GC.

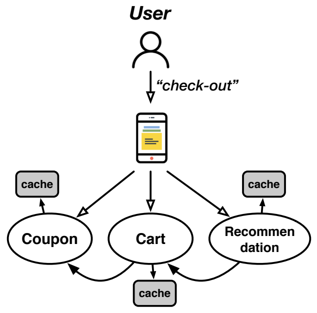

Figure 1: A simplified model to shape the multi-services scenario in Alibaba

2.2 STW pauses: the culprit for tail latency

Since garbage collectors will pause application threads for memory reclamation, it will significantly affect the response time of requests in interactive services. To better understand the effect of GC, we leverage a simulated online environment for analysis. The simulated environment is built with 120 service instances, each of which is deployed in a container. All services are unmodified applications extracted from the real industrial workload in Alibaba. During testing, those services will be fed with requests at a given throughput. In our setting, the cluster will handle 200 user requests per second, and this value is chosen to stress the coupon services. All requests are traces collected from the production environment. The default garbage collector for services is CMS (Concurrent Mark Sweep [28]), a classic concurrent collector introducing relatively long STW pauses.

To understand the relationship between application behavior and GC pause time, we add a new Java option -*XX:InstrumentedPauseTime* to the vanilla OpenJDK 8. When the value is not zero, JVM will add a *sleep* call at the end of GC to extend the GC pause time. The duration of sleeping time can be adjusted by modifying the value of -*XX:InstrumentedPauseTime*. We are mainly interested in the coupon service as it is latency-sensitive. Our findings are listed below.

Stop-The-World (STW) pauses is a killer factor for the tail latency. We exploit a scatter plot in Figure 2 to illustrate the relationship between GC and request latency. Points in the scatter plot stand for the completion time of a request (measured in the server-side), while red vertical lines stand for the start time of GC. As Figure 2 suggests, each GC cycle will follow some stragglers, which significantly affect the tail latency. Although the request latency could be influenced by many factors such as network, disk I/O, and other collaborative services, GC is the one to dominate the tail latency. Note that this experiment actually underestimates the effect of GC on the request latency, as the statistics are collected from servers, which overlook the queuing time in the client-side. One can expect more requests are affected by GC if each request can be tracked in the upstream services, which is unfortunately not supported in the cluster environment.

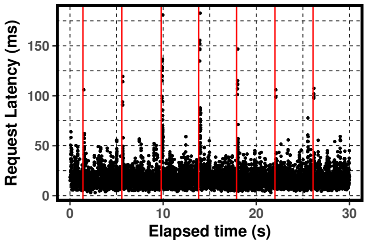

Figure 2: The relationship between STW pauses and request latency in the coupon service. The collector is CMS

GC pause time shows a super-linear relationship with tail latency. During the evaluation, we change the value of -*XX:InstrumentedPauseTime* for all five coupon service instances from 0 to 10ms and collect the log from them. Figure 3 shows the change in the request latency for a coupon service instance in a cumulative distribution function (CDF) form, compared with that in the vanilla setting. The result suggests that the increased pause time has a magnified impact on the tail latency: When the GC pause is added by 10 ms, the 99th percentile latency is increased by 11.435 ms, and the 99.9th percentile latency is enlarged by 32.950 ms. It is because requests in clients are generated at any time, regardless of the running state of services. When the coupon service instance is undergoing a garbage collection, the pending requests will gradually increase and queue up. Once GC ends, a pending request cannot be processed until the preceding ones are finished. If GC pauses are extended, those newcomers must wait for not only a longer pause but also more pending requests, so the tail latency will increase faster than GC pauses.

In the real-world cooperative multi-services scenario (such as the check-out case in Alibaba), the problem can be deteriorated because all participating services may be affected by GC. For example, Mass et al. [25] have observed that Cassandra replicas on GC will hinder the whole storage system from constructing a quorum, which leads to prohibitive user-experienced latency. Therefore, GC pauses is a key factor for tail latency reduction in interactive services.

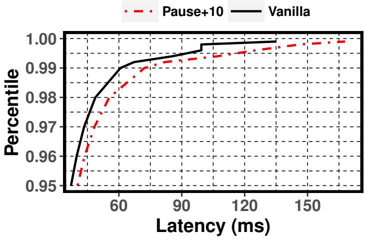

Figure 3: The CDF of request latency for the coupon service atop CMS

2.3 Is concurrent GC helpful?

Due to the detriment of STW pauses, interactive services usually adopt *concurrent GC* for better application latency. Concurrent GC can be roughly divided into two categories: *partially-concurrent collectors* and *mostly-concurrent collectors*. Partially-concurrent collectors, such as CMS (mentioned above) and G1 [11], allow the co-execution for mutators and GC threads in only some phases of GC. Therefore, they still introduce STW pauses, and they provide solutions to further reduce them. *Mostly-concurrent collectors*, such as ZGC [33] and Shenandoah [13], nearly eliminate STW pauses so that mutators can run constantly. We study those two kinds of collectors on interactive services respectively.

Partially-concurrent GC. As shown in Figure 2, the tail latency problem exists in partially concurrent collectors like CMS since they still pause mutators for collection. Fortunately, partially-concurrent collectors usually provide options to adjust the duration of pauses. For example, CMS allows users to adjust the size of the heap area required to be collected, while G1 can be restricted with a pre-assigned maximum pause time. After setting those options, partially-concurrent collectors will adjust the heap layout to meet the requirement.

We exploit G1 to study the effect of those adjustable options. G1 is a highly-tunable partially-concurrent collector which becomes the default one since OpenJDK 9. It is a generational collector whose heap space consists of *young space* and *old space*. Its GC algorithm contains three parts: *minor GC* on the young space, *mixed GC* on the young space and a part of the old space, and *major GC* on the whole heap. The minor GC, which is stop-the-world, happens the most frequently. To reduce the duration of pauses, G1 provides an option *-XX:MaxGCPauseMillis* for users to control them. Therefore, we launch the coupon service on G1 by setting the option to various values (30ms, 40ms, 60ms) and evaluate the performance respectively. This evaluation is single-point, where only one coupon service is launched to process requests. With the single-point evaluation, the latency can be accurately collected from the client-side, including the aforementioned queuing delay. The requests are sent in a fixed throughput to simulate a stressful scenario (4000 requests per second in our setting), and they are still real-world traces extracted from the online environment in Alibaba. The duration for data collection is a minute.

Table 1 shows the statistics on GC and application for different settings. With smaller *MaxGCPauseMillis*, both the minimum and the average GC pause time are reduced. However, young GC is triggered much more frequently. It is because G1 controls the GC time by tuning the size of the young space, which serves for memory allocation requests from mutators. Since young GC is triggered when the memory resource in the young space is exhausted, its frequency will increase when the young space shrinks. As a result, although the per-GC pause time is cut down by lowering *MaxGCPauseMillis*, the overall time consumed by GC grows larger. With larger overall GC pause time, more application requests are affected, and less computing resource is available for mutators. Therefore, the tail latency problem is not resolved but becoming much more severe: the p99 latency with the 30ms setting is 13X of that with 60ms. Besides, the average CPU utilization in the 30ms setting is also increased by 15.3% compared with the 60ms setting. This experiment suggests that partially-concurrent GC achieves shorter pauses by consuming more CPU resources, which may end up with worse tail latency.

Metrics	30ms	40ms	60ms
Minimum GC pause (ms)	21.815	21.459	39.856
Average GC pause (ms)	34.441	40.724	48.491
The number of GC	550	392	111
p99 latency (ms)	1942.09	1389.99	148.85
Average CPU utilization	51.45%	50.81%	36.17%

Table 1: The statistics on GC and the coupon application with different settings of G1GC

Mostly-concurrent GC. Compared with partially-concurrent GC, mostly-concurrent GC allows mutators to execute nearly all the time. Recently released mostly-concurrent collectors, like ZGC and Shenandoah, claim to have reduced GC pauses to several milliseconds regardless of the heap size. In this work, we mainly study Shenandoah[1], a mostly-concurrent garbage collector released in OpenJDK 12.

We launch the coupon service atop Shenandoah and evaluate it with the same setting as G1. After collecting the GC log, we conclude that Shenandoah is very effective in reducing the pauses, and the average pause time is only 18.764 ms. However, the latency of requests is prohibitive: the p99 latency is over 3 seconds, which is 1.86X even compared with the worst case in G1 (30 ms). We observed that the time when GC threads are active is 53.05 seconds, which means that GC threads are active nearly all the time. Meanwhile, the average CPU utilization reaches 83.05% (the peak utilization reaches 96.74%), which suggests that GC threads consume much more CPU resources than other collectors, and mutators do not have enough CPU slices to sustain such a high throughput. As a result, the p99 latency with Shenandoah is not decreased but increased when encountering stressful workload.

To conclude, both partially-concurrent GC and mostly-concurrent GC are making a tradeoff between the duration of GC pauses and the CPU efficiency. Shorter GC pauses mean that GC threads will consume more computing resources and thus affect the performance of mutators. We instead want to build a garbage collector with both short pauses and moderate CPU efficiency to support the interactive services.

3 Implications for a new GC design

Before proposing our design, we take a closer look at the designs of prior concurrent garbage collectors to uncover the opportunities to build a new garbage collector for our goals: short GC pauses and moderate CPU utilization. We then reveal the *skewed memory write* behavior in interactive service applications, which is crucial to our design. We also introduce *memory protection keys* (MPK), a recently released hardware feature, and suggest how collectors can benefit from it.

3.1 Problems in concurrent garbage collectors

According to the behavior of mutators during GC, concurrent garbage collectors can be roughly divided into two categories. However, both of them have problems hindering them from achieving both satisfying GC pause time and CPU efficiency.

Idle computing resources for partially-concurrent collectors. STW pauses in partially-concurrent collectors require all mutators to suspend and leverage all computing resources to collect objects. This design avoids interferences between mutators and GC threads, but it also results in idle cores during GC due to its scalability issues.

There are two reasons why garbage collectors cannot scale well. First, the collection algorithm is somewhat similar to

[1] We exploit Shenandoah as a baseline in this paper as it provides backward support to OpenJDK 8, a long-time-support version which is widely leveraged in both industries (like Alibaba) and open-sourced projects.

graph traversal: GC threads will start from some *root objects* and mark all reachable ones through references among objects. The traversal is highly unpredictable as we do not know how many references a thread will process in advance. Therefore, collectors are prone to load-imbalance and often turns to work-stealing to achieve dynamic balancing. However, work-stealing is also ineffective in that it has to search for tasks from all other threads and contend with others during task fetching. Prior work [37] shows that work-stealing even causes performance slowdown in extreme cases. Second, the scalability of collectors is affected by many factors. Recent studies have shown that the NUMA architecture [17], synchronization protocols [16], and even the Linux scheduling mechanism [38, 40] could have a significant influence on the GC scalability. Therefore, it is difficult to come up with a general algorithm which is scalable for various scenarios.

Given those reasons, partially-concurrent collectors exploit a conservative mechanism where the number of GC threads is smaller than that of cores. In OpenJDK, the number of GC threads by default is about five-eighths of the total core count. This policy also works for STW collectors like PSGC. The developers of OpenJDK explain their choice in the comment of the source code: *For very large machines, there are diminishing returns for large numbers of worker threads. Instead of hogging the whole system, use a fraction of the workers for every processor after the first 8.* This default setting mitigates performance degradation as the number of cores increases and has been used in prior GC studies [40]. However, it also results in idle cores during collection. Instead of searching for a perfectly scalable collection algorithm, we want to introduce some concurrent mutators to leverage those idle cores while still preserving the performance of collectors. Note that introducing concurrent mutators during GC will not hurt the overall CPU efficiency much, as the duration of STW pauses only occupies a very small portion of the whole application's execution time in interactive services.

Considerable runtime overhead for mostly-concurrent collectors. Unlike partially-concurrent collectors, mostly-concurrent ones allow mutators to run simultaneously with GC threads nearly all the time to reduce the application latency. However, GC threads and mutators must synchronize with each other as they may modify the same objects simultaneously, which introduces overhead for both GC threads and mutators. Besides, mostly concurrent collectors further introduce *barriers* in mutators for GC invariant checking. A barrier is a piece of code instrumented before specific instructions. For example, Shenandoah exploits *read barriers* for mutators, meaning that mutators need to check the invariants for every single read operation on references, no matter if GC is active. Those two factors introduce significant runtime overhead to the runtime. Therefore, although Shenandoah has been optimized through aggressive Just-In-Time (JIT) compilation, it still causes a 24% slowdown for real-world workload compared with G1 [13].

3.2 The skewed memory write behavior

Memory behavior of applications is quite crucial to GC performance and thereby affect the design of collectors. For example, the memory behavior of big-data processing workload is at odds with assumptions in traditional GC algorithms and stimulates a series of big-data-friendly garbage collectors [18, 31]. To this end, we study the memory behavior of latency-sensitive services to explore new space for garbage collector design.

Session-based execution model. Since services are interactive, their execution can be divided into many *sessions*. The service will process a request when a session starts and generate a response before the session ends. Sessions are mostly isolated from each other: a session will not try to access the objects created by other sessions unless those objects are globally visible through shared data structures. Therefore, we presume that the memory behavior of those session-based applications will be skewed, i.e., *the memory accesses within a session will fall into a very small range where the session allocates memory.* The memory range is referred to as *working set* in this paper. We have conducted an in-depth analysis to validate this hypothesis.

Memory behavior analysis. To analyze the memory behavior of those session-based applications, we first need to demarcate all sessions. We add two new JVM calls, *Sessionbegin* and *Sessionend*, to achieve this goal. After *Sessionbegin* is invoked, the JVM will track all memory the session allocates. When *Sessionend* is called, the JVM will print out the size of the overall allocated memory, which is the working set size for the current session.

Our hypothesis is that session-based interactive services share similar memory behavior. To confirm this, we have also studied three other applications: *SpecJBB2015*, a simulated online supermarket, *Cassandra* [9], a key-value store, and *ShopCenter*, another interactive service used in Alibaba. All of them will process requests from clients in sessions and send responses back. Note that both ShopCenter and Coupon leverage production traces for analysis. To profile their memory behavior, we instrument *Sessionbegin* right before the request is processed and *Sessionend* when the processing finishes.

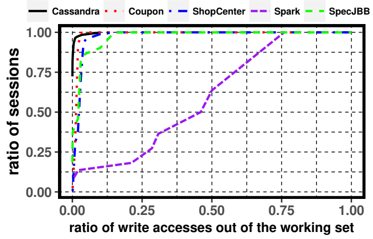

Figure 4: The CDF for the memory range of write accesses in various applications

Figure 4 shows the CDF curve of memory writes for three different interactive applications. As for the coupon service, over 99.5% sessions have less than 3% writes out of their working sets. The working set of a session usually spans several megabytes, which is quite small compared to the Java heap (typically tens to hundreds of gigabytes). The other applications share similar memory behaviors. For Cassandra, even the worst case has 72.4% writes inside its own working set. Other kinds of applications, however, do not follow this behavior. As for Spark, a big-data processing framework, 50% sessions (a session in Spark is defined as the process the worker handles a task assigned by the master) have more than 46% writes out of their working sets.

This experiment confirms our hypothesis that memory writes in sessions of interactive services are skewed. The skewed memory write behavior opens up an opportunity for optimization: since mutators mostly update objects inside their working sets, they can run simultaneously aside GC threads with rare interference if GC threads avoid reclaiming their working sets. Since previous garbage collectors do not put the skewed memory write behavior into consideration, this finding motivates us to design a new garbage collector to guarantee both satisfying latency and CPU utilization.

3.3 MPK and Garbage Collectors

Since barriers in concurrent GC are costly due to its high execution frequency, some collectors [2, 4, 10] have turned to a virtual-memory-based mechanism for a transparent and efficient solution. The virtual-memory-based mechanism leverages the access permissions on the page table entries and relies on hardware to check the invariants. For example, a GC thread can mark a virtual page as *being-collected* by setting its permission as read-only. Mutators writing to this page will trigger a page fault and execute synchronization-related operations in a pre-registered handler. GC threads working on other pages will have no overhead as no page fault is triggered. This method can eliminate the need for the barrier code, and it can also be used in other areas, such as software transactional memory [1].

Unfortunately, threads in a process will share the same permissions on all page table entries. In the previous example, if a GC thread also wants to modify the being-collected page, which should be legal, it still suffers from a page fault. Those *false page faults* impede collectors to implement an efficient protection mechanism.

Intel MPK (Memory Protection Keys) is a hardware feature available recently in the SkyLake server CPUs. With MPK, users can categorize virtual pages into different *domains*, which will be denoted with special bits in the corresponding page table entries. Furthermore, they can manually grant different permissions for each domain to different threads through a special register. This hardware feature makes it possible to support finer-grained *thread-level isolation* by adjusting the permissions over domains for each thread. Previous work has studied the usage of MPK in the security area [14, 20, 35, 43], but it could also be leveraged for performance consideration.

4 Design

According to our analysis, we build *Platinum* for both satisfying latency and CPU efficiency.

4.1 Overview

Platinum is built atop PSGC, a STW garbage collector in OpenJDK. Compared with concurrent collectors, PSGC is more CPU-efficient as it always pauses mutators during GC to achieve maximum collection throughput. Nevertheless, it still results in idle cores due to scalability issues. *Platinum* inherits the generational design from PSGC to divide the heap into *young space* and *old space*. The young space further consists of three sub-spaces. The *eden-space* (usually the largest sub-space) serves for allocation, while the other twos, *from-space* and *to-space*, are used to store objects surviving at least one GC cycle. Only objects having lived for long will be copied into *old space*. It contains two GC algorithms: minor GC for the young space and major GC for the whole heap. *Platinum* mainly considers the minor GC while leaving the major GC as future work.

Figure 5 illustrates the infrastructure of *Platinum*. The design highlights of *Platinum* include:

Sufficiently leveraging computing resources. *Platinum* collects the cores not used by GC threads and grants them to mutators for better application latency, hence resolving the idle computing resources problem in partially-concurrent GC.

Isolated execution between GC threads and mutators through heap partition. According to the skewed memory behavior in interactive services, *Platinum* partitions the heap space so that GC threads and mutators can focus on processing objects in different parts of the heap. This design minimizes the synchronizations between GC threads and mutators, so the coordination overhead in mostly-concurrent collectors is greatly reduced in *Platinum*.

Hardware-assisted barrier elimination. *Platinum* leverages the MPK hardware feature to remove the need for software barriers adopted in prior mostly-concurrent collectors. This design further reduces the runtime overhead and improves CPU efficiency. *Platinum* also exploits the RTM feature to ensure the atomicity of write operations in mutators.

4.2 Platinum in steps

Similar to the minor GC algorithm in PSGC, *Platinum* is copy-based: GC threads will simultaneously scan the young space for live objects and copy them to their new address. The process of *Platinum* GC is mainly in three steps:

1. Initial marking. This step is somewhat similar to the initial marking pause in G1 [11]. In the initial marking phase of *Platinum*, GC threads will scan the runtime stack of muta-

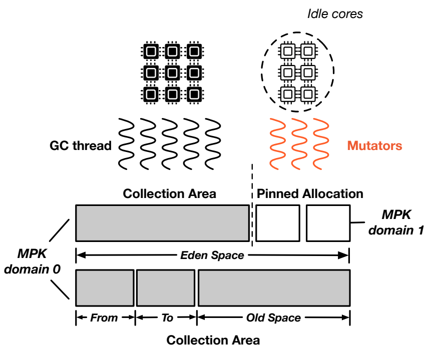

Figure 5: Overview of *Platinum*

tors to mark live objects. Those live objects on the stack will be treated as *root objects* for further object copying. This step is stop-the-world because the values on the stack are changed quite frequently, and we want a stable state at the beginning of a collection. It usually takes only a few milliseconds to finish initial marking.

2. Concurrent scavenge. After initial marking, *Platinum* will invoke mutators to resume their execution while GC threads will concurrently scan the heap to identify and copy live objects. Thanks to the isolated execution mechanism (detailed in Section 4.4), GC threads and mutators will focus on processing objects in different areas of the heap and hardly interfere with each other. Therefore, GC threads can directly copy live objects without considering the behavior of mutators. This step occupies the most time of the whole GC process in *Platinum*.

3. Stop-the-world scavenge. When GC threads have finished their work, *Platinum* will pause running mutators again. Since some objects in mutators' working sets are not processed by GC threads in the concurrent scavenge step, they may contain "stale" references to objects which have been evacuated. Therefore, *Platinum* should scan those objects for correctness guarantee. Since the number of objects is quite small, this step will not take long.

With the above three steps, *Platinum* can: (1). improve the application latency because mutators are allowed to run in most time of GC; (2). avoid consuming too much CPU resources because GC threads are isolated from mutators to retain satisfying collection throughput. Therefore, *Platinum* can take into account both latency and CPU efficiency at the same time. We will introduce the core designs of *Platinum* in the rest of this section.

4.3 Idle core collection

To make *Platinum* effective, the application should configure the number of GC threads to be smaller than that of cores (or directly adopt the default setting in OpenJDK). When *Platinum* is initialized, it will automatically bind the GC thread into different CPU cores. Other cores with no GC threads running will be remembered by *Platinum* as *idle cores*.

When *Platinum* is not active, mutators are free to run on any cores. When GC is triggered, *Platinum* will constrain mutators to only choose idle cores for execution to avoid contending computing resources with GC threads. This is achieved by setting the affinity values of mutators with the *sched_setaffinity* interface in Linux. Those affinity values will be reset at the end of GC. This design ensures not only idle cores are sufficiently used by mutators but also each GC thread monopolizes its assigned core.

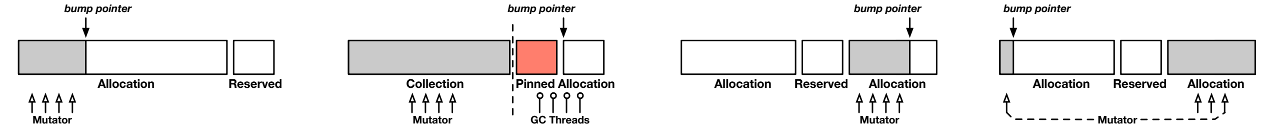
4.4 Isolated execution with heap partition

To achieve isolated execution between GC threads and mutators, *Platinum* partitions the heap into three *areas* during GC (shown in Figure 5). The first area, namely *collection area*, will be collected by GC threads. The collection area covers the most part of Java heap, including from-space, to-space, old-space, and the largest part of eden-space.

The other two areas, in contrast, are used by mutators and thus not collected in this GC cycle. Since write operations of mutators fall into a very small range (see Section 3.2), we use the *pinned area* to include objects which are highly possible to be modified by mutators in the near future. The last part is the *allocation area*, which is used by mutators to allocate new objects during garbage collection. Those newly allocated objects should be considered alive and only be scanned in the next collection cycle.

Figure 6 illustrates how the three areas work in *Platinum*. During normal execution, *Platinum* will partition the eden-space into two areas (Figure 6a). The larger one will serve memory allocation requests from mutators while the smaller one will be reserved. *Platinum* also adopts a *bump pointer* to denote how much memory has been used.

When the bump pointer reaches the end of the allocation area, GC will be triggered, and GC threads will become active. In the initial marking phase, *Platinum* will partition the eden-space into the three areas mentioned before (Figure 6b). The reserved area in the normal execution will become the *allocation area* where concurrent mutators create new objects during GC. The larger one will be further split into *collection area* and *pinned area*. GC threads will only collect the collection area while mutators mainly modify the pinned area and the allocation area. Compared with the collection area, the pinned area resides close to the bump pointer. This design choice is based on the memory allocation mechanism in JVM: each mutators will first allocate a *segment* from the global heap, and then allocate memory from the segment until it is filled up. Therefore, *Platinum* locates the pinned area adjacent to the allocation area to contain the latest segments allocated by different threads. The size of the pinned area is preset to a fixed proportion of the whole eden-space. The default value is 1/128, which can include segments from tens of mutators while inducing moderate pauses during the stop-the-world scavenge step. *Platinum* also allows users to tune this value for better performance. Users can leverage the aforementioned *Sessionbegin* and *Sessionend* API to cal-



(a) The heap space is divided into two areas during normal execution

(b) GC starts: partition the heap into three areas for isolated execution

(c) GC ends: re-partition the heap into two areas

(d) When the bump pointer reaches the end, it will "jump" to the start address for memory allocation

Figure 6: The heap layout in *Platinum*. The colored part stands for allocated memory.

culate the working set size for their applications during prerun, and modify the pinned area to a proper size accordingly.

During the concurrent scavenge step, GC threads will apply range checks to determine if an object falls into the collection area before accessing it, and only those in the collection area will be processed. Those range checks avoid the case where GC threads try to copy an object which mutators are modifying. Since the collection area is consecutive, range checks can be implemented with cheap comparison instructions and thus introduce little overhead. As a result, GC threads and mutators are enforced to concentrate on processing objects in different areas, which eliminates the need for synchronization and thereby mitigates the runtime overhead. For objects not processed during concurrent scavenge, they will be scanned and updated in the subsequent stop-the-world scavenge step.

Before GC ends, GC threads become inactive, and *Platinum* should reorganize the eden-space (Figure 6c). Since a part of the space has been occupied by live objects (pinned and allocation area), *Platinum* will mark it allocated. The rest of the space will still be partitioned into two areas, while the reserved one will reside adjacent to the pinned area in the last GC. The bump pointer will grow from the original allocation area and goes to the start address once it reaches the end (Figure 6d). When the allocation area is exhausted, a new GC cycle is activated.

4.5 Hardware-assisted barrier elimination

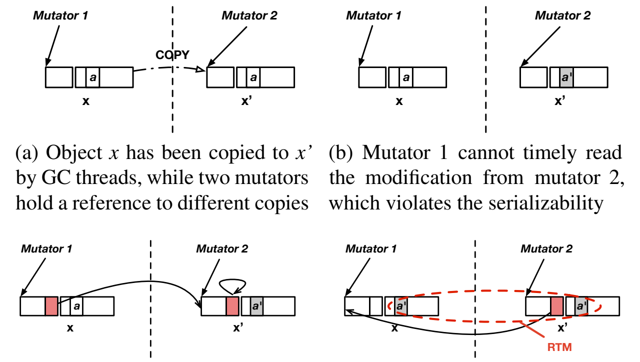
Heap partition restricts GC threads to only process objects in the collection area and thus reduces the coordination overhead. However, since mutators are running Java code, they are free to access any objects in the Java heap, including those in the collection area, which violates the *isolated execution* semantic. A traditional solution proposed by prior concurrent collectors is to leverage *barriers* to detect and correctly handle those operations. A barrier is a piece of code instrumented before specific operations for the interest of GC. For our problem, a garbage collector can adopt *write barriers*, which instrument range check operations before every write. As shown in Figure 7, for a field update operation (*y.x* = *z*), the collector should insert a range check to ensure that the address of the field (*y.x*) is not in the collection area. If the range check fails, mutators should turn to a prepared slow path (*atomic_update*) to update the field atomically to ensure correctness.

```
// barrier code start
if (in_collection_area(y.x)) {
    atomic_update(y.x, z);
}
// barrier code end
else {
    // Field update
    y.x = z;
}
```

Figure 7: An example of write barriers

As mentioned in Section 3, barriers can cause significant overhead as they are instrumented with *every* specific instruction, no matter if GC is active. For write barriers, they must be executed before every write operation, including interpreter code, JIT code, and even part of native code inside JVM. We instead provide a hardware-assisted solution atop MPK to eliminate the write barriers.

To leverage MPK, *Platinum* divides the Java heap space into two *domains*: *GC domain* and *mutator domain*. The *GC domain* only contains the collection area, while the *mutator domain* consists of the pinned area and the allocation area. When threads are initialized, they will be granted with corresponding permissions: mutators have read-write permissions to the mutator domain and read-only permissions to the GC domain; GC threads have read-write permissions for both two domains. The permissions are fixed throughout the lifecycle of a thread. On the other hand, the address ranges for those two domains are changed with the three areas dynamically. When the collector is inactive, the whole Java heap space belongs to the mutator domain so that mutators are free to access any objects. When GC starts, the collection area should be put into the GC domain. Afterward, if concurrent mutators' write operations fall into the GC domain, they will trigger page faults, and thus no software barriers are required. Thanks to MPK, *Platinum* can *automatically* detect write operations violating the isolated execution mechanism, and the control flow will be transferred to a customized handler to correctly process those operations. Although processing a page fault is more costly than executing a software barrier, the possibility of triggering a page fault in interactive services is much smaller than that for software barriers, and the amortized overhead can be reduced.



(a) Object *x* has been copied to *x'* by GC threads, while two mutators hold a reference to different copies

(b) Mutator 1 cannot timely read the modification from mutator 2, which violates the serializability

(c) *Shenandoah* exploits an indirection pointer so that accesses to the old object will be forwarded to the new one

(d) *Platinum* instead updates both two copies atomically by putting the updates into the same hardware transaction

Figure 8: The dual-copy problem and solutions

4.6 Handling violated writes

When a write operation from a mutator falls into the collection area, the customized handler will take over and temporarily request for read-write permissions for the GC domain. This request is safe as the code in the handler is totally controlled by *Platinum*. Afterward, the handler is responsible to simulate the original write operation on the mutator's behalf by modifying the corresponding object in the collection area.

However, the simulation process must be deliberately designed as GC threads are concurrently copying those objects. If an object has been copied, the old one and the copied one will co-exist in the Java heap until GC ends. Since mutators may still have references to the old object, the consistency between the two copies must be maintained. Consider the case in Figure 8a where object *x* has been copied (say *x'*). Suppose mutator 2 gains a reference to *x'* and modifies a field *a* in *x'* (Figure 8b), the modification should be visible to all mutators. However, if mutator 1 still holds a reference to *x* and reads its content, it can only get a stale value of *a*. We refer to it as the *dual-copy problem*, which breaks down the serializability of the whole program.

Prior concurrent collectors have similar problems as they also allow mutators to run in scenarios where two copies of the same object are both visible in the heap. They leverage *read barriers* to force mutators always to access the newest one. The implementation of read barriers has many variants, and one of them is to use Brook's style indirection pointers [5] as Shenandoah [13] does. This solution requires adding an extra field in the header of every Java object, which stores a pointer to the newest copy of this object. As illustrated in Figure 8c, *x* points to *x'* while x' points to itself. In this way, when mutator 1 tries to access *x*, the indirection pointer of *x* will guide it to access *x'* instead so that it can get the updated value of *a*. This solution is simple and straightforward, but it introduces considerable overhead, as analyzed in Section 3.1.

Rather than using read barriers, *Platinum* guarantees correctness by updating *both* copies in the customized page fault handler. As shown in Figure 8d, *Platinum* keeps the added field in Shenandoah to store a *back pointer* to the old copy. For the old object, since the original PSGC will store a *forwarding* pointer in its header referring to the new object, the added field is useless. In the above example, when updating *x'*, *Platinum* will locate *x* with the back pointer and update the value of *a* for both *x* and *x'*. Even though mutator 1 retains a reference to *x*, it can still fetch the updated content by directly reading *x*. This mechanism certainly doubles the write operations, but it relies on the observation that only a few write operations from mutators will happen in the collection area, so the overhead will be trivial.

Prior work like Sapphire [21] also exploits similar mechanisms, but it struggles to make the updates atomic, i.e., the updates to both copies should be visible to mutators simultaneously. Fortunately, recent hardware development has provided us with new opportunities for design. *Platinum* embraces the *Restricted Transactional Memory* (RTM) feature by Intel, which guarantees the atomicity of a piece of code by wrapping it into a hardware transaction. Since RTM requires that the working set of the transaction should be small (otherwise the abort rate will dramatically increase), we only put the update operations into the hardware transaction to construct a very small working set (less than 100 bytes). We have also prepared a fall-back handler in case the transaction fails. The handler retries the transaction in most cases, but it will try to grab a global lock if the transaction fails for many times (which happens very rarely). With RTM's help, *Platinum* can update both objects atomically and return to normal execution, which provides a strong consistency guarantee and introduces moderate overhead.

5 Evaluation

Platinum is implemented in the HotSpot JVM of OpenJDK 8u141 with about 7,500 LoCs. We leverage three various applications for evaluation:

SpecJBB2015. SpecJBB2015 is a business benchmark that simulates an online supermarket to process incoming purchasing requests. Alibaba usually exploits it as a simplified example to simulate the online production environment.

Cassandra. Cassandra is an open-sourced key-value store which is usually leveraged as a latency-sensitive application by prior work [7, 40]. We leverage YCSB as the testbed, but it is executed in a closed-loop model where a client will not send a second request until its receives the response for its last one. This model cannot reflect the fact that requests have to wait until prior ones are finished. Therefore, we have modified the execution model of YCSB to open-loop, where clients send requests in a fixed throughput regardless of the responsiveness of servers. The version of Cassandra for our evaluation is 3.11.4.

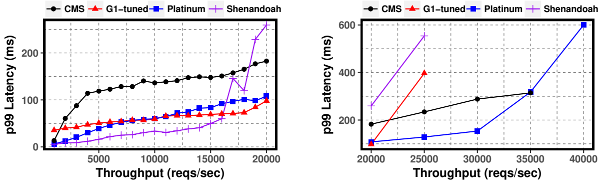
Coupon. Coupon is an online interactive service used in Alibaba, and we use it to confirm that *Platinum* actually works in real applications.

We also compare the performance of *Platinum* against other mainstream garbage collectors.

CMS. Concurrent-Mark-Sweep (CMS) is a classic partially-concurrent garbage collector. Its major GC is concurrent, and the minor GC is stop-the-world. We leave CMS untuned to show its original performance.

G1. G1GC (G1) is a highly-tunable partially-concurrent garbage collector which prioritizes latency over throughput. It is designed to replace CMS in the future versions of OpenJDK. We have manually tuned the value of *MaxGCPauseMillis* for performance consideration. Since G1 is an experimental collector in OpenJDK 8, we also try the later OpenJDK 9 for evaluation. However, OpenJDK 9 is not supported by the coupon service and Cassandra, and our evaluation on SpecJBB2015 shows similar results for those two versions. Therefore, we only report the result for OpenJDK 8.

Shenandoah. Shenandoah is a work-in-progress mostly-concurrent garbage collector. The application latency is quite low, but the introduction of *read barriers* and other concurrent phases strongly affect CPU utilization.



(a) low-throughput

(b) high-throughput

Figure 9: The p99 latency results on SpecJBB2015 for different collectors with various throughput settings.

5.1 SpecJBB2015

We use the preset mode to evaluate SpecJBB2015 atop different collectors to understand its performance under various levels of throughput. In Alibaba, different throughput settings can be used to simulate different types of workload. The experiment is running on a physical machine with dual Intel Xeon Gold 6138 CPUs (80 logical cores) and 16GB Java heap size. The number of concurrent GC threads is set as the default value (53). We tune G1 with different *MaxGCPauseMillis* values and find that it reaches the shortest per-GC pause time when the value is 50ms, so we adopt this value for evaluation (referred to as *G1-tuned*). Figure 9 shows the 99th percentile latency for *Platinum*, CMS, G1, and Shenandoah. The results in Figure 9a show that *Platinum* always performs better than CMS under moderate throughput, and the 99th percentile latency is reduced by 38.4%-79.3%. *Platinum* also achieves comparable performance against our tuned G1. The improvement in latency mainly thanks to the mostly-concurrent collection in *Platinum*.

When the throughput becomes higher (shown in Figure 9b), G1 reaches its limit at 25000 requests per second. As a mostly-concurrent collector, the latency of Shenandoah is ultra-low in low throughput but dramatically rises when the throughput is 17000 and also reaches its limit at 25000. Note that G1 and Shenandoah shares a similar concurrent marking algorithm, and the main difference in their design choices is that G1 pauses mutators during collection while Shenandoah allows concurrent execution. Therefore, G1 has better GC efficiency and performs better under high throughput, while Shenandoah induces shorter pauses and performs better under low throughput. In contrast, *Platinum* can sustain the highest throughput of all collectors, thanks to the cost-effective isolated execution model during concurrent collection.

We also measure the CPU utilization for collectors under three different QPS settings (5000, 15000, 25000) to represent low, moderate, and high throughput. As Table 2 shows, the CPU utilization of *Platinum* is only slightly higher than CMS and better than both G1 and Shenandoah under all settings. Since we did not tune CMS for application latency, it reaches reasonable CPU consumption but far worse tail latency compared against other collectors. When the throughput reaches 25000, both G1 and Shenandoah show considerable CPU consumption compared with *Platinum*, which results in the severe tail latency problem (Figure 9b), while the CPU utilization in *Platinum* is still moderate.

Name	CMS	G1	Shenandoah	Platinum
Specjbb (qps=5000)	14.57%	16.53%	17.85%	15.11%
Specjbb (qps=15000)	31.77%	37.25%	43.03%	32.79%
Specjbb (qps=25000)	48.79%	77.66%	77.80%	50.56%
Cassandra (qps=80000, RI)	11.87%	14.35%	14.07%	12.99%
Cassandra (qps=80000, WI)	12.10%	15.97%	14.93%	13.79%
Coupon (qps=4000)	38.47%	36.17%	83.05%	34.50%

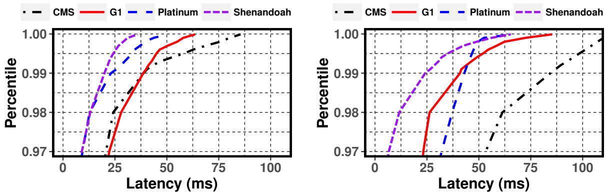
Table 2: The CPU utilization for four garbage collectors, with different applications

5.2 Cassandra

We evaluate Cassandra under the same settings as SpecJBB2015. Two different types of workload are leveraged for evaluation: (1) read-intensive workload (RI) with 76000 reads and 4000 updates per second; (2) write-intensive workload (WI) with 40000 reads and 40000 updates per second. We have also tuned G1 to achieve its best performance, and the value of *MaxGCPauseMillis* is 10ms. Figure 10 illustrates the tail latency for both scenarios with CDFs. As for the read-intensive workload, *Platinum* has comparable performance with Shenandoah, and improves the 99th percentile latency by 40.5% and 40.4% for CMS and our tuned G1 respectively. In *Platinum*, the latency for 97.2% of requests is less than 10ms, and the number is 9.5% and 3.2% larger than G1 and CMS. The improvement drops for write-intensive workload, and only 91.2% of requests finish in 10ms. This can be explained by more violated writes from mutators due to more update operations on the globally-visible data structures. Nevertheless, the p99 latency of *Platinum* is comparable with our best-tuned G1 and improved by 44.9% compared with CMS.

All collectors show moderate CPU consumption in Cassandra. It is because Cassandra is an I/O-intensive application and spends much more time on accessing its storage compared with other scenarios. Since our tuned G1 reduces the application latency by greatly shrinking the young space and increasing the accumulated GC time, it reaches the highest CPU utilization among all collectors.

Table 3 further shows GC-related statistics in 30 seconds among different collectors in the read-intensive workload. It also shows the results for three different settings in G1. The untuned CMS has the least overall time among all collectors (except for G1-100ms and G1-60ms), but its average pause time is relatively large. As for G1, when setting *MaxGCPauseMillis* from 100 to 10, the overall GC time is enlarged by 2.5X, which results in higher CPU consumption. Compared with other collectors, Platinum reaches both satisfying average GC pause time (close to Shenandoah) and overall GC time (close to G1-100ms).



(a) Read-Intensive (b) Write-Intensive

Figure 10: The CDF results for Cassandra under two different workload

GC settings	Average pause (ms)	Overall time (ms)	p99 latency (ms)
CMS	28.168	366.189	38.776
G1-10ms	16.144	1037.864	38.677
G1-60ms	38.998	775.032	62.794
G1-100ms	58.739	413.583	76.732
Shenandoah	3.97	522.499	27.700
Platinum	4.66	433.335	23.061

Table 3: GC and latency statistics for Cassandra RI

5.3 Coupon

We finally show the performance of *Platinum* on the coupon service. Since we do not have enough physical MPK-enabled machines to conduct the clustered evaluation in Section 2.2, this evaluation still exploits the single-point environment mentioned in Section 2.3 on a 96-core machine with 16GB Java heap. The throughput is set to 4000 requests per second to simulate stressful throughput in the production environment. Since we have studied the performance of G1 on the coupon service before, the value of *MaxGCPauseMillis* is set to 60ms.

Figure 11 shows the CDF generated according to the response time of requests. The results indicate that *Platinum* can mitigate the long tail problem, especially for p99 latency. Thanks to the cost-efficient garbage collection, the p99 latency in *Platinum* is improved by 66.8% and 23.5% for CMS and G1. Since the real-world workload also contains requests whose response time is greatly extended by lags in other remote services, *Platinum* cannot help to improve them much and result in slightly better p999 latency against other collectors. The application latency for Shenandoah is very large (for example, the 99th percentile latency is 3.6s), which is out of range in Figure 11. Compared with statistics in Table 1, the average pause time and GC count in *Platinum* is 7.247ms and 162 respectively.

As for CPU utilization, *Platinum* consumes 34.5% of overall CPU resources, which is the smallest among all collectors. The CPU consumption is 1.67% and 3.97% smaller than G1 and CMS. As for Shenandoah, the CPU is close to saturated (83.05%), which can explain why application latency is quite large. To conclude, the evaluation results on all three applications confirm that *Platinum* finds a sweet spot between low application latency and moderate CPU utilization.

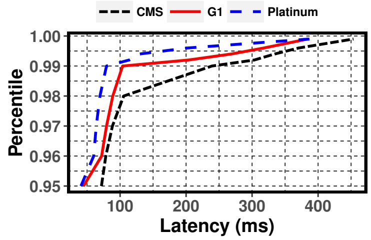


Figure 11: The CDF results for the coupon service

5.4 Breakdown analysis

Varying the pinned area size. Table 4 shows the runtime statistics of the Cassandra-WI workload with different sizes of the pinned area. When enlarging the pinned area, the average number of page faults for each GC cycle decreases, and the tail latency can be slightly improved. However, since the pinned area will only be reclaimed in the next GC cycle, enlarging its size will reduce the available memory in the eden space and increase the overall GC time. Therefore, users can tune the size of the pinned area to reduce the tail latency according to the application behavior.

Area size	Overall GC time (ms)	Avg. page faults	p99 latency (ms)
1/128	1007.327	13738	43.038
1/32	1106.951	12137	41.391
1/16	1145.982	11879	43.773
1/8	1206.859	10237	39.619

Table 4: GC-related statistics for Cassandra WI

GC Performance breakdown. This experiment breaks the accumulated GC time of Cassandra-WI into phases. As shown in Figure 12, mutators are allowed to run concurrently with GC threads most of the time (78.3%). Since the initial marking phase only scans the thread stacks, it lasts shortly and only takes up 1.1%. Meanwhile, the STW scavenge phase accounts for 15.6% to modify the stale references in the pinned area and the collection area.

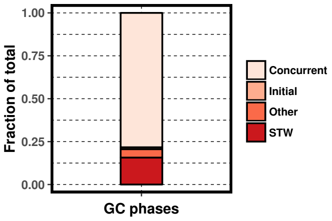

Figure 12: Phase-level breakdown for *Platinum*

The performance on Spark. We also evaluate the performance of *Platinum* on Spark, with its built-in *PageRank* application. Our evaluation shows that the execution time with *Platinum* is 7.93% longer compared with G1. Since the memory and GC behavior in Spark is much different from interactive services, it induces more page faults and larger stop-the-world pauses, which is the main reason for performance slowdown.

6 Related Work

Reducing pause time. STW pauses introduced by garbage collections have been studied for years. For STW garbage collectors, some work aims to reduce the pause time by sufficiently leveraging the computing resources. Gidra et al. [15, 16, 17] study the performance of PSGC in NUMA machines and provide NUMA-aware optimizations. Suo et al. [40] and Qian et al. [37] refine the work-stealing algorithm to offer a more scalable minor GC algorithm. Another line of work focuses on designing new concurrent collectors to co-run mutators with GC threads to reduce the pauses. In the OpenJDK HotSpot JVM, the latency-aware G1GC [11] has recently become the default collector, and two mostly-concurrent collectors, ZGC [33] and Shenandoah [13], are also attractive. Stopless [36] provides real-time GC support while preserving lock-freedom and fragmentation control. Österlund et al. [34] improve the pause time of G1GC with a non-blocking handshake between threads. The design of *Platinum* learns from those concurrent collectors to propose a CPU-efficient solution.

The intensive usage of language runtime in the big data area has stimulated studies on building big-data-friendly garbage collector with low pauses. Nguyen et al. [31, 32] put the data objects generated by the big data systems into segregated spaces where objects are managed with separated GC algorithms. Gog et al. [18] provide a similar region-based algorithm but mainly for the CLR runtime. Bruno et al. [6, 7, 8] divide the heap into many generations and pre-tenure objects that are believed to live long through runtime analysis. *Platinum* is built for reducing pauses for another kind of scenario: latency-sensitive, session-based interactive services.

Hardware-assisted GC. Hardware features also affect the design choices of garbage collectors. Prior work has studied on improving the performance of GC with primitives available in commodity hardware. Belay et al. [3] leverage virtualization technology to escalate Java runtime to the non-root ring 0 mode and accelerate GC with VM page management. Ugawa et al. [42] enhance the original Sapphire garbage collector with the RTM feature, and Ritson et al. [39] explore the usage of RTM in various collectors. Wu et al. [45] extend the area of garbage collector from normal DRAM to non-volatile memory (NVM) and studies crash consistency issues during GC. *Platinum* leverages RTM and MPK features to build a new concurrent garbage collector.

Except for commodity hardware, there is also a trend to build customized hardware, or GC accelerators, for various considerations. Azul Systems has built a customized system including CPU, chip, board, and OS to run garbage collected JVMs efficiently. Their GC algorithm is also largely modified to leverage those customized features [10, 23, 41]. Mass et al. [26] build a hardware GC accelerator to achieves higher GC throughput and lower power consumption.

Runtime optimization in distributed environments. Distributed applications are running atop multiple runtimes on different machines. Maas et al. [25, 27] show that GC in a single JVM can have a magnified effect on the whole applications and proposes policies to orchestrate GC among different JVMs. Lion et al. [24] find frequent JVM re-start in task-based workload and provides a JVM pool to skip the time-consuming warm-up phase. Nguyen et al. [30] optimize the communication between JVMs by providing an efficient serialization protocol, while Navasca et al. [29] allow Java threads to directly operate on the serialized byte streams with compiler techniques. Wang et al. [44] propose to dynamically change the memory limits of JVMs to fit the cloud environment. Both Fang et al. [12] and Călin et al. [22] leverage efficient spilling to reduce the memory footprint of large data-parallel applications. *Platinum* also quantifies the effect of GC in a distributed cloud environment and proposes a hardware-assisted algorithm to optimize the GC performance.

7 Conclusion

Latency and CPU efficiency are both essential for interactive services. Unfortunately, traditional garbage collectors cannot achieve both goals at the same time. This paper provides *Platinum*, a collector allowing concurrent but isolated execution of mutators and GC threads, with hardware assistance. The evaluation shows that *Platinum* significantly reduces the tail latency while preserving moderate CPU utilization compared with prior concurrent garbage collectors.

PinK: High-speed In-storage Key-value Store with Bounded Tails

Junsu Im, Jinwook Bae, Chanwoo Chung*, Arvind* and Sungjin Lee

DGIST

Massachusetts Institute of Technology

Abstract

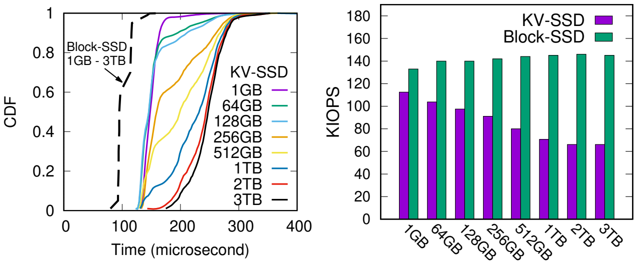
Key-value store based on a log-structured merge-tree (LSM-tree) is preferable to hash-based KV store because an LSM-tree can support a wider variety of operations and show better performance, especially for writes. However, LSM-tree is difficult to implement in the resource constrained environment of a key-value SSD (KV-SSD) and consequently, KV-SSDs typically use hash-based schemes. We present *PinK*, a design and implementation of an LSM-tree-based KV-SSD, which compared to a hash-based KV-SSD, reduces 99^{th} percentile tail latency by 73%, improves average read latency by 42% and shows 37% higher throughput. The key idea in improving the performance of an LSM-tree in a resource constrained environment is to avoid the use of Bloom filters and instead, use a small amount of DRAM to *keep/pin* the top levels of the LSM-tree.

1 Introduction

Offloading the key-value (KV) functionality onto a storage device has received a lot of attention recently from both academia and industry [11, 21, 24, 32, 49]. A representative device in this class is Samsung's key-value SSD (KV-SSD) [24], which directly serves KV requests. By offloading most commonly used operations of KV databases (e.g., RocksDB [17]), KV-SSDs not only improve I/O latency and throughput of KV clients, but also reduce the CPU and DRAM resource requirements on the host-side.

The idea of KV-SSD is promising but the current proposals and devices often provide inconsistent tail latency and throughput. This is because most of KV-SSDs are based on hash [16, 21, 24, 32, 46, 49], which is attractive because it is rather simple to implement but has some inherent limitations. A hash-based KV-SSD maintains a hash table in the controller DRAM, each entry of which typically contains a key (or the signature of a key) and a pointer to the corresponding KV pair in the flash. The hash table is used to quickly index key-value pairs by simple table lookups. However, when the DRAM size is not large enough to accommodate all the hash table entries, parts of the hash table must be stored in flash. This inevitably involves expensive flash accesses and complex hash table management when accessing entries that are not in memory. Even worse, if a hash collision occurs, multiple flash accesses are required, resulting in long and unpredictable tail latency and drop in throughput.

To understand the behavior of hash-based KV-SSDs, we conducted a set of experiments on a 4TB KV-SSD prototype (KV-PM983 [40]). We created KV pools ranging in size from 1GB to 3TB, and chose the average key and value sizes to be 32B and 1KB, respectively [5]. Thus, a 3TB KV pool would hold 3 billion KV pairs. We ran random `GET()` requests on these KV pools for 10 minutes using KVBench [38]. No GC occurred during our experiments.



(a) CDF of read latency (b) Read throughput

Figure 1: Performance comparison of KV-SSD & Block-SSD depending on the total amount of data stored (1GB∼3TB)

Figure 1 shows that the KV-SSD suffered from inconsistent read latency, and its throughput dropped as the number of objects stored increased. The average read latency increased from 149.49 μs (1GB pool) to 245.31 μs (3TB pool). We also observed long tail latency: for the 99.99^{th} percentile, the tail latency increased from 323 μs to 1020 μs. Even worse, the read throughput dropped to 64 KIOPS from 112 KIOPS. Although we did not have access to any of the internal details of the KV SSD design (*e.g.,* the hash function), it is easy to conclude that the performance and tail latency get worse in a hash-based implementation as the total number of stored KV pairs increases. This hypothesis was further supported by another experiment, where we used the same setup to run FIO [6] on a 4TB Block-SSD [41], which loads its FTL table in DRAM for 4KB page mapping. FIO exhibited stable latency and throughput, regardless of the amount of data stored. Such severe performance variability and unpredictable I/O behaviors make KV-SSDs less attractive than normal SSDs.

An alternative to hash is *log-structured merge tree* (LSM-tree) [34]. The tail latency in such a system is bounded by the number of levels in the tree. Since an LSM-tree indices KV pairs in a multi-level *sorted* tree, it might also require a much smaller DRAM for indexing KV pairs. LSM-tree also supports range-queries and scans efficiently, without any extra bookkeeping or support from KV clients [24]. Our experiments, however, revealed that a conventional implementation of LSM-tree on an SSD controller failed to deliver the promised benefits. In fact, it showed worse performance than hash in some cases.

The first problem we discovered was the tail latency. Most LSM-tree implementations use Bloom filters to skip lookups in a tree level to improve *average* read latency. Owing to the probabilistic nature of Bloom filters, however, one cannot ensure the *worst-case* read latency; indeed, we observed long tails as in hash-based KV-SSD. The second problem was high write-amplification. Even if we use key-value separation like Wisckey [30], compaction, an essential task of LSM-tree to sort KV indices and balance its indexing trees, involves many extra storage accesses. Moreover, this LSM-tree compaction cost exacerbates the FTL's garbage collection (GC) cost. The third problem was that rebuilding Bloom filters and sorting KV pairs for compaction requires lots of CPU cycles, which overburden embedded-class microprocessors found in SSD controllers. This lack of processor performance deteriorates the I/O performance dramatically.

In this paper, we propose an LSM-tree-based in-storage key-value engine, called *PinK*, which overcomes all the problems mentioned above. The novelty of PinK design stems from four specific techniques it uses. At the heart of PinK is *level pinning*. Instead of keeping probabilistic Bloom filters in DRAM, PinK pins exact key-value indices of the top levels of the tree to DRAM. This removes unnecessary flash lookups on the pinned levels in a deterministic manner, thereby enabling us to provide predictable read latency with bounded tails. Elimination of Bloom filters also reduces the resource requirement for computing them. Second, the level pinning helps us reduce flash I/Os caused by compaction. Since KV indices are kept in DRAM, PinK can sort them in DRAM without any I/Os. The pinned indices are protected by built-in capacitors, so flushing out up-to-date indices to flash is not necessary. (This idea is feasible only for small amount of DRAM). Third, we discovered that the majority of GC I/Os are induced by updating indices of LSM-tree. By delaying index updates until the compaction phase, PinK reduces GC I/Os greatly. Finally, by adding hardware comparators in between the SSD controller and NAND chips, and performing KV sorting while reading KV pairs, PinK completely eliminates CPU costs for compaction.

We have implemented PinK on MIT's FPGA-based SSD platform [22], and used the LSM-tree implementation of LightStore [11] as our starting point, because its source code is publicly available. Using YCSB [13] benchmarks, we have shown that PinK outperforms existing KV-SSD designs in several aspects. Compared to a hash-based KV-SSD, PinK reduces 99^{th} percentile tail latency by 73%, improves average read latency by 42% and shows 37% higher throughput. Furthermore, compared to LightStore, PinK reduces 99^{th} percentile tail latency by 22%, improves average read latency by 22% and shows 44% higher throughput.

Paper Organization: In Section 2, we explain background closely related to this study. Section 3 analyzes the performance of the LSM-tree algorithm in KV-SSD. Section 4 presents an overall design of PinK, along with optimization techniques. Section 5 presents experimental results. We conclude in Section 6.

2 Background

2.1 NAND Flash-based SSD

A conventional Block-SSD is designed to support the standard block I/O interface. It exposes a linear array of 4KB logical blocks which are accessed by block I/O primitives (*e.g.,* `READ` and `WRITE`). A flash translation layer (FTL) in the SSD firmware is responsible for providing the block I/O interface [3]. To hide the out-of-place update nature, the FTL writes incoming data to free flash pages in an append-only manner. To redirect 4 KB logical blocks to free pages, the FTL maintains a mapping table indexed by logical block address (LBA), and each entry points to the corresponding flash page. The mapping table is kept in the controller DRAM and its size is approximately 0.1% of the SSD capacity [39, 43]. For example, for a 4TB SSD, 4GB DRAM is required. A mapping table has to be persistent (non-volatile) and is protected by built-in capacitors to guard against sudden power failures [7]. Similar to other log-structured systems [36], the FTL has to perform garbage collection (GC) to reclaim free space.

2.2 KV-SSD

A KV-SSD is a new type of SSDs [24, 45] which provides the key-value interface. KV-SSDs look like a container of key-value objects, where each object is labeled by a unique key and contains an associated value (*i.e.,* data). In contrast to a block addressed SSD, both the key and the associated value are of variable sizes. A key can be as long as 255 bytes [45] or even be a character string, and a value can be as big as 2MB [45]. In addition to `GET()` and `SET()`, the basic operations to access KV objects, KV-SSDs support a rich set of operations like iterations, range queries, and transactions [24, 25]. A more detailed description can be found in SNIA's KV-SSD specification [45].

Making SSDs support the KV interface requires a redesign of the FTL because the existing table-based translation is not suitable for managing KV objects. A variety of KV-SSD designs have been proposed both in academia (*e.g.,* NVMKV [32], KAML [21], and BlueCache [49]) and industry (*e.g.,* Samsung's KV-SSD prototype [24, 40]). All these KV-SSDs are based on hash-based data structure, which we discuss next.

2.3 Hash-based KV-SSD

A hash-based KV-SSD maintains a hash table with many buckets in DRAM, where each bucket holds metadata (*i.e.,* a key and a pointer) for a specific KV object in flash [16, 21, 32, 49]. A primary design issue of hash-based KV-SSD is the management of a huge hash table requiring large amounts of DRAM. Suppose that the SSD capacity is 4 TB and the key and value sizes are on average 32B and 1KB, respectively [5]. If the number of buckets is 2^{32} ($= 2^{42}/2^{10}$) and the bucket size is 36B (32B for a key and 4B for a pointer), 144GB of DRAM is required to hold the complete hash table. If KV-SSDs have large enough DRAM to hold the entire hash table, in addition to the $O(1)$ time complexity for calculating an index, a KV access only takes $O(1)$ flash access to read/write the KV pair [44]. However, as mentioned previously, SSDs do not have as much DRAM.

To reduce DRAM usage, some use signatures [9, 16, 26, 46, 49]. Instead of an exact key, a short signature of the key is kept in the bucket. The exact key and its value are stored in the flash. Using signatures reduces the hash table size greatly – if a 16-bit signature is used, 24GB of DRAM is required. But it causes *signature collision* which happens when different keys have the same signature. 24GB DRAM is still huge for an SSD. The DRAM size can be further reduced by keeping only popular buckets in a fixed-size DRAM (*e.g.,* 4GB) while storing the rest in the flash [18]. This, however, causes extra flash reads. If a designated bucket is not available in DRAM (*i.e., hash table miss*), we have to fetch the bucket from the flash to find the location of a desired KV object. Consequently, the table miss increases flash read costs from $O(1)$ to $O(1+\alpha)$ where α is a miss ratio. Even worse, signature collisions add an unpredictable number of flash reads until the collision resolves, resulting in unbounded read tail latency in the worst case. As shown in Figure 1, this instability of the hash-based KV-SSD deteriorates as the hash table grows.

This inconsistent performance may be due to inefficient collision resolution policies. There are advanced hash strategies, such as Cuckoo [35] and Hopscotch [19, 26], which provide constant worst-case lookups and may avoid the tail latency. But this benefit comes at the cost of degraded write speed and/or frequent rehashing. Hash algorithms also cannot efficiently support range and scan operations [24].

2.4 LSM-Tree-based KV-SSD

An LSM-tree is another data structure that is used widely to implement persistent key-value stores. It is usually implemented purely in host software and can support a wider set of KV operations (*e.g.,* RocksDB [17] and Cassandra [27]). It is also used in big all-flash array (AFA) systems such as Purity [12]. Because of its increasing popularity across a variety of systems, many LSM-tree variants have been proposed [4, 23, 47]. Recently LSM-tree has also been used in some implementations of KV-SSDs like LightStore [11] and iLSM-SSD [28].

LSM-tree is a hierarchical structure that consists of multiple trees, each called a *level*. Each level is sorted and behaves as a write buffer for the next level, which has a larger size. Since LSM-tree keeps only the highest level in DRAM, its memory requirement is much smaller than hash. Also, a KV access in LSM-tree requires at most $O(h-1)$ flash accesses owing to its sorted nature, where h is the number of levels, and thus the worst-case latency of LSM-tree is bounded. Many LSM-tree implementations use Bloom filters to improve the average read cost to $O(1)$ flash access [14].

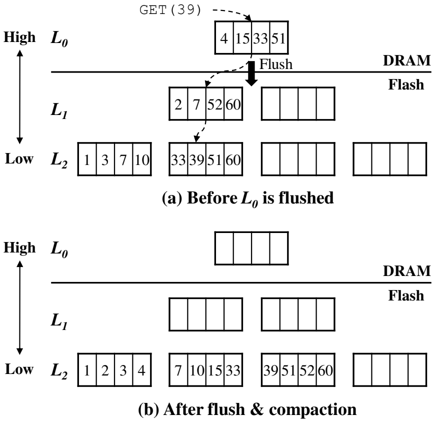
However, LSM-tree-based KV-SSDs have suffered from a lack of CPU power for the compaction process, which is required to keep LSM-tree balanced. In addition, Bloom filters, which is used to skip some levels probabilistically, cannot improve the read tail latency. The design of PinK was motivated by these and some additional inefficiencies in running the conventional LSM-tree on resource-constrained KV-SSDs; we discuss these inefficiencies in Section 3.

2.5 Hash vs LSM-Tree

NAND flash scales faster than DRAM. According to [20], the capacity of NAND flash has increased 1.43 times per year, while that of DRAM has increased 1.13 times. This requires us to take into account a DRAM scalability issue in choosing algorithms for KV-SSDs. Assuming the same trend, the hash suffers from more degradation in read performance since the table miss rate becomes higher as NAND flash scales further. The LSM-tree also experiences degradation since it uses fewer bits per KV pair for Bloom filters. However, the read performance of the LSM-tree is more scalable due to the space-efficient structure of Bloom filters. Monkey has almost the same read performance when the ratio between the size of DRAM and total data set decreases from 0.16% to 0.02% (see Figure 11(a) in [14]). Conversely, the hash suffers from notable performance degradation when the DRAM size does not grow relative to the data set as shown in Figure 1. The LSM-tree also exhibits lower update costs than the hash when the entire indices do not fit in DRAM. In the hash, indices in the map have to be updated in place, which in turn involves expensive read-modify-writes in the flash. On the other hand, the LSM-tree shows cheaper update costs since it appends new or updated entries to the flash thanks to its leveled structure. As a result, the LSM-tree offers better write performance when DRAM becomes less sufficient.

3 Challenges in implementing LSM-tree in a KV-SSD

In this section, we analyze the performance and present key technical challenges when an LSM-tree is implemented in a resource constrained environment of an SSD controller. We have used LightStore [11] as the baseline for an LSM-tree-based KV-SSD which separates keys and values to speed up writes and uses Bloom filters to speed up reads. We expect iLSM-SSD [28] to exhibit similar read and write performance as LightStore because it follows same concepts.



(a) Before L_0 is flushed

(b) After flush & compaction

Figure 2: LSM-tree organization ($h = 3$, $T = 2$). A rectangle represents a KV object and the number inside is the key.

3.1 LSM-Tree Structure

The LSM-tree maintains multiple levels of sorted KV indices, L_0, L_1, ..., and L_{h-1}, where h is the height of an LSM-tree (see Figure 2). The level 0, L_0, is kept in DRAM as a write buffer, whereas the rest are stored in persistent media (*e.g.,* flash). In the LSM-tree, the levels are organized so that a lower level is T times larger (*i.e.,* the size factor T) than a higher one. Each level is divided into fixed-size runs, where the size of each run is usually the same as that of L_0.

The LSM-tree has two unique properties: **#1.** for each level, KV objects are unique and kept sorted by their keys; and **#2.** the key range of one level may overlap the key range of other levels due to overwrites (see Figure 2).

When a SET() request comes, a KV object is first buffered in L_0. Once L_0 becomes full, buffered KV objects are flushed out to L_1. All the objects in L_0 are written to L_1 in an append-only manner. Similarly, once L_i becomes full, its KV objects are evicted to L_{i+1}. Since the key ranges of adjacent levels may overlap, flushing out KV objects from a higher level to a lower level has to be done in a manner not to violate Property #1. Therefore, the LSM-tree algorithm performs a process called *compaction* while flushing KV objects to a lower level. Compaction reads objects from two adjacent levels, sorts them in the memory, and writes the sorted objects to next lower level as shown in Figure 2(b). Compaction incurs a huge I/O overhead. This overhead can be mitigated by separating keys from values and by avoiding moving values which are not affected by compaction (see Wisckey [30]).

The LSM-tree maintains an in-memory data structure that points to runs of levels in the flash. Each run contains a header that holds the locations of KV objects (KV indices) in the flash. Searching for a key at a specific level is fast. Once a header is read from the flash, the location of a desired KV object can be quickly found since they are sorted by key. However, finding the desired key in the entire tree requires looking in multiple levels because key ranges at different levels may overlap (Property #2). In the worst case, all levels have to be searched as shown by GET(39) in Figure 2(a). The number of the worst-case flash lookups is $O(h-1)$ (Note: L_0 is excluded since it stays in DRAM). Bloom filters are often used to avoid useless lookups on levels that do not have desired keys [14, 15]. Usually, each level or run in the tree has its own filter.

3.2 Performance Analysis

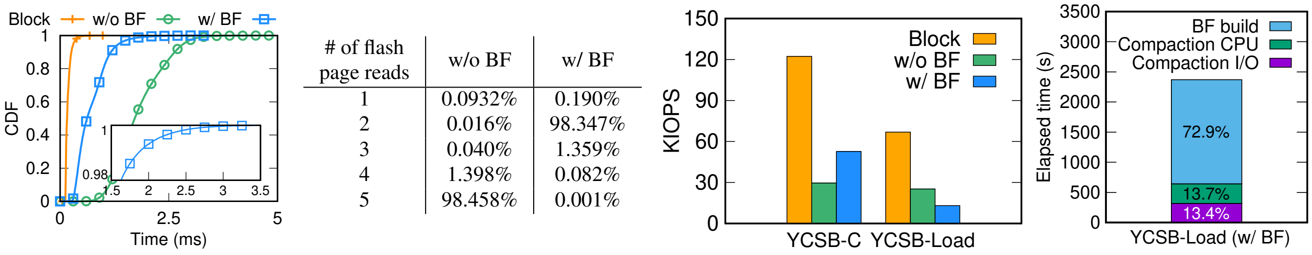
Our PinK implementation uses the same FPGA-based hardware platform as LightStore [11], which has quad-core ARM Cortex A53 running at 1.2GHz and 4GB DRAM. This controller specification is similar to those of latest SSDs with in-storage computation capability [33, 37]. PinK is equipped with a 256GB NAND flash card which provides 1.1 GB/s read and 600 MB/s write throughputs, respectively, and offers 122,349 IOPS for 4KB reads and 66,843 IOPS for 4KB writes, respectively.

To understand the weaknesses of the conventional LSM-tree implementations, we first improved the Bloom filter implementation in LightStore [11] by replacing the original one with Monkey [14]. We leveraged AArch64 SIMD instructions in implementing Monkey. Key-value separation [30] was employed by default.

For fast evaluation, we reduce the SSD capacity to 64GB. The number of levels in the tree is set to 5 ($h = 5$) with a size factor of 23. We assume that 64 MB of DRAM (0.1% of 64GB) is available and it is used to keep Bloom filters for levels. We either enable or disable Bloom filters (Monkey) to understand its impact on performance. To characterize basic performance, we run two extreme workloads, YCSB-Load (100% writes) and YCSB-C (100% reads). Average key and value sizes are 32B and 1KB. We first run YCSB-Load with 44 million (44GB) uniformly random KV-pairs, and then run YCSB-C with 10 million Zipfian requests. Results with other workloads can be found in §5.

To understand the impact of the LSM-tree algorithm, we compare the performance of the LSM-tree KV-SSD with that of a Block-SSD implemented on the same platform. The Block-SSD employs a page-level FTL whose flat mapping table, indexed by LBA, can be loaded entirely on DRAM. A physical page mapped to a logical block can be found with only one memory reference.

Figure 3(a) shows the CDF of the read latency of YCSB-C. Without Bloom filters, the LSM-tree KV-SSD shows long read latency over the Block-SSD. Figure 3(b) summarizes the number of flash page reads to service a GET() request. If GET() is directly served by L_0 (*i.e.,* a write buffer), a page read is not necessary. Otherwise, the LSM-tree looks up lower levels to fetch KV indices from the flash. The majority (98.4%) of GET() requests touch up to the last level (L_4), issuing four page reads. This is because almost all the KV pairs (95%) are stored on L_4. When Bloom filters are enabled, it offers better read latency, but is affected from long tails. With Bloom filter,



# of flash page reads	w/o BF	w/ BF
1	0.0932%	0.190%
2	0.016%	98.347%
3	0.040%	1.359%
4	1.398%	0.082%
5	98.458%	0.001%

(a) Read latency (YCSB-C) (b) Flash page read counts (YCSB-C) (c) I/O throughput (d) Compaction time breakdown

Figure 3: Experimental results of the conventional implementation of LSM-tree on an SSD controller

on average, one flash lookup is required for retrieving a KV object as in Figure 3(b). Owing to its probabilistic nature, however, 1.4% of the total `GET()`s still require more than one flash lookup, which are large enough to cause long tails (see the zoom-in figure in Figure 3(a)).

Figure 3(c) illustrates the I/O throughput. The read throughput of the LSM-tree with Bloom filter in YCSB-C is about half of the throughput that the Block-SSD provides. This is expected because Monkey requires two flash reads, on average, for retrieving KV indices to serve `GET()`.

As we can see in Figure 3(c), in YCSB-Load, we observe serious drops in the write throughput, compared to the Block-SSD. Even with Wisckey, compaction I/Os account for 75.5% of the total I/Os (both reads and writes). While not included in Figure 3(c), I/Os for GC also badly affect the write throughput. According to our analysis (see §5.2), the write amplification factor (WAF), which is 2.52 when only compaction I/Os occur, increases to 5.02 once GC starts to trigger. We find that moving valid pages for GC involves cascade updates of KV indices maintained by the LSM-tree.

The high CPU overheads of the LSM-tree also slow down the write throughput. Due to slow speed of ARM CPUs, sorting KV pairs for compaction, which involves string comparisons, becomes a bottleneck. As shown in Figure 3(d), it takes almost the same time as performing compaction I/Os. The CPU time does not include the Bloom filter reconstruction time which will be discussed soon. The compaction overhead has been addressed by KVell [29], but it requires a huge DRAM to hold all indices, which is not available in KV-SSDs.

The cost of rebuilding Bloom filters is also high. Bloom filters should be rebuilt for newly created levels after compaction, which requires expensive hash computations and lots of memory accesses. In our experiment, a hash computation is accelerated by SIMD instructions, but its negative impact is still huge. The rebuilding overhead for Bloom filters can be optimized as was done in [8]. Even if we assume the reconstruction time improves significantly, say 8X-11X, as in [8], the Bloom filter reconstruction still takes 20-25% of total compaction time. Note that it is unclear whether such huge improvement is achievable in ARM-based SSD controllers. Be advised that, our LSM-tree is carefully designed so that I/Os and computation are maximally overlapped. However, this cannot completely hide high computation costs.

The problems we have observed can be summarized as follows: **#1.** LSM-tree exhibits higher average-latency because of multi-level search, and also exhibit unpredictable tail latency because of Bloom filters; **#2.** Bloom filters require lots of computational power to reconstruct. They have to be reconstructed after each compaction; **#3.** Level compaction (excluding Bloom filter reconstruction) also requires a lot of computation and I/O bandwidth; **#4.** Compaction I/Os may trigger GC which in turn generates more I/Os, resulting in high write amplification.

4 Design of PinK

Bloom filters are used to reduce the average read latency. Another way of reducing the read latency would be to keep popular KV indices in DRAM. LSM-tree by nature keeps the recently written indices in the top levels. In PinK, we eliminate the Bloom filters and mitigate the increased read latency by pinning top-K levels (§4.2 and §4.3). We will show that level-pinning requires only a small amount of DRAM. Tail latency is already bounded to the height of the tree. Another benefit of level-pinning is that it eliminates the flash I/Os required for compaction of two levels which are already pinned in DRAM. The throughput can be further improved by using hardware accelerators that performs compaction for pinned and flash-resident levels (§4.4). Finally, to alleviate the GC costs associated with compaction, we delay GC by putting updated KV indices in L_0 (§4.5). This reduces the write amplification which affects lifetime of SSDs.

4.1 Overall Architecture

PinK supports variable-sized keys (16B∼128B) and values (1KB∼2MB), along with a rich set of KV operations (*i.e.,* `GET()`, `SET()`, `DELETE()`, `SCAN()`, and `ITERATOR()`), except for a few features like namespaces. Like KV-SSDs, PinK is able to guarantee durability and atomicity of KV operations [7, 24, 42]. While the lack of space does not permit us to describe the details of all the operations, we focus on explaining key data structures and operations which are different from the conventional LSM-tree-based KVSs.

Data Structures. Figure 4 illustrates four types of data structures of PinK: a *skiplist* and *level lists*, which all reside in

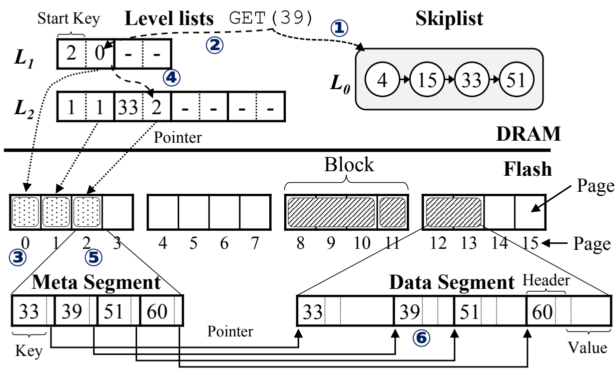


Figure 4: An overall architecture of PinK with its key data structures in DRAM and flash. The tree hierarchy and KV objects are identical to those of Figure 2(a). Given `GET(39)`, ① PinK first looks up the skiplist (L_0). Since a matched one is not found, ② it goes down to L_1, ③ reading a meta segment from the page 0. It does not have a desired key, so ④ PinK visits L_2 and reads ⑤ the page 2 to get a meta segment. Finally, ⑥ it can find the location of the value for the key '39'. Three flash reads are required to serve `GET(39)`.

DRAM, and *meta segments* and *data segments*, which all reside in flash. Overall, the design of PinK is not much different from the LSM-tree-based KVS combined with Wisckey [30], but it is optimized to maintain compact data structures in the controller DRAM for better performance in storage devices. Also, the headers of each data structure are designed to be handled easily by HW accelerators. PinK directly deals with NAND chips to perform indexing, GC, and wear-leveling obviating any need for a costly FTL found in most SSDs.

A *skiplist* corresponds to L_0 in the LSM-tree algorithm and works like a write buffer which buffers incoming KV objects temporarily. The size of L_0 is configured to be large enough (*e.g.,* 8MB$\sim$64MB) to fully utilize the parallelism of multiple NAND channels when KV objects are flushed out to the flash. Each skiplist entry has four fields: <key size, key, value size, value>, and all the entries are sorted by key.

Once the skiplist becomes full, buffered objects are materialized to L_1 as the forms of *meta segments* and *data segments*. In L_1 (and all the lower levels), keys and values are separated into meta and data segments, respectively. A meta segment contains keys and pointers to its associated values in data segments. In addition to values, a data segment stores keys and their sizes to support GC (see §4.5). The size of a meta segment is fixed to a flash page size (*e.g.,* 8KB $\sim$ 16KB), but a data segment can be of any size – it is like a huge log containing KV objects pointed to by meta segments.

Since meta segments are referenced by the software to look for a KV object and by the hardware accelerators for compaction, they are organized to be manipulated by both of them. A meta segment is composed of an array of <key, pointer> pairs sorted by key, plus a header. A pointer is a 4B integer, but a key size varies from 16B to 128B. To quickly find a variable-size key using binary search, a meta segment header maintains the start locations (2B each) of <key, pointer> pairs. If a meta segment is 16KB, it contains up to 1024 <key, pointer> pairs where at most 2KB is used as a header. For HW accelerators, a header and <key, pointer> pairs are aligned to 16B for simple implementation. We discuss this in §4.4 in detail.

PinK maintains another in-memory data structure, *level lists*, which keep track of meta segments at every level in the flash. If the tree has five levels (*i.e., $h = 5$*), there are four level lists except for L_0. Each level list is organized as an array of pairs of fixed-sized pointers (4B each, 8B total); the first one points to the physical location of a meta segment in the flash; the second one points to a start key of that meta segment. Note that start keys of meta segments are stored separately in DRAM to support variable-sized keys (16-128B). This facilitates us to implement binary search to find a desired meta segment in a level list.

Two in-memory data structures, L_0 and the level lists, are protected by capacitors. This provides enough time for PinK to safely flush out them to the flash in the event of power failures or when a system is turned off. PinK also does not need to use a write-ahead log (WAL) to provide atomicity and durability of data.

Data Structure Size. Compared to the hash, PinK requires much smaller DRAM for indexing KV objects. Assume that an SSD capacity is 4TB and each meta segment is 16KB. As in §3, the average sizes of keys and values are 32B and 1KB, respectively [5]. Each entry in a meta segment is 36B (32B key and 4B pointers). A 16KB meta segment can hold 398 <key, pointer> pairs. In a 4TB SSD, there exist 2^{32} 1KB objects, and thus the number of meta segments in the flash is about 10.8M (= $2^{32}/398$). Each of these must be pointed to by some level lists. Each level list entry is 8 B, and each entry has a corresponding start key whose average size is 32B. Thus, only 432MB (= 10.8M×(8B + 32B)) DRAM is needed to hold all the level lists.

4.2 Improving I/O Speed with Level Pinning

Eliminating Read Tails. Retrieving a KV object from PinK requires multiple flash lookups. In the worst case, $O(h-1)$ flash lookups are required to access a KV object. Bloom filters are typically used to avoid useless lookups on levels that do not have desired keys [14, 15]. As pointed out earlier, however, it cannot avoid long tails and causes high CPU costs.

In order to guarantee worst-case latency and to get rid of Bloom filters, PinK adopts *level pinning*. The idea of the level pinning is straightforward. If the LSM-tree has h levels, PinK keeps meta segments for top-k levels ($k \leq h-1$) in DRAM. This simple technique greatly reduces read tails. To process `GET()`, it first searches for a key in top-k levels in DRAM. Only when a key is not found in memory, it looks up the rest of levels resident in the flash. With the level pinning, the number

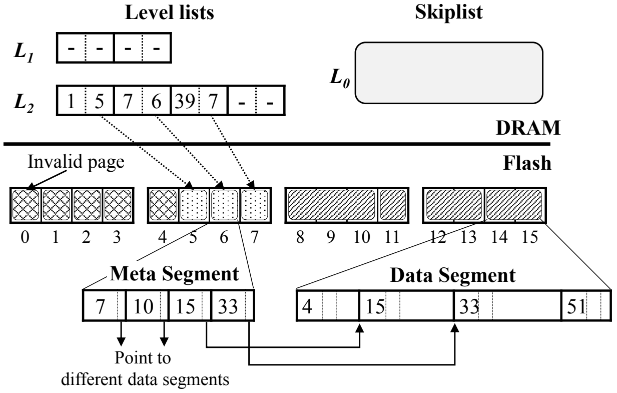

Figure 5: The DRAM and flash layouts of PinK after L_0 (in Figure 4) is flushed out with compaction. The tree hierarchy and KV objects are identical to those of Figure 2(b).

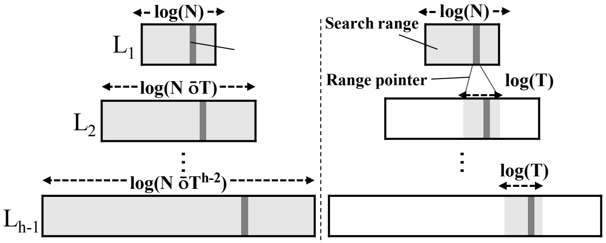
of the worst-case flash lookups is reduced to $O(h-k-1)$.

Level-pinning Memory Requirement. One might think that the level pinning would require large amounts of DRAM, but this is not the case. In the LSM-tree, a upper level (L_i) is T times smaller than a lower level (L_{i+1}), which implies that the level size increases *exponentially* by a factor of T. In the 4TB SSD organized with 5 levels, the amount of DRAM required to pin meta segments for L_1, L_2, L_3, and L_4 are 0.91MB, 50.86MB, 2.83GB, and 161.63GB, respectively. Meta segments for L_1, L_2, and even L_3 can be loaded in DRAM, considering a large controller DRAM of an SSD (*e.g.,* 4GB DRAM for 4TB SSD). The data structures of PinK do not require large amounts of DRAM (*e.g.,* 432MB), which enables us to pin more levels.

Reducing Compaction I/Os. Another benefit of the level pinning is that it eliminates flash I/Os involved in compaction. The level pinning maintains the meta segments of specific levels in DRAM. Thus, PinK does not need to issue any I/Os since pinned meta segments can be updated in DRAM directly. Dirty segments do not need to be written back to the flash because they are protected by capacitors.

To understand its benefit, let us consider how PinK performs compaction using the examples in Figures 4, and 5. Figure 5 is the data layout after the compaction. We assume that L_1 is pinned to DRAM. Before flushing out L_0, PinK fetches the corresponding meta segments from L_1 (*i.e.,* the page 0 in Figures 4 and 5) and sorts KV indices of L_0 and L_1, which creates two sorted meta segments. The sorted meta segments are then flushed out to L_1 (*i.e.,* the pages 3 and 4 in Figure 5). The level lists are updated accordingly. PinK recognizes that L_1 becomes full, and thus flushes out L_1 to L_2. To do this, PinK reads two meta segments from each of L_1 and L_2 (the pages 1∼4 in Figure 5), sorts them, and finally writes three sorted segments to L_2 (*i.e.,* the pages 5∼7). Since L_1 is pinned, PinK eliminates 3 reads and 2 writes out of 5 reads and 5 writes which occurs while conducting the compaction.



(a) level list search (b) Optimized level list search

Figure 6: Search path optimization with range pointers

4.3 Optimizing Search Path

When the LSM-tree retrieves a KV pair, it has to perform binary search on level lists until it finds a matching meta segment for a given key. This does not cause a serious overhead for higher levels (*e.g.,* L_1 and L_2) whose level lists have few entries. On the other hand, since level lists belonging to lower levels (*e.g.,* L_{h-1}) have many entries, the search overhead becomes huge. Figure 6 (a) shows how the LSM-tree performs binary search on the level lists. Suppose L_1 has N entries. Because a level size increases by a factor of T, L_2 has $N \cdot T$ entries, L_3 has $N \cdot T^2$ entries, and finally L_{h-1} has $N \cdot T^{h-2}$ entries. The worst-case time complexity of computation is thus expressed as $O(h^2 \cdot \log(T))$. The conventional LSM-tree with Bloom filters offers much lower computation time on average because it is able to skip binary search operations on unnecessary levels by performing membership tests first. PinK does not use Bloom filters and thus, cannot exploit this

To reduce the search overhead, PinK uses two techniques. The first one is to reduce string comparison costs by using a prefix of a key. Recall that each entry of a level list has two pointers, each of which points to a meta segment and a start key string, respectively. We further include a prefix which holds exactly the first four bytes of a start key. During binary search, PinK compares the first four bytes of an input key with a prefix. Only when they match, it performs a full string comparison using the pointer to the key.

The second one is to reduce search ranges of the level lists by borrowing fractional cascading technique [10]. Each entry of a level list now has another 4-byte pointer, called a range pointer. It locates the next lower level's entry which has the greatest start key but whose key is less than or equal to that of the upper level entry. Given a key to search, PinK does binary search for L_1 and finds an entry, say $e^i_{L_1}$, in L_1's level list. If a meta segment pointed to by $e^i_{L_1}$ does not have a matched KV index, PinK has to go down to the next level, L_2. The range pointer of $e^i_{L_1}$ becomes the lower search bound for L_2. Then, the range pointer of the next entry $e^{i+1}_{L_1}$ in the same level (*i.e.,* L_1) is the upper search bound. As shown in Figure 6 (b), using two pointers, the number of entries we have to do binary search in L_2 is reduced to T, on average, since a level size increases by a factor of T. This can be applied for lower levels, L_3, ... , L_{h-1}. Thus, the average time complexity reduces to $O(h \cdot \log(T))$.

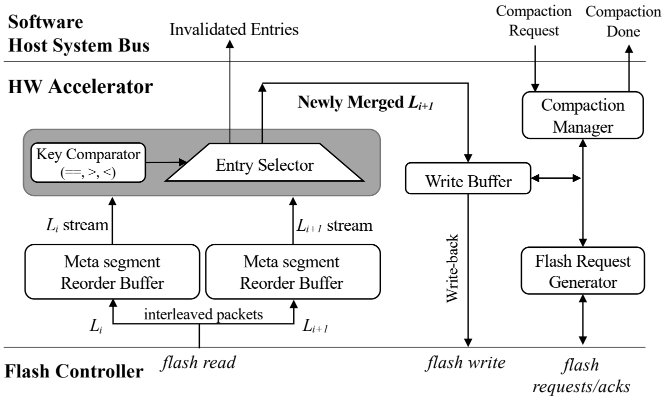


Figure 7: Compaction accelerator for flash-resident levels

With prefixes and range pointers, each entry size in the level lists increases to 16 bytes from 8 bytes. Fortunately, the lowest level L_{h-1}, which has the largest entries, does not maintain range pointers. As a result, additional DRAM is about 43.9MB in the same setting as in §4.1.

4.4 Speeding up Compaction

While the level pinning effectively reduces the number of I/Os for compaction, it does not remove the computation cost for sorting KV pairs. We address this problem by offloading some compaction tasks to a special HW accelerator in the SSD controller. The idea behind this is that compaction is just like merging two sorted lists of KV indices into a single sorted list. The HW accelerator placed between the flash and the host data bus can easily merge two flash-resident levels as meta segments of two levels are streamed from flash at wire speed. The accelerator writes the merged meta segments back to the flash without CPU involvement. By using the HW accelerator, we not only alleviate the computation overhead but improve I/O bus utilization since no to-be-merged and merged segments transferred over system bus. Remaining I/O bandwidth can be utilized by DRAM and flash for other tasks such as searching upper levels or managing pinned levels.

Figure 7 describes the architecture of the HW accelerator. We briefly present how the compaction accelerator for flash-resident levels works. The PinK software requests the accelerator to perform compaction by providing lists of the meta segments' flash addresses of two levels (L_i and L_{i+1}) to be merged and a list of flash addresses to which the merged meta segments (L_{i+1}) are written back. The flash request generator schedules multiple read requests to maximize the flash bandwidth utilization. Since the packets of different flash channels are interleaved, we need to use per-channel reorder buffers for each level to serialize the stream of meta segments.

Once we have sorted meta segment streams from two levels, the compaction engine (gray box in Fig. 7) only needs to keep comparing the keys of two levels and emitting the smaller one. The accelerator generates the output stream at wire speed without any computation overhead. When two keys match, the entry from the upper level (L_i) supersedes as it is more recent one. Note that the accelerator informs the software the metadata of invalidated entries from L_{i+1} for various purposes such as garbage collection. The generated merged meta segment stream (L_{i+1}) is written back to the flash via small write buffers. Once the operation completes, the accelerator responds with the number of flash pages consumed by the newly generated L_{i+1} meta segments so that the software can reclaim unused flash addresses previously provided to the accelerator.

While not shown in detail, we have a similar accelerator for merging pinned levels that reads from and writes back to host DRAM. DMA engines are used instead of a flash request generator and we do not need reorder buffers.

4.5 Optimizing Garbage Collection

The LSM-tree appends all the data to the flash. As compaction is repeated, obsolete data, which are no longer referenced to by the tree, are accumulated in the flash and must be erased by GC later. There are roughly two types of obsolete data that are created by compaction. The first type is old meta segments. While performing compaction, PinK writes new meta segments that replace old ones. For example, the meta segments stored in the pages 0, 1, and 2 in Figure 5 are not managed by the tree anymore since they contain old indices. The second type is an outdated KV object which was updated with a new one or removed by a client. Outdated KV indices are discarded from the LSM-tree during compaction (see §4.4) so that no meta segments point to them. But, their KV data are still stored somewhere in a data segment(s).

To erase obsolete data and to keep maintaining free space, PinK triggers GC when free space is nearly exhausted. It selects a victim flash block, copies valid data (*i.e.,* pages or KV pairs) to a free block, and erases the victim. For hot-cold separation, meta segments are isolated in different blocks from data segments. PinK should perform GC differently depending on the type of blocks selected as a victim.

GC for Meta Segment: If a victim block to GC is a meta-segment block and thus has only meta segments, PinK retrieves a start key of a meta segment by reading its page. Then, it looks up the level lists to see if there is any entry pointing to it. If not, PinK skips it since that segment is obsolete (*e.g.,* the page 4 in Figure 5). Otherwise (*e.g.,* the page 5), it moves the page (*i.e.,* meta segment) to a free page, and then updates the entry so that it locates a new flash page. Cleaning meta segments is cheap because it involves valid page copies and updates of the level lists in DRAM.

GC for Data Segment: Cleaning a data-segment block requires more efforts. Each data segment keeps metadata (*i.e.,* keys and sizes) as noted in §4.1. By scanning a data segment from the victim block, PinK extracts keys for values to move for GC. Using these numbers, PinK looks up the level lists and finds associated meta segments to check the validity (valid or not) of each value. If a meta segment is not pinned in DRAM, it must be read from the flash. In this way, PinK collects a list of valid values in the victim.

The simplest approach to reclaim free space, which is used by Wisckey, is to copy valid values to free pages and to erase the victim block. The meta segments associated with the values should be updated and flushed out to the flash so that they point to the new locations of the values. For meta segments pinned in DRAM, no flash writes are necessary. This approach, however, creates many updates on meta segments in the flash. We observe that many victim values are associated with flash-resident meta segments because they were written long time ago and their meta segments were likely to be demoted to lower levels. Moreover, only few values belong to the same meta segment (*e.g.,* 1$\sim$2 values, on average, in random write workloads). Thus, to move only 1$\sim$2 values, one meta-segment update is required.

To avoid this, PinK takes an approach that delays updates of meta segments in the flash. PinK writes valid KV pairs to L_0 again and then just erases the victim block. Corresponding meta segments now point to wrong flash pages erased by GC, but this is not a problem at all. Read requests to the rewritten KV pairs are served by higher levels, and old entries in the meta segments will eventually be discarded during compaction later. This approach slightly increases compaction costs, but greatly reduces GC costs by reducing meta segment updates. This is because victim KV pairs rewritten to L_0 are coalesced with neighboring KV pairs and then are written to the same meta segment together.

Note that since KV pairs sitting in lower levels are moved to L_0 during GC, it possibly hurts read latency. However, it does not affect the worst-case read latency, which is one of our design goals, because it is bounded by the number of pinned levels.

4.6 Durability and Scalability Issues

Durability with Limited Capacitor: We have assumed that a built-in capacitor in the device can protect the entire DRAM. However, unlike high-end enterprise SSDs, some SSDs do have not enough capacitors to protect all the metadata in DRAM. Running PinK on such devices results in a metadata durability issue. PinK can address this issue by regularly writing data structures that reside in DRAM (*e.g.,* level lists, pinned levels, and L_0) into flash. L_0 can be durable by logging incoming write requests into a log area in the flash before processing the requests. Hash-based KV-SSD also needs to do the same task if its write buffer is not backed by capacitors. Level lists and pinned levels become dirty after compaction is conducted. PinK should flush out newly created level lists as well as pinned levels to the flash to make them persistent. Hash-based KV-SSD has to write dirty KV indices to in-flash buckets as well whenever they are updated. The metadata flush operation of PinK would be cheaper than that of hash-based KV-SSD, thanks to the write-optimized structure of LSM-tree.

DRAM Scalability: We have also assumed that the size of DRAM scales as the size of flash in SSDs (*i.e.,* DRAM capacity is kept 0.1% of the total capacity of flash). As mentioned in Section 2.5, the size of DRAM scales slower than that of flash. Thus, SSDs might ship with insufficient DRAM to pin all the top levels. This problem can be resolved by pinning fewer levels. It increases the worst-case index lookup cost, but PinK offers better worst-case performance than the hash and the conventional LSM-tree. The details are discussed in the last experiment of Section 5.2 Another option we can consider is reducing the height of the tree so that all the levels, except for the last one, can fit into DRAM. This sacrifices write performance owing to increased compaction cost, but bounds $O(1)$ lookup cost in the worst case.

5 Experiments

We present experimental results on PinK. Particularly, we seek to answer the following questions: (*i*) Does the level pinning improves both read latency and write throughput along with shorter tails? (*ii*) Is the HW sorter effective to reduce the compaction cost? (*iii*) What is the impact of GC on performance?

5.1 Experimental Setup

We have implemented PinK on our FPGA-based SSD platform with quad-core ARM Cortex-A53 (Xilinx ZCU102 [48]). The FPGA is used to implement HW accelerators and flash chip controller. The SSD platform has a 256GB custom flash array card. The size of a page is 8 KB, and the number of pages per block is 256. (See §3.2 for more detailed performance numbers.) It is connected to a host through 10 GbE (1.25 GB/s) whose bandwidth is high enough to saturate the maximum throughput of the flash array card. The I/O queue depth is set to 64, which is sufficient to fully utilize the parallelism of 8-channel and 8-way in our flash array card. We scale down the SSD capacity to 64GB, and DRAM for KV indexing structures (*e.g.,* the level lists and pinned meta segments) is set to 64MB – 0.1% of the SSD capacity.

We evaluate PinK using seven workloads from YCSB, a realistic cloud benchmark [13]. The details of the workloads are described in Table 1. Default key and value sizes are set

Table 1: A summary of YCSB workloads

	Load	A	B	C	D	E	F
R:W ratio	0:100	50:50	95:5	100:0	95:5	95:5	50:50* (*RMW)
Query type	Point					Range	Point
Request distribution	Uniform	Zipfian			Latest [13]	Zipfian	

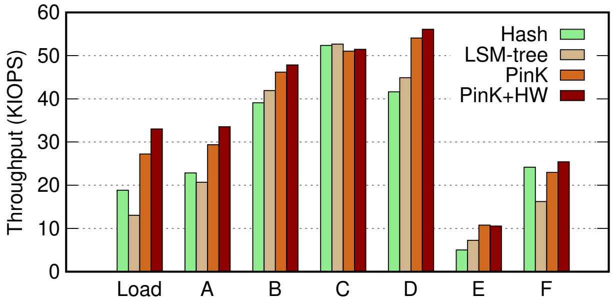

Figure 8: Overall throughputs of the four KV-SSD setups

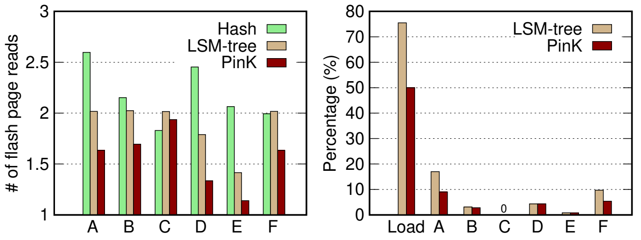

(a) Flash page reads per query

(b) Compaction I/Os

Figure 9: The impact of the level pinning on flash read I/Os (a) and compaction I/Os (b)

to 32B and 1KB, respectively, which represent averages of common KV workloads [5]. For evaluation, we first created a 44GB KV pool on the 64GB SSD ('Load' in Table 1) – total 44M unique KV pairs are written. Then, we ran each workload ('A'∼'F' in Table 1) which sends 10M KV requests to the loaded data set. We initialized the SSD with the Load phase before any other workload executed. On the host, 64 YCSB clients ran simultaneously to maximize throughput. With 44GB data, the storage utilization was 69%. We assigned 10% of the SSD capacity (*i.e.,* 6.4GB), for over-provisioning.

To compare with PinK, we have implemented a hash-based KV-SSD based on what we described in §2.3. The KV-SSD denoted by `Hash` uses an 8-bit signature for each KV pair to balance a hash-table size and a signature collision rate. Note that, in our experimental setup with a relatively small data set, the 8-bit signature is large enough to provide a low collision rate. It requires 320MB of the hash table, which is much larger than the 64MB of DRAM for indexing. Therefore, `Hash` keeps only popular buckets in DRAM using the LRU replacement policy. `Hash` uses additional 1MB DRAM for a write buffer.

We compare `Hash` with two PinK configurations: one with no HW accelerator (`PinK`) and the other with HW accelerators (`PinK+HW`). The conventional LSM-tree implementation based on LightStore [11] (`LSM-tree`) is included for our evaluation. `LSM-tree` is equivalent to PinK, except that it does not employ the optimization techniques explained from §4.2 to §4.5. For `PinK`, `PinK+HW`, and `LSM-tree`, the number of total levels is set to 5. `PinK` and `PinK+HW` pin top-3 levels, $k = 3$. The meta segment size is the same as an 8KB page size. With 8KB meta segments, the amounts of DRAM for the level lists is 10MB (including both prefix and range pointers). The rest of DRAM, 54MB, thus can be used to pin levels. `LSM-tree` uses 9MB for level lists and 55MB of DRAM for bloom filters. As in `Hash`, for L_0 (a write buffer), 1MB DRAM is additionally assigned to `PinK`, `PinK+HW`, and `LSM-tree`.

5.2 Performance Analysis

YCSB Throughput: We measured IOPS of the four KV-SSD setups (`Hash`, `LSM-tree`, `PinK`, and `PinK+HW`) using YCSB. Figure 8 shows the results. `PinK+HW` outperformed `Hash` and `LSM-tree`, providing 37% and 44% higher throughputs, on average, respectively. `LSM-tree` suffered seriously from high CPU overheads caused by rebuilding bloom filers as well as sorting KV pairs. By eliminating bloom filters and reducing compaction I/Os, `PinK` improved IOPS by 34%, on average, over `LSM-tree`. Using the HW accelerators for sorting further improved the performance. As depicted in Figure 8, `PinK+HW` achieved 7.2% higher IOPS than `PinK` on average.

Those benefits of PinK were evident for the workloads with many writes. For Load, YCSB-A, and YCSB-F, we observed that `PinK+HW` improved IOPS by 56∼152% and 10∼21% over `LSM-tree` and `PinK`, respectively. Even with the workloads having relatively small writes (*i.e.,* YCSB-B, D), `PinK+HW` exhibited 14∼24% and 3% higher IOPS than `LSM-tree` and `PinK`, respectively. For the read-only workload, YCSB-C, no performance benefits were observed with `PinK` and `PinK+HW`.

One of the observations we did not expect was that PinK significantly outperformed `LSM-tree` for YCSB-D which issues only a small number of writes. This was due to the somewhat unique I/O behavior of YCSB-D that read recently-written KV pairs frequently. In PinK, recently-written KV pairs were stored in top levels pinned to DRAM. Thus, the majority of `GET()` requests were directly served by pinned levels, avoiding flash I/Os.

`LSM-tree` performed worse than `Hash` for the write-intensive benchmarks (Load, YCSB-A and F) owing to CPU overheads, but exhibited higher IOPS for the read-oriented workloads (YCSB-B, C and D). For YCSB-E with range queries, the LSM-tree-based KV-SSDs showed much higher IOPS than `Hash`, thanks to their sorted indexing structure.

Impact of Level Pinning: Figure 9 shows the impact of the level pinning on read and write I/O counts. As shown in Figure 9(a), `PinK` reduced the number of flash reads per query by 33% and 62% over `LSM-tree` and `Hash`, respectively. Since `PinK` pinned exact KV indices in DRAM, it eliminated many flash reads.

`Hash` was badly affected from hash misses and collisions. `Hash` maintained only signatures in DRAM. Thus, even when it has hits on `SET()` requests, it had to retrieve exact keys from flash unless designated buckets were empty. `LSM-tree` exhibited two flash page reads per query: one for a KV index and the other for a value (1 KB). This is because Monkey bloom filters [14] used in `LSM-tree` requires one read to fetch

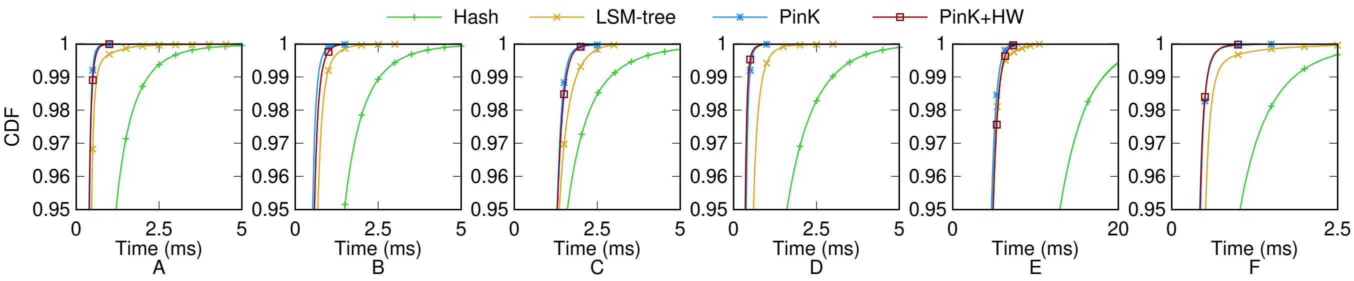

Figure 10: CDF graphs of read latency of `Hash`, `LSM-tree`, `PinK`, and `PinK+HW` under YCSB

indices, on average. For YCSB-D and E, the number of reads per query was less than 2. Since YCSB-D tends to read recently written KV pairs, many of `GET()`s were directly served by L_0 or pinned levels. YCSB-E contained range queries, so `LSM-tree` could fetch several desired KV indices by one read.

Figure 9(b) shows the percentage of compaction I/O out of the total I/O for LSM-tree operations (both reads and writes). By absorbing many index updates in pinned levels, it reduced the number of compaction I/Os by 52% over `LSM-tree`. Except for Load and YCSB-A with many writes, compaction I/Os only accounted for less than 20% of the total I/Os. However, as shown in Figure 8, the negative impact of compaction I/O ratio on the throughput was significant.

YCSB Read Latency: Figure 10 shows CDF graphs of read response times of the four KV-SSD setups. Table 2 also lists average, 99^{th}, 99.9^{th}, and 99.99^{th} percentile read latency of `Hash`, `LSM-tree`, and `PinK`. As expected, `PinK` and `PinK+HW` showed better average latency with shorter tails compared to the others. Thanks to bloom filters, `LSM-tree` performed fairly well compared to hash-based one, but had long tails as expected. `Hash` suffered from long tails due to multiple flash I/Os caused by hash misses and collisions. YCSB-E showed longer latency than the others because it issued range queries that carry multiple `GET()` commands.

Impact of Search Path Optimization: To understand the impact of the search path optimization, we carried out experiments with optimization techniques enabled one by one. `NO-OPT` represents PinK with no optimization, `Range` is PinK with range pointers, and `ALL` is with both range pointers and prefix. We used Load and YCSB-C workloads.

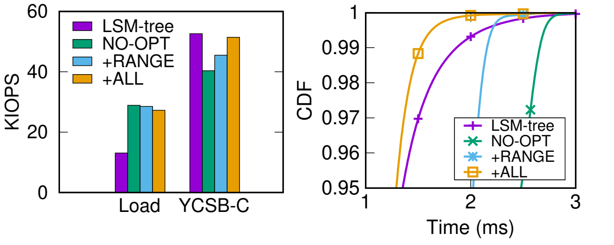
Table 2: Comparison of average and tail latency (unit: μs)

	Percentile	A	B	C	D	E	F
`Hash`	Average	410	573	592	501	5,628	370
	99^{th}	2,180	2,550	2,900	3,030	17,550	1,850
	99.9^{th}	4,180	4,600	5,710	5,090	25,360	3,260
	99.99^{th}	9,430	9,340	9,830	7,530	34,420	5,180
`LSM-tree`	Average	302	395	722	294	3,142	329
	99^{th}	640	960	1,870	890	5,790	680
	99.9^{th}	1,700	1,630	2,680	1,370	8,800	1,890
	99.99^{th}	5,250	3,140	3,450	3,210	10,740	3,750
`PinK`	Average	236	290	732	161	3,027	248
	99^{th}	490	700	1,820	490	5,550	540
	99.9^{th}	670	1,040	2,180	720	6,640	800
	99.99^{th}	1,300	1,800	2,370	1,060	7,590	1,540

Figure 11 (a) shows the throughputs under Load and YCSB-C. For Load, there were slight performance drops as the optimization technique was added. This was due to overheads required for managing additional data structures. These were not significant. For YCSB-C with 100% reads, high throughput improvements were observed. In particular, `ALL` exhibited almost the same read throughput as `LSM-tree`. This means that the search overheads were almost eliminated. While `LSM-tree` has the same worst case computation time of $O(h^2 \cdot log(T))$ as that of `NO-OPT`, `LSM-tree` has better throughput because its Bloom filter can much improve the average computation overhead by skipping searching of many levels. Figure 11 (b) presents the CDF of read latency under YCSB-C. We observed similar performance trends. `ALL` showed almost the same read latency as `LSM-tree` but with shorter tails.

Garbage Collection: With all the workloads of YCSB, GC did not involve many valid page copies. This was because almost all of the victim blocks were meta-segment blocks that held invalid KV indices. To simulate a situation where GC severely triggered, we designed another set of experiments. We first created a KV pool with 44M unique KV pairs, and then ran a synthetic workload that issued 100M `SET()`s with uniformly random keys to overwrite existing KV pairs. WAF reached 3.27 and became stable with little fluctuation after 90M `SET()`s were issued. This indirectly confirms that we issued sufficient I/Os to induce heavy GC I/O traffic.

Figure 12 analyzes the number of page writes issued during GC. `Hash` involved a smaller number of page writes for GC than `PinK`. After moving valid flash pages, both `Hash` and `PinK` have to update in-flash hash buckets or meta segments



(a) Throughput

(b) Read Latency

Figure 11: Impact of search path optimizations

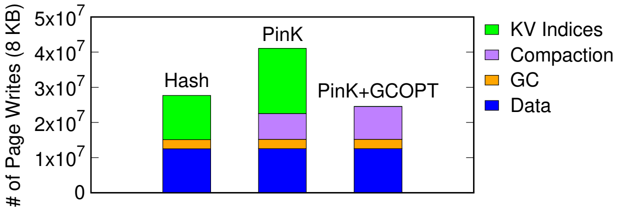


Figure 12: Analysis of GC cost: 'Data' represents pages written by `SET()`. 'GC' indicates pages written to move valid values for GC. 'Compaction' represents pages written to meta segments during compaction. 'KV Indices' indicates pages written to update meta segments or in-flash hash indices.

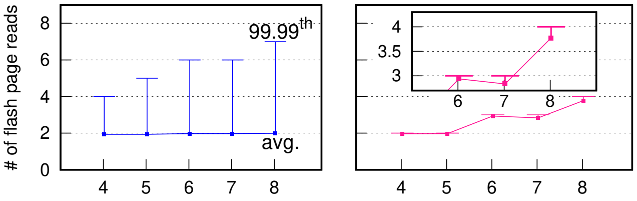
so that they point to the new locations of the moved pages (denoted by 'KV Indices' in Figure 12). Since a bucket size of `Hash` (8B signatures) is smaller than that of `PinK` (32B keys), more buckets are packed into a single flash page for `Hash`. Thus, the number of flash page I/O for updating KV indices becomes smaller than that of `PinK`. Even worse, `PinK` suffered from extra compaction I/Os.

`PinK+GCOPT` addresses this problem by rewriting victim KV pairs to L_0, instead of directly updating meta segments (see §4.5). This removed all flash writes associated with 'KV Indices', but potentially increased compaction costs since the indices for the victim pages in L_0 will be eventually written to meta segments again. This extra compaction cost was not so high. We observed that victim KV pairs in L_0 were likely to be coalesced with neighboring KV pairs and their indices were written to the same meta segment together.

Our results tell us that the compaction I/O cost of the LSM-tree, which is considered a major reason that makes people choose the hashing rather than the LSM-tree, is actually not a serious problem in achieving high I/O performance.

Read Latency and LSM-tree Height (h): Until now we have assumed that h and k are fixed to 5 and 3, respectively, and except for the last level, the rest is pinned to DRAM. As explained earlier (§4.2), this is a reasonable setup given that it required DRAM as small as 0.1% of flash storage and modern SSDs have more DRAM than that. However, to improve write performance further [31], one might want to increase the height of the tree. Unfortunately, as the tree gets taller, PinK cannot pin all the higher levels to DRAM. Given 64MB DRAM, for example, for h = 6, 7, and 8, the amount of DRAM required to pin all the levels but the last one are 176, 292, and 437MB, respectively. For h = 6 and 7, PinK cannot pin two lowest levels, and, for h = 8, the last three levels cannot be pinned. Even in such cases, the worst-case read latency can be bounded, but it increases to 3 reads (for h = 6 and 7) and 4 reads (for h = 8).

To understand its impact, using YCSB-C (100% reads), we measured the number of flash reads per query with various tree heights (h). Figure 13 shows the average read counts and 99.99^{th} percentile read counts of `LSM-tree` and `PinK`. The average read count of `LSM-tree` was close to 2. Again,



(a) Bloom filter (b) PinK

Figure 13: The number of flash page reads with varying h

regardless of h, Monkey required one flash read for fetching KV indices, on average. However, owing to its probabilistic nature, the tail latency increased greatly, and the gap between the tail and the average got wider as h increased.

Unlike `LSM-tree`, `PinK` exhibited stable read counts. While the average read count increased along with h, the worst-case read count was bounded as $O(h-k-1)$. For YCSB-C, there were no huge differences between the average and the tail read counts. This is because YCSB-C had low temporal locality and thus the majority of `GET()` were served by the flash-resident last level This experimental results confirm that PinK can provide more *stable* read latency even when h is set high and all the levels cannot be pinned to DRAM.

6 Conclusion

We have presented a novel LSM-tree-based KV-SSD design, called *PinK*. By pinning KV indices of top levels of the LSM-tree to DRAM, PinK is able to guarantee the worst-case read latency, while improving average read latency. Moreover, by combining the level pinning with hardware accelerators, PinK not only eliminated sorting overheads, but reduced I/O operations related to compaction greatly. Our experimental results show that PinK outperformed existing hash-based KV-SSDs in tail read-latency, average read-latency, and I/O throughput. In future, we plan to explore the idea of the level pinning in general-purpose KVS like RocksDB. We think the main challenge in realizing this idea is providing durability for pinned levels in the host system. Using emerging technologies such as persistent memory may offer a solution.

Acknowledgments

We would like to thank our shepherd, Dr. Rusty Sears, and four anonymous reviewers for all their helpful comments. We also thank Samsung Electronics for providing KV-SSD prototypes. This work was supported by Samsung Research Funding & Incubation Center of Samsung Electronics under Project Number SRFC-IT1701-11. Arvind and Chanwoo Chung was partially funded by NSF (CCF-1725303) and Samsung Semiconductor (GRO grants). PinK source code can be found at [1] and [2].

Abstract

Achieving cost and performance efficiency for cloud-hosted databases requires exploring a large configuration space, including the parameters exposed by the database along with the variety of VM configurations available in the cloud. Even small deviations from an optimal configuration have significant consequences on performance and cost. Existing systems that automate cloud deployment configuration can select near-optimal instance types for homogeneous clusters of virtual machines and for stateless, recurrent data analytics workloads. We show that to find optimal performance-per-$ cloud deployments for NoSQL database applications, it is important to (1) consider heterogeneous cluster configurations, (2) jointly optimize database and VM configurations, and (3) dynamically adjust configuration as workload behavior changes. We present OPTIMUSCLOUD, an online reconfiguration system that can efficiently perform such joint and heterogeneous configuration for dynamic workloads. We evaluate our system with two clustered NoSQL systems: Cassandra and Redis, using three representative workloads and show that OPTIMUSCLOUD provides 40% higher throughput/$ and 4.5× lower 99-percentile latency on average compared to state-of-the-art prior systems, CherryPick, Selecta, and SOPHIA.

1 Introduction

Cloud deployments reduce initial infrastructure investment costs and provide many operational benefits. An important class of cloud deployments is NoSQL databases, which allow applications to scale beyond the limits of traditional databases [17]. Popular NoSQL databases such as Cassandra, Redis, and MongoDB, are widely used in web services, big data services, and social media platforms. Tuning cloud-based NoSQL databases for performance[1] under cost constraints is challenging due to several reasons.

First, the search space is very large due to VM configurations and database application configurations. For example, cloud services provide many VMs that vary in their CPU-family, number of cores, RAM size, storage, network bandwidths, etc., which affect the VM's $ cost. At the time of writing, AWS provides 133 instance types while Azure provides 146 and their prices vary by a factor of 5,000×. On the NoSQL side, there are many performance-impacting configuration parameters. For example, Cassandra has 25 such parameters and sub-optimal parameter setting for one parameter (e.g., the *Compaction method*) can degrade throughput by 3.4× from the optimal. On the cloud side too, selecting the right VM type and size is essential to achieve the best Perf/$.

Second, there is the need for *joint* optimization while taking into account the dependencies between the NoSQL-level and VM-level configurations. For example, our evaluation shows that the optimal cache size of Cassandra for a VM type `M4.large` (with 8GB of RAM) is 8× the optimal cache size for `C4.large` (with 3.75GB RAM). Additionally, larger-sized VMs do not always provide better Perf/$ [67] as they may overprovision resources and unnecessarily increase the $ cost.

Third, there are many use cases of cloud applications where the workload characteristics change over time, sometimes unpredictably, necessitating reconfigurations [7, 11]. A configuration that is optimal for one phase of the workload can become very poor for another phase of the workload. For example, in Cassandra, with a large working set size, reads demand instances with high memory, while writes demand high compute power and fast storage.

Changing the configuration at runtime for NoSQL databases, which are stateful applications (i.e., with persistent storage), has a performance impact due to the downtime caused to the servers being reconfigured. Therefore, for fast changing workloads, frequent reconfiguration of the overall cluster could severely degrade performance [41]. Consequently, deciding *which* subset of servers to reconfigure is vital to minimize reconfiguration performance hit and to achieve globally optimal Perf/$ while respecting the user's availability requirements. However, changing the configurations of only

[1] We use the standard metrics of throughput and (tail) latency for measuring database performance. Specifically, we target maximizing throughput normalized by price in $, i.e., performance-per-unit-$ or Perf/$ for short.

a subset of servers naturally leads to *heterogeneous* clusters, which no prior work is equipped to deal with.

Existing Solutions: State-of-the-art cloud configuration tuners such as CherryPick [5] and Selecta [32] focus mainly on stateless, recurring workloads, such as big-data analytics jobs, while Paris [67] relies on a carefully chosen set of benchmarks that can be run offline to fingerprint which application is suitable for which VM type. Due to their target of static workloads and stateless jobs, a single cloud configuration is selected based on a representative workload and then fixed throughout the operation period. However, small workload changes can cause these "static tuners" to produce drastically degraded configurations. For example, a 25% increase in workload size with CherryPick makes the proposed configuration 2.6× slower than optimal (Section 5.4 in [5]). Also, in our experiments (Sec. 4.3), we find that CherryPick's proposed configuration for the write-heavy phase achieves only 12% of the optimal when the workload switches to a read-heavy phase. Hence, these *prior systems are not suitable for dynamic workloads*.

SOPHIA [41] addresses database configuration tuning for clustered NoSQL databases and can handle dynamic workloads. However, like the static tuner RAFIKI [40], SOPHIA's design focuses only on NoSQL configuration tuning and does not consider cloud VM configurations nor dependencies between VM and NoSQL configurations. Naïvely combining the NoSQL and VM configuration spaces causes a major increase in the search space size and limits SOPHIA's ability to provide efficient configurations (Sec. 3.5). Further, due to its atomic reconfiguration strategy (i.e., either reconfigure all servers or none), it suffers from all the drawbacks of the homogeneity constraint. Table 1 compares key features of OptimusCloud to various prior works in this field.

Our Solution: We introduce our system OptimusCloud, which jointly tunes the database and cloud (VM) configurations for dynamic workloads. **There are three key animating insights behind the design of OptimusCloud.** The *first* is that jointly tuning the database and cloud (VM) configurations for dynamic workloads is essential. To show how important this is, we benchmark one Cassandra server with a 30-min trace from one of our three workloads (MG-RAST) on 9 different EC2 VM types[2]. For each type, we use 300 different database configurations selected through grid search. We show the performance in terms of Ops/s for the best, default, and worst configurations in Fig. 1. We see a big variance in performance w.r.t. the database configurations—up to 74% better performance over default configurations (45% on average). Further, the best configurations vary with the VM type and size (for the 6 VM types shown here, there are 5 distinct best DB configurations). This emphasizes the need for tuning both types of configurations *jointly* to achieve the best Perf/$. The *second key insight* is that in order to optimize the Perf/$ for a dynamic workload, it is necessary to perform non-atomic reconfigurations, i.e., for only part of the cluster. Reconfiguration in a distributed datastore is a sequential operation (in which one or a few servers at a time are shutdown and then restarted) to preserve data availability [31, 41]. This operation causes transient performance degradation or lower fault tolerance. Reconfiguration is frequent enough for many workloads that this performance degradation should be avoided, e.g., MG-RAST has a median of 430 significant switches per day in workload characteristics. Accordingly, *heterogeneous configurations* have the advantage of minimizing the performance hit during reconfiguration. Further, in the face of dynamic workloads, there may only be time to reconfigure part of the overall cluster. Also, from a cost-benefit standpoint, maximizing performance does not need *all* instances to be reconfigured (such as to a more resource-rich instance type), rather a carefully selected subset. We give a simple example to make this notion concrete in Section 2. The *third key insight* is that for a particular NoSQL database (with its specifics of data placement and load balancing), it is possible to create a model to map the configuration parameters to the performance of each server. From that, it is possible to determine the overall heterogeneous cluster's performance. OptimusCloud leverages performance modeling to search for the optimal cluster configuration.

The workflow of OptimusCloud comprises offline training and online prediction and reconfiguration phases as shown in Fig. 2. At runtime, OptimusCloud takes user require-

Figure 2: Overview of OptimusCloud*'s workflow. First, a workload predictor is trained with historical traces from the database to be tuned. Second, a single server performance predictor is trained to map workload description, VM specs, and NoSQL application configuration to throughput. Third, a cluster-level performance predictor is used to estimate the throughput of the heterogeneous cluster of servers. In the online phase, our optimizer uses this predictor to evaluate the fitness of different VM/application configurations and provides the best performance within a given budget.*

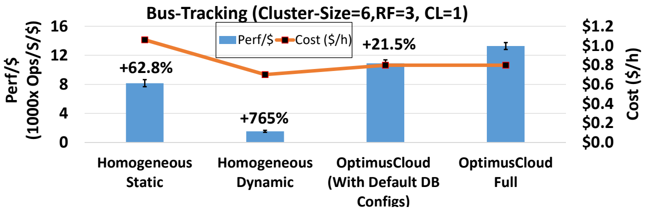

*Figure 3: Importance of creating heterogeneous clusters (*OptimusCloud *Full) over homogeneous clusters (both Static and Dynamic) for Bus-Tracking application. ments of budget, availability, and consistency. It then combines the performance model with a workload predictor and a cost-benefit analyzer to decide: when the workload changes sufficiently, what should be the new (possibly heterogeneous) configuration. It decides what minimal set of servers should be reconfigured.

Evaluation: We apply OptimusCloud to two popular NoSQL databases—Cassandra and Redis—and evaluate the system on traces from two real-world systems, and one simulated trace from an HPC analytics job queue. All three use cases represent dynamic workloads with different query blends. We evaluate the Perf/$ achieved by OptimusCloud and compare this to three leading prior works, CherryPick [5], Selecta [32], and SOPHIA [41]. Additionally, we compare ourselves to the best static configuration determined with oracle-like prediction of future workloads and the theoretical best. OptimusCloud achieves between 80-90% of the theoretical best performance for the 3 workloads and achieves improvements between 9%-86.5%, 18%-173%, 17%-174%, and 12%-514% in Perf/$ over Homogeneous-Static, CherryPick, Selecta, and SOPHIA respectively without degrading P99 latency (Sec. 4). Fig. 3 shows the improvement in Perf/$ due to OptimusCloud's heterogeneous configurations.

We make the following novel contributions in this paper.

1. We design a performance modeling-based technique for efficient *joint optimization* of database *and* cloud configurations to maximize the Perf/$ of a clustered database.

2. We design a technique to identify the minimal set of servers in a clustered database to reconfigure (concurrently) to obtain a throughput benefit. This naturally leads to heterogeneous configurations. To reduce the much larger search space that this causes, we design for a simplification that groups multiple servers that should be configured to the same parameters.

3. We show that OptimusCloud generalizes to two distinct NoSQL databases and different workloads, cluster sizes, data volumes, and user-specified requirements for replication and data consistency.

The rest of the paper is organized as follows. Section 2 gives the necessary background for the problem and a quantitative rationale. Section 3 describes the details of OptimusCloud's design. We evaluate OptimusCloud in Section 4 and survey related work in Section 5.

2 Background and Rationale

To evaluate the generalizability of OptimusCloud, we select two popular NoSQL databases with very different architectures.

2.1 Cassandra

Cassandra is designed for high scalability, availability, and fault-tolerance. To achieve these, Cassandra uses a peer-to-peer (P2P) replication strategy, allowing multiple replicas to handle the same request. Other popular datastores such as DynamoDB [20] and Riak [34] implement the same P2P strategy and we select Cassandra as a representative system from that category. Cassandra's replication strategy determines where replicas are placed. The number of replicas is defined as "Replication Factor" (RF). By default, Cassandra assigns an equal number of tokens to each node in the cluster where a token represents a sequence of hash values for the primary keys that Cassandra stores. Based on this token assignment, a Cassandra cluster can be represented as a ring topology [16]. Fig. 5 shows an example of 4 Cassandra servers and RF of 2.

2.2 Redis

Redis is an in-memory database and serves all requests from the RAM, while it writes data to permanent storage for fault tolerance. This design principle makes Redis an excellent choice to be used as a cache on top of slower file systems or datastores [54]. Redis can operate as either a stand-alone node or in a cluster of nodes [53] where data is automatically sharded across multiple Redis nodes. Our evaluation applies to the clustered mode of Redis. When a Redis server reaches the maximum size of its allowed memory (specified by the `maxmemory` configuration parameter), it uses one of several policies to decide how to handle new write requests. The default policy will respond with error. Other policies will replace existing records with the newly inserted record (the `maxmemory-policy` configuration parameter specifies which records will be evicted). The value of `maxmemory` needs to be smaller than the RAM size of the VM instance and the headroom that is needed is workload dependent (lots of writes will need lots of temporary buffers and therefore larger headroom). Thus, it is challenging to tune `maxmemory-policy` and `maxmemory` parameters with changing workloads and these two form the target of our configuration decision.

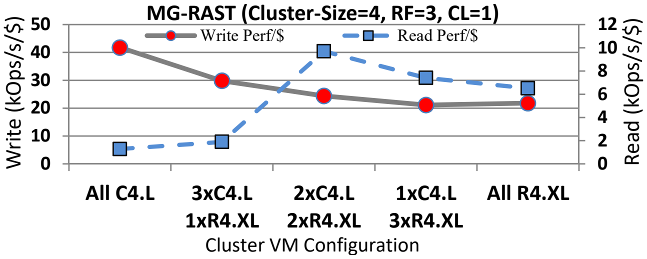

Figure 4: Change in Perf/$ for the write (solid) and read throughput (dotted) as we reconfigure the nodes from C4.large to R4.xlarge.

2.3 Example Rationale for Heterogeneous Configurations

Here we give a motivating example for selecting subset of servers to reconfigure. Consider a Cassandra cluster of 4 nodes with a consistency-level (CL[3]) = 1 and replication-factor (RF[4]) = 3, i.e., any pair of nodes has a complete copy of all the data. Also, assume that we only have two cloud configurations: C4.large, which is compute-optimized, and R4.xlarge, which is memory-optimized. C4.large is cheaper than R4.xlarge by 58% [8], whereas R4.xlarge has larger RAM (30.5GB vs 3.75GB) and serves read-heavy workloads with higher throughput. Now we test the performance of all possible combinations of VM configurations (All C4.L, 1 C4.L + 3R4.XL, ... etc.) for both read-heavy and write-heavy phases of the MG-RAST workload and show the saturation level throughput for each configuration in Fig. 4. The "All C4.large" configuration achieves the best write Perf/$ (41.7 KOps/s/$), however, it has the worst read Perf/$ (only 1.28 KOps/s/$) because reads of even common records spill out of memory. Now if two servers are reconfigured to R4.xlarge, the write Perf/$ decreases (24.4 KOps/s/$), while the read performance increases significantly (9.7 KOps/s/$), showing an improvement of 7.5× for read throughput over the all C4.large configuration. The reason for this huge improvement is Cassandra's design by which it redirects new requests to the fastest replica [19], directing all read requests to the two R4.xlarge servers. *Now we notice that switching more C4.large servers to R4.xlarge does not show any improvement in either reads or writes Perf/$, as the two R4x.large servers are capable of serving the applied workload with no queued requests.* This means that switching more servers will only reduce the Perf/$. Thus, the best Perf/$ is achieved by configuring to all C4.large in write-heavy phases, while configuring only 2 servers to R4x.large in read-heavy phases. **Therefore, heterogeneous configurations can achieve better Perf/$ compared to homogeneous ones under mixed workloads.**

3 Design

3.1 Workload Representation and Prediction

OptimusCloud uses a query-based model [4] to represent time-varying workloads. This model characterizes the applied workload in terms of the proportion of the different query types and the total volume of queries, denoted by W.

We use a workload predictor to learn time-varying patterns from the workload's historical traces, and predict the workload characteristics for a particular lookahead period. We notate the time varying workload at a given point in time t as $W(t)$. The task of the workload predictor is to provide OptimusCloud with $W(t+1)$ given $W(t)$,$W(t-1)$,... , $W(t-h)$, where h is the length of history. OptimusCloud then iteratively predicts the workload till a lookahead time l, i.e., $W(t+i), \forall i \in (1,l)$. We execute OptimusCloud with a simple Markov-Chain prediction model for both MG-RAST and Bus-tracking workloads while we have a deterministic fully accurate predictor for HPC. We do not claim any novelty in workload prediction and OptimusCloud is modular enough to easily integrate more complex estimators, such as

[3] CL: the minimum number of Cassandra nodes that must acknowledge a read or write operation before the operation can be considered successful

[4] RF: the total number of replicas for a key across a Cassandra cluster

neural networks [37, 39].

3.2 Performance Prediction

Combining NoSQL and cloud configurations produces a massive search space, which is impractical to optimize through exhaustive search. However, it is well known that not all the application parameters impact performance equally [40, 41, 62] and therefore OPTIMUSCLOUD reduces the search time by automatically selecting the most impactful parameters. Further, there exist dependencies among parameters, such as the dependency between the VM type (EC2) and Cassandra's *file-cache-size* (FCS) (Fig. 7). OPTIMUSCLOUD uses *D*-optimal design [48] to optimize the offline data collection process for training our performance model. *D*-optimal design answers this question: "*Given a budget of N data points to sample for a workload, which N points are sufficient to reveal the dependencies between configuration parameters?*". We experimentally determine that the significant dependencies in our target applications are at most pairwise and therefore we restrict the search to linear and quadratic parameters. We create a set of filters for feasible combinations of parameter values by mapping each parameter to the corresponding resource (e.g., *file-cache-size* parameter is mapped to RAM). Afterward, we check that the sum of all parameters mapped to the same resource is within that resource limit of the VM (e.g., the total size of all Cassandra buffer memories should not exceed the VM instance memory). We feed to *D*-optimal design the budget in terms of the number of data points that we can collect for offline training.

After collecting the data points determined by the *D*-optimal design, we train a random forest to act as a regressor and predict the performance of a single NoSQL server for any given set of configuration parameters, both database and VM. The average output of the different decision trees is taken as the final output. We choose random forest over other prediction models because of its easily interpretable results [50] and it has only two hyper-parameters to tune (`max_depth` and `forest_size`) compared to black-box models such as DNNs. OPTIMUSCLOUD trains a second random forest model to predict the overall cluster performance, using the predicted performance for each server, RF, CL and data-placement information. For both random forests, we use 20 trees and a maximum depth of each as 5 as that gives the best result within reasonable times.

3.3 Selection of Servers to Reconfigure

Selecting the right servers to reconfigure in a cluster is essential to achieve the best Perf/$. We introduce the notion of *Complete-Sets* to determine the right subset of servers to reconfigure. **We define a *Complete-Set* as the minimum subset of nodes for which the union of their data records covers all the records in the database at least once.**

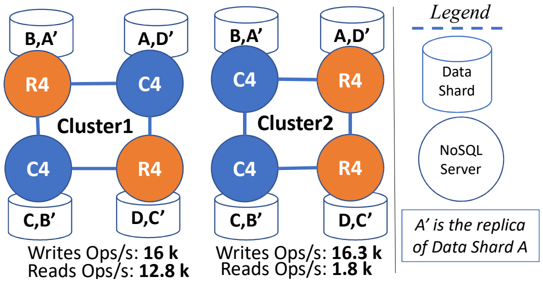

Figure 5: (RF=2, CL=1) Cluster performance depends not just on the configuration of each server, but also on the relative positions of the instances on the token ring. Cluster1 achieves 7× reads Ops/s over Cluster2 with the same VM types and sizes.

To see why the notion of *Complete-Set* is important, consider the two clusters shown in Fig. 5. Both clusters 1 and 2 use 2 C4.large and 2 R4.large and hence have the same $ cost. However, *Cluster1* achieves 7× the read Ops/s compared to *Cluster2*. The reason for the better performance of *Cluster1* is that it has one *Complete-Set* worth of servers configured to the memory-optimized R4.large architecture and therefore serves all read requests efficiently. On the other hand, *Cluster2*'s read performance suffers since all read requests to shard `B` (or its replica `B'`) have to be served by one of the C4.large servers, which has a smaller RAM and therefore serves most of the reads from desk. Accordingly, read requests to shards `B` or `B'` represent a bottleneck in *Cluster2* and cause a long queuing time for the reading threads, which brings down the performance the *entire* cluster for all the shards.

This means that all the servers within a Complete-Set must be upgraded to the faster configuration for the cluster performance to improve. Otherwise, the performance of the Complete-Set will be bounded by the slowest server in the set. OPTIMUSCLOUD partitions the cluster into one or more *Complete-Sets* using the cluster's data placement information. To identify the Complete-Sets, we collect the data placement information for each server of the cluster. OPTIMUSCLOUD queries this information either from any server (such as in Cassandra, using `nodetool ring` command) or from one of the master servers (such as in Redis, using `redis-cli cluster info` command). In Redis, identifying the Complete-Sets is easier since data tokens are divided between the master nodes only, while slaves have exact copies of their master's data. Therefore, a *Complete-Set* is formed by simply selecting a single slave node for every master node.

Maintaining Data Availability: To maintain data availability during reconfiguration of a Cassandra cluster, at least *CL* replicas of each data record must be up at any point in time. This puts an upper limit on the number of *Complete-Sets* that can be reconfigured concurrently as $Count(Complete\text{-}Sets) - CL$.

We show that the number of Complete-Sets in a cluster is *not* dependent on the number of nodes in the cluster, but is a constant factor. This is because when the cluster size increases, the range of keys assigned to every node decreases

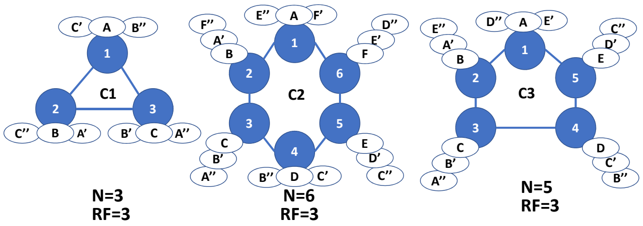

Figure 6: Replication examples with 3 different cluster sizes with RF=3. Cluster C1 has 3 nodes and each node has a complete copy of the data, therefore each node is a Complete-Set. Cluster C2 has 6 nodes and has the following Complete-Sets: [1,4] , [2,5] & [3,6]. Cluster C3 has 5 nodes (not divisible by RF=3), therefore it has two Complete-Sets: [1,3 (or 4)], [2,4 (or 5)].

and therefore the number of nodes that form a Complete-Set increases. This means that since OPTIMUSCLOUD reconfigures the instances in groups of one or more Complete-Sets concurrently, the total time to reconfigure a cluster is a constant factor independent of the cluster size. Figure 6 shows examples of *Complete-Set* for different cluster sizes

Property: OPTIMUSCLOUD **partitions the cluster into** S **Complete-Sets, and** S **is independent of the cluster size** N.

Proof. For a cluster of N servers with replication factor RF, there exists a total of RF copies of each record in the cluster, with no two copies of the same record stored in the same server. Assuming each node in the cluster is assigned an equal portion of the data (which NoSQL load-balancers try to achieve [35]), the size of a *Complete-Set* is $Size_{CompSet} = \lceil \frac{N}{RF} \rceil$. Consequently, the number of *Complete-Sets* in the cluster $S = \lfloor \frac{N}{Size_{compSet}} \rfloor$. If RF divides N, then the number of *Complete-Sets* is $S = \frac{N}{Size_{CompSet}} = RF$. Else, say $N\%RF = r$, then $S = \frac{RF}{1-r/N+RF/N}$, which is $\approx RF$ since in practice RF is not large, 3 being a practical upper bound. Thus, the number of *Complete-Sets* is independent of the cluster size and hence the reconfiguration time is also a constant.

□

Search Space Size Reduction: Heterogeneous configurations make the search space size much larger than with homogeneous configurations. Consider a cluster of N nodes and I VM options to pick from. If we are to pick a homogeneous cloud configuration for the cluster, we have I options. However, if we are to pick a heterogeneous cloud configuration, our search space becomes I^N. If we assume balanced data placement among the servers in the cluster (as clustered NoSQL databases are designed for), the search space becomes $C(N+I-1, I-1)$ (distribute N identical balls among I boxes). However, this search space size is still too large to perform an exhaustive search to pick the optimal configurations. A cluster of size N=20 nodes and I=15 VM options gives 1.3×10^9 different configurations to select from. One may use domain-specific insights about the domain to reduce the search space for specific applications [36] or for customized distributed strategies [28]. However we aim for generalizability here.

We use one insight about Complete-Sets to reduce the search space. The nodes within each Complete-Set should be homogeneous in their configuration. Otherwise, the performance of the Complete-Set will be equal to that of the slowest node in the set. *This means that the smallest atomic unit of reconfiguration is one Complete-Set.* This insight reduces the search space, while still allowing different *Complete-Sets* to have different configurations. Thus, the search space reduces to $C(S+I-1, I-1)$=680 configurations when $S = RF = 3$. **Also note that the configuration search space is constant rather than growing with the size of the cluster.**

3.4 Selecting the Reconfiguration Plan

3.4.1 Objective Function Optimization

The objective of OPTIMUSCLOUD is to find a reconfiguration plan that maximizes Perf/$ of the cluster under a given budget and with a minimum acceptable throughput. A *reconfiguration plan C* is represented as a time series of a vector of configurations (both NoSQL and VM):

$$\mathbf{C} = \left[\{C_1, C_2, \cdots, C_M\}, \{t_1, t_2, ..., t_M\}\right] \tag{1}$$

Where M is the number of steps in the plan and timestamp t_i represents how long the configuration C_i is applied. The lookahead is $t_L = \sum_{i=1}^{M} t_i$. The optimization problem is defined as:

$$\mathbf{C}^* =_{\mathbf{C}} \frac{f\left(\mathbf{W},\mathbf{C}\right)}{Cost\left(\mathbf{C}\right)} \tag{2}$$

$$\text{subject to } f\left(\mathbf{W},\mathbf{C}\right) \geq \text{minOps} \ \& \ Cost\left(\mathbf{C}\right) \leq \text{Budget}$$

Here, $f\left(\mathbf{W},\mathbf{C}\right)$ is the function that maps the workload vector $\mathbf{W}$ and the configuration vector $\mathbf{C}$ to the throughput (the cluster prediction model) and $\mathbf{C}^*$ is the best reconfiguration plan selected by OPTIMUSCLOUD. The two constraints in the problem prevent us from selecting configurations that exceed the budget or those that deliver unacceptably low performance.

The optimization problem described in Equation 2 falls under the category of gradient-free optimization problems [38], in which no gradient information is available nor can any assumption be made regarding the form of the optimized function. For this category of optimization problems, several meta-heuristic search methods have been proposed, such as, Genetic Algorithms (GA) , Tabu Search [64], and Simulated Annealing. We use GA due to two relevant advantages. First, constraints can be easily included in its objective function (i.e., the fitness function). Second, it provides a good balance between exploration and exploitation through crossover and mutation [59]. We use Python `Solid` library for GA [58] and `Scikit-learn` for random forests [55].

3.4.2 Cost-Benefit Analysis

Changing either NoSQL or cloud configurations at runtime has a performance cost due to downtime caused to nodes being reconfigured. We find that most of the performance-impacting NoSQL parameters (83% for Cassandra) necessitate a server restart and naturally, changing the VM type needs a restart as well. When a workload change is predicted in the online phase, OptimusCloud uses its performance predictor to propose new configurations for the new workload. Afterward, OptimusCloud estimates the reduction in performance given the expected downtime duration and compares that to the expected benefit of the new configurations. OptimusCloud selects configurations that maximize the difference between the benefit and the cost (both in terms of Throughput/$) . This cost-benefit analysis prevents OptimusCloud from taking greedy decisions, whenever the workload changes. Rather, it uses a long-horizon prediction of the workload over a time window to decide which reconfiguration actions to instantiate and when.

The benefit of the i^{th} step in the plan is given by:

$$B_{(i+1,i)} = \sum_{t \in t_{i+1}} f\left(W_t, C_{i+1}\right) - f\left(W_t, C_i\right) \tag{3}$$

where $f\left(W_t, C_{i+1}\right)$ is the predicted throughput using the new configuration C_{i+1}. The configuration cost is given by:

$$L_{(i+1,i)} = \sum_{p \in (C_i - C_{i+1})} t_{down} \times \delta_p \times f\left(W_t, C_i\right) \tag{4}$$

where p is any *Complete-Set* that is being reconfigured to move from configuration C_i to C_{i+1}, t_{down} is the expected downtime during this reconfiguration step, and δ_p is the portion of the cluster throughput that p contributes as estimated by our cluster predictor. We then normalize the benefit (Equation. 3) and the cost (Equation. 4) by the difference in price between configurations C_i and C_{i+1}. The value of t_{down} is measured empirically and its average value is 30 sec for NoSQL configurations and 90 sec for VM configurations.

3.5 Distinctions from Closest Prior Work

We describe the substantive conceptual differences of OptimusCloud from two recent, related works: Selecta and SOPHIA. OptimusCloud provides joint configuration tuning of both NoSQL and cloud VMs, while it considers heterogeneous clusters to achieve the best Perf/$. In Selecta, only heterogeneous cloud storage configurations are permissible (i.e., HDD, SSD, or NVMe). Accordingly, the configuration space in Selecta is much smaller and simpler to optimize using matrix factorization techniques. A simple extension of Selecta to our large search space produces very poor performance due to the sparsity of the generated matrix and the dependency between NoSQL and cloud configurations as we empirically show in Sec. 4.6.

In SOPHIA, only NoSQL parameters are configured and no computing platform parameters such as VM configurations are optimized. Even within NoSQL configurations, it only considers homogeneous configurations. Accordingly, SOPHIA makes a much simpler decision to either configure the complete cluster to the new configuration, or keep the old configuration—correspondingly its cost-benefit analysis is also coarse-grained, at the level of the entire cluster. For fast-changing workloads, it therefore often has to stick to the current configuration since there is not enough time to reconfigure the entire cluster (which needs to be done in a partly sequential manner to preserve data availability). *Similar to Selecta, a simple extension of SOPHIA to VM options cannot achieve the best Perf/$ for dynamic workloads, as it can only create homogeneous configurations across all phases of the workload.* We empirically show this in Sections 4.3 and 4.7.

4 Experimental Setup and Results

In this section, we evaluate OptimusCloud under different experimental conditions for the 3 applications. We deploy OptimusCloud and the datastore clusters (Cassandra or Redis) in Amazon EC2 in the US West (Northern California) Region. We also deploy a separate set of nodes in the same region to serve as workload generators (i.e., shooters). We vary the number of shooting threads in runtime to simulate the changes in the request rate in the workload trace. The results are averages of 20 runs, with each run using a different subset of the training data. Our evaluation answers four broad questions. (1) How does OptimusCloud compare in terms of Perf/$ and P99 latency with three state-of-the-art systems (which can only create homogeneous configurations) and two oracle-based baselines? (2) What is the accuracy of each module of OptimusCloud, such as, the workload and the performance predictors? (3) How do application requirements such as RF and CL impact OptimusCloud? (4) How does OptimusCloud generalize to different applications (we use three), databases (Cassandra and Redis), and levels of prediction errors?

Major Insights: We draw several key insights from our evaluation. **First**, the flexibility afforded by being able to reconfigure different parts of the cluster to different configurations is useful—all three prior protocols being compared (and in fact, all works to date) can only create homogeneous configurations. *Further, the proactive approach of initiating reconfiguration upon predicted workload change helps to handle dynamic workloads and keeps latency low (CherryPick and Selecta are both reactive).* **Second**, OptimusCloud's design reduces the heterogeneous configurations search space significantly. Accordingly, it is able to search efficiently and finds higher performing VM and NoSQL configurations than cluster configurations selected by CherryPick, Selecta, or SOPHIA. This improvement persists across applications (highest for the more predictable HPC analytics workload and lowest for the MG-RAST workload) (Fig. 8, 10, 11), different (RF,CL) values (larger values of RF and smaller values of CL) (Fig. 10), and data volumes (benefit stays unchanged) (Fig. 8). **Third**, OptimusCloud achieves comparable or better P99 latency than the baselines, thus showing that it does not sacrifice raw performance in search of the performance per unit cost.

MG-RAST			BUS-Tracking		
MC-Order	Lookahead	RMSE	MC-Order	Lookahead	RMSE
First	5m	43.7%	First	15m	6.9%
First	10m	68.7%	**First**	**1h**	**7.4%**
Second	**5m**	**43.4%**	Second	5m	7.12%
Second	10m	68.2%	Second	1h	7.4%

Table 2: (MC stands for Markov Chain). Workload prediction RMSE for MG-RAST and Bus-tracking workloads with different lookahead periods.

4.1 Applications

Here we give the details for our three use case applications, which together span a wide range in terms of predictability and nature of the requests in the workload. **MG-RAST** is a global-scale metagenomics portal [7], the largest of its kind, which allows many users to simultaneously upload their metagenomic data to the repository, apply a pipeline of computationally intensive processes and optionally commit the results back to the repository for shared use. Its workload does not have any discernible daily or weekly pattern, as the requests come from all across the globe and we find that the workload can change drastically over a few minutes. A total of 80 days of real query trace were analyzed, 60 days for training and 20 days for testing. In production, MG-RAST is executed with the values RF=3, CL=1 and it shows abrupt switches in the Read-Ratio (typically from RR=0 to RR=1) and vice versa. The frequency of these switches are 430/day on median. This presents a challenging use case as only 5 minutes of accurate lookahead is possible.

The second workload is the **Bus-Tracking** application [39] where read, scan, insert, and update operations are submitted to a backend database. The data has strong daily and weekly patterns to it. This workload has less frequent switches of 60/day on median. For this workload, 60 days of real query trace were analyzed for the application (40 for training and 20 for testing). The relative proportions of the different kinds of queries are 42.2% updates, 54.8% scans, 2.82% inserts, and 0.18% reads. As shown in Table 2, the prediction accuracy for Bus-Tracking workload is much better compared to the MG-RAST workload, as expected due to the more regular patterns, and here we use a longer lookahead period of 1 hour.

The third use case is a queue of **data analytics jobs** such as would be submitted to an HPC computing cluster. Here the workload can be predicted over long time horizons (order of an hour) by observing the jobs in the queue and leveraging the fact that a significant fraction of the job patterns are recurring. Thus, our evaluation cases span the range of patterns and corresponding predictability of the workloads. We simulate a shared queue of batch data analytics jobs. We modeled the jobs on data analytics requests submitted to a real Microsoft Cosmos cluster [26]. Each job is divided into stages and the workload characteristics of the job change with every stage. The job size is a random variable $\sim$ U(200,100K) operations. The workload switches are 780/day on median, with a level of concurrency of 10 jobs. We achieve accurate prediction over a lookahead duration of 1 hour and we use that for our setting with this use case.

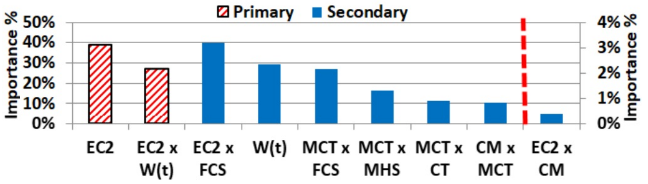

Figure 7: Importance of various parameters, including pairwise combinations. Parameters with black solid bars are w.r.t. the right Y-axis. EC2 configuration, the workload, and top 5 Cassandra parameters describe 81% of data variance, after which there is a significant drop in importance, denoted by the red dotted line. Top parameters are: file_cache_size (FCS), memtable_cleanup_threshold (MCT), memtable_heap_space (MHS), compaction_throughput (CT), and compaction_method (CM)

4.2 Baselines

We compare OPTIMUSCLOUD to the following baselines:

1. *Homogeneous-Static*: We use our cluster predictor to select the single best configuration to use for the entire duration of the predicted workload. The entire workload is assumed to be known in advance, making this an impractically optimistic baseline. Nevertheless, it is a measure of how well a *statically determined* homogeneous configuration can perform when powered by a hypothetically perfect workload predictor.
2. *CherryPick*: We use CherryPick's Bayesian Optimization (BO) to find a heterogeneous cloud configuration which maximize our objective metric. When the workload changes, BO collects 20 points and selects the best cloud configuration. This process takes about 3 minutes with parallelization on a 16-core machine. The reconfiguration is done by restarting servers all at once, thus making data unavailable transiently.
3. *Selecta*: We use Selecta's SVD prediction model to select the optimized homogeneous configuration with workload changes. We populate the SVD matrix with the same training data as used for training of OPTIMUSCLOUD. Further, we give a benefit to Selecta that all the workload characteristics are assumed to be pre-filled in the matrix (or close to it) so that it does not have to execute and profile the workload that arrives at runtime, but can be looked up in the matrix. Both CherryPick and Selecta run reactively with workload changes and neither can change the application configuration. They operate in a greedy manner initiating reconfiguration whenever the workload changes, unlike OPTIMUSCLOUD that optimizes for the workload over a lookahead time window.
4. *SOPHIA*: We use SOPHIA for homogeneous NoSQL configurations while the VM configurations are fixed to the recommended VM types in Cassandra's and Redis' documentations i.e., Compute-Optimize C4.large for Cassandra [2] and Memory-Optimized R4.large for Redis [1].
5. *Theoretical-Best*: This is a baseline that knows what is the best-performing configuration for every workload. It then switches the cluster to this configuration without any downtime cost. Though impractical, this baseline provides a quantitative upper bound for any protocol and is used for normalization of our results.

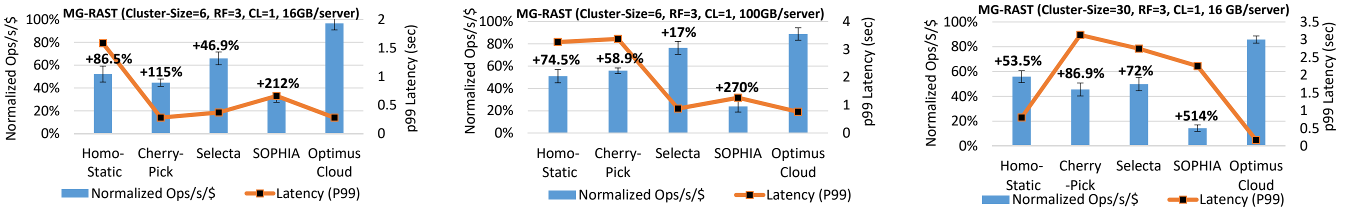

Figure 8: Evaluation of MG-RAST traces in Cassandra using OPTIMUSCLOUD *vs state-of-the-art tuning systems. The primary Y-axis represents the ratio of the normalized Ops/s/$ achieved by each system to the theoretical-best performance.* OPTIMUSCLOUD *achieves the highest Perf/$ and lowest P99 latency.*

4.3 End-to-end System Evaluation

We evaluate how effective OPTIMUSCLOUD and each of the baselines are in selecting the best reconfiguration plan. In Fig. 8 we show the evaluation for the MG-RAST application, the most challenging one for us due to its unpredictable workload characteristics. We use a 1 hour trace from MG-RAST and apply it to a cluster of 6 or 30 servers We show the performance of the different plans with data volume per server of 16GB and 100GB. The performance of each solution is normalized by that of the Theoretical-Best. OPTIMUSCLOUD's plan achieves the highest Ops/s/$ and the lowest latency over all baselines. OPTIMUSCLOUD achieves 86% and 74% improvement over Homogeneous-Static for the 16GB and 100GB cases respectively. This shows there is no single static configuration that can achieve the optimal performance for all phases of the workload. Compared to CherryPick and Selecta, OPTIMUSCLOUD achieves 87% and 45% improvement on average. This is because both systems are striving to create a homogeneous configuration to meet the performance requirement and end up increasing the cost. Further, CherryPick incurs the delay of performing the Bayesian optimization, which takes 3 minutes on average and causes the cluster to operate with sub-optimal configurations during this long delay. The aggressive reconfiguration of CherryPick and Selecta (shutting down all servers and restarting all together) causes a significant performance hit (throughput of zero) for the cluster. Compared to SOPHIA, OPTIMUSCLOUD achieves 212% and 270% improvement in Perf/$. This highlights the benefit of jointly tuning VM and database configurations.

We draw several other conclusions. First, with increasing data volume, the throughput of all protocols goes down because what would once fit in memory (R4.large has 16 GB) now has to go to disk. But the effect on Selecta and CherryPick is smaller because they use expensive and well-resourced memory VMs. Consequently, the performance benefit of OPTIMUSCLOUD decreases. Second, Selecta is achieving better performance than CherryPick, which is consistent with the results reported in [32]. This is because of the longer response time of CherryPick's Bayesian Optimization versus Selecta's matrix lookup. In terms of latency, OPTIMUSCLOUD scales well (comparing the N=6 to N=30), while Selecta and CherryPick both suffer (latency increases of 7.4× and 11×). This is because the control message traffic is very large in these two baselines as they aggressively shut down and restart all the servers together to achieve a reconfiguration, causing the scalability bottleneck. We also notice that SOPHIA scalability is better than the other baselines as it performs sequential reconfiguration. OPTIMUSCLOUD achieves as low tail-latency as Selecta and CherryPick for small scales, and lower at larger scale due to the reason above. Homogeneous-Static has a high latency for all cases due to its inability to adapt to dynamic workloads. The comparison with Selecta and CherryPick shows how important it is to apply *online* reconfiguration to minimize tail-latencies for fast changing workloads.

4.4 Sensitive Parameter Identification

We test the feasibility of pruning the joint configuration search space (i.e., VM and NoSQL), while maintaining the dependencies among the configuration parameters. We collect a total of 3K data points equally from 15 different VM types. We use D-optimal design to decide which data points to collect for building the performance prediction model. Fig. 7 shows the importance of the most impactful parameters, either singly or pairwise, as determined from the regression model. The instance architecture (EC2) and the workload (W(t)) are the most impactful, followed by top-5 database configuration parameters. Note that the costs of changing different configuration parameters are different as it takes about 90 sec to change EC2 type, whereas changing Cassandra's configuration only requires around 30 sec with no impact on the cluster's $ cost. Expectedly, the instance architecture has high inter-dependency with the NoSQL parameters because the architecture controls the physical resources available to the DBMS.

4.5 Single Server Performance Prediction

We evaluate three possible single server prediction models for inclusion in OPTIMUSCLOUD. In each case, we use a Random Forest using 75%:25% for training and prediction.
1. *N-Solitary-Models*: This builds a separate prediction model per architecture. It predicts the performance of a given architecture/configuration combination using previously collected data points from the same architecture.
2. *Combined-Categorical*: This builds a combined model using all points from all architectures, while it represents the architecture as a categorical parameter (with integral values).

Workload	MG-RAST		BUS		HPC	
Metric	R^2	*RMSE*	R^2	*RMSE*	R^2	*RMSE*
N-Solitary -Models	0.2	3401.4	0.127	109.9	0.04	2778
Selecta	-0.14	4149.3	0.66	110.6	0.932	2451
OPTIMUS -Categorical	0.41	1334.2	0.986	21.87	0.983	1172.9
OPTIMUS -Numerical	**0.89**	**1260.9**	**0.988**	**19.77**	**0.986**	**1076.2**

Table 3: ***Comparison of different Single-server prediction techniques.*** OPTIMUSCLOUD ***achieves better performance in terms of R^2 and RMSE over all baselines.***

Thus, knowledge transfer is limited across architectures.
3. *Combined-Numerical*: This also builds a combined model for all architectures. However, it describes the architecture in terms of its resources e.g., C4.large is represented as vCPU 8, RAM 3.75 GB, Network-Bandwidth 0.62 Gbits/s. Thus this allows extrapolating model knowledge across architectures. We test the accuracy of each predictor using the same number of data points (100 points per architecture) and show the result in terms of R^2 (Table 3). We see that using a separate model per architecture gives very poor performance due to the lack of knowledge transfer between architectures. Moreover, the numerical representation shows a significant improvement in prediction performance over the categorical representation due to better knowledge transfer across architectures. Thus, we use the *Combined-Numerical* model in OPTIMUSCLOUD.

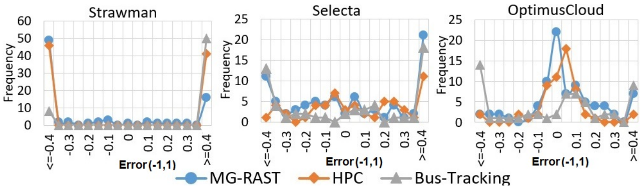

Figure 9: Performance prediction error histogram for heterogeneous clusters. We notice that OPTIMUSCLOUD***'s error percentage is within -15% to +15% for 70% of the test points, with R^2 value of 0.91 and RMSE of 7.7 KOps/s. On the other hand, the best strawman shows poor performance (RMSE 36 KOps/s) while Selecta performs better (RMSE 21 KOps/s).***

4.6 Cluster Performance Prediction

We evaluate the accuracy of our cluster performance prediction model. We use a cluster of 6 nodes with RF=3, CL=1 and investigate the impact of changing the EC2 architecture of each *Complete-Set*. Thus, the cluster is partitioned into 3 *Complete-Set*s. We use 3 families of EC2's 4th generation (C4, R4, M4) and three different sizes of each family (large, xlarge, 2xlarge). We collect 330 data points covering all combinations of assigning instance types to these 3 *Complete-Set*s.

In Fig. 9, we compare our model with a strawman predictor that uses the sum of Ops/s for each individual server as the overall cluster performance (we also tested Average, Min, and Max and got worse performance). This strawman achieves poor prediction performance with a low R^2 value of 0.08 and an unacceptably high RMSE of 36 KOps/s. We also compare our model with the latent factor collaborative filtering technique, SVD, used in Selecta [32], which we reimplement using the sci-kit `surprise` library [30]. Selecta achieved better R^2 value of 0.69 and a lower RMSE of 21 KOps/s compared to the strawman predictor. However, our model achieves better performance due to the fact that our Random-Forest model can use non-linear combinations of the elementary features (up to quadratic), while SVD is confined to using linear combinations only. The shapes of the error curves are also different—the Selecta and the strawman curves are bathtub-shaped indicating significant overestimation or underestimation, while the OPTIMUSCLOUD curve is bell-shaped with a mean close to zero. The bathtub curves are due to the fact that these protocols are ignorant of the token assignment of the cluster and consider erroneously that each node's throughput has the same contribution to the cluster throughput.

4.7 Evaluation with Diverse Workloads

Now we evaluate the performance for different workloads, cluster scales, and (RF, CL) requirements.

HPC Workload: Figure 10 shows the improvement of OPTIMUSCLOUD over the baselines for the HPC data analytics traces. We first change RF from 1 to 3, holding CL at 1. Then we change CL from 1 to quorum, which is 2, holding RF at 3. OPTIMUSCLOUD's plan achieves the highest Perf/$ and the lowest latency over all baselines for all setups. At RF=3, OPTIMUSCLOUD achieves 20% and 24% better Perf/$ over Homogeneous-Static configuration for CL=1 and CL=Q respectively. This again shows the importance of dynamic reconfiguration to handle workloads with changing characteristics. In comparison to CherryPick, OPTIMUSCLOUD achieves 143% and 89% better performance for CL=1 and CL=Q respectively and 130% and 80% over Selecta. Compared to SOPHIA, OPTIMUSCLOUD achieves 23% and 12.5% better Perf/$. Notice that when RF=1 and CL=1, OPTIMUSCLOUD can no longer perform non-atomic configurations since the *Complete-Set* in this case is the entire cluster. Thus, its improvement over Homogeneous-Static decreases to 9%.
As RF goes up, the amount of data on each node goes up bringing down the absolute performance. Homogeneous-Static is affected more than OPTIMUSCLOUD and therefore the benefit of OPTIMUSCLOUD increases. CherryPick and Selecta are relatively unaffected by increasing RF as they had low throughputs to begin with and they reconfigure all the nodes at once, irrespective of RF and CL. SOPHIA benefits from increasing RF since it can reconfigure more servers concurrently without degrading data availability. As CL goes up, again CherryPick and Selecta are relatively unaffected. The performance of OPTIMUSCLOUD goes down because the maximum number of *Complete-Sets* that OPTIMUSCLOUD can reconfigure at a time is inversely proportional to CL. Thus, its benefit over CherryPick and Selecta reduces. However, we note that for most of our target environments, CL is unlikely

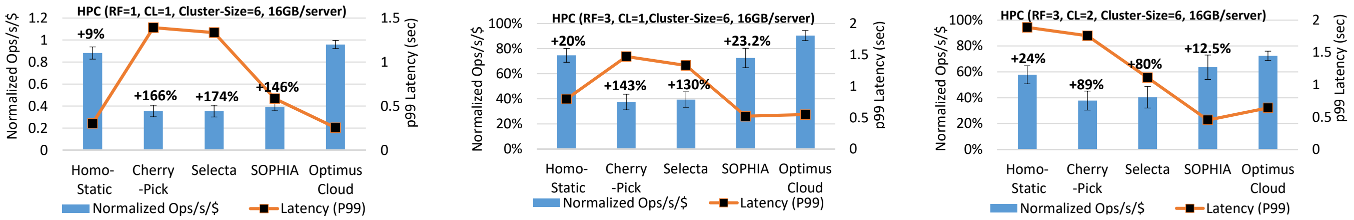

Figure 10: HPC workload evaluation with 10 concurrent jobs, and varying (RF,CL) requirements

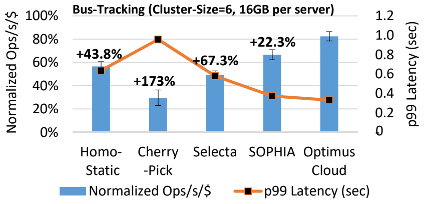

Figure 11: Bus-Tracking workload pattern with RF=3, CL=1

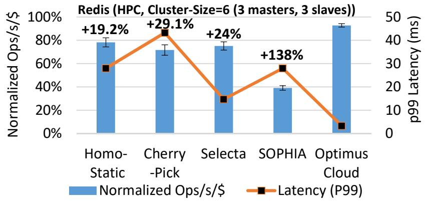

Figure 12: Evaluation on Redis for HPC workload with a cluster of 6 servers

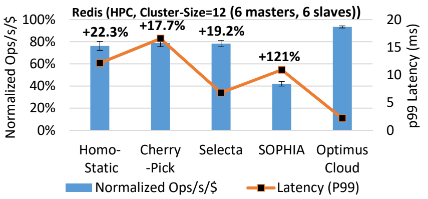

Figure 13: Evaluation on Redis for HPC workload with a cluster of 12 servers

to be higher than 1 as deployments often favor availability and latency over consistency. In terms of latency, OPTIMUSCLOUD achieves the lowest P99 latency across all setups. We also notice that SOPHIA has lower latency than other baselines as it performs a gradual reconfiguration of the different server instances to maintain data availability.

Bus-Tracking Workload: This workload has strong weekly and daily patterns, which allows the workload predictor to provide accurate predictions for long lookahead periods. For a 1 day-trace, the result is shown in Fig. 11. OPTIMUSCLOUD achieves better performance/$ over Homogeneous-Static, CherryPick, Selecta, and SOPHIA by 46%, 178%, 67%, and 28% respectively. As before, OPTIMUSCLOUD achieves the lowest tail latency across all techniques. The tail latency metric is very important for this workload as it represents a user-facing application. We observe that OPTIMUSCLOUD achieves higher gains in performance over CherryPick and Selecta compared to the MG-RAST workload, which shows the benefit of longer accurate predictions for OPTIMUSCLOUD.

4.8 Evaluation with Redis

Redis has a very different architecture than Cassandra and is therefore a suitable target to evaluate the generalizability of OPTIMUSCLOUD. Here we use Redis in clustered mode as a distributed cache (a common use case for Redis)—if the key is found in Redis' memory, it is served by Redis, else, it is served by a slower disk-based database. We apply the HPC analytics workload to a cluster of 6 or 12 Redis servers, keeping the replication degree as 2. We select HPC workload as it has the shortest key-reuse-distance between the three workloads and for which using Redis as a cache is most beneficial [10, 21]. We tune Redis' `maxmemory-policy` and `maxmemory` parameters and observe that changing the cloud configurations for more or less RAM size has an impact on the best value of both parameters. We also found that Redis' Perf/$ is sensitive to workload parameters such as job size, access distribution, and read-to-write. We start by collecting 108 data points for different jobs with varying job sizes, access distributions, and read-write ratios. Job size is a random variable with U(0.5M,1.5M) operations. Access distribution is randomly selected from *Uniform*, *Latest*, and *Zipfian*. Read-write ratio is a random variable with distribution U(0,1). We experiment with traces of 75 jobs which span a total of 5 hours. Our performance predictor achieves an R^2 of 0.922 averaged over 20 runs. From Fig. 12, we see that OPTIMUSCLOUD achieves a better Perf/$ of 19% (Homogeneous-Static), 29% (CherryPick), 24% (Selecta), and 138% (SOPHIA). Also, OPTIMUSCLOUD reduces the tail latency by 8.4X (Homogeneous-Static), 13X (CherryPick), 4.4X (Selecta), and 8.1X (SOPHIA).

We draw the following insights. First, as SOPHIA uses an expensive cluster of R4.large (as recommended in Redis' documentation [1]), it achieves a very low Perf/$. Second, both CherryPick and Selecta switch from R4.large to the less expensive C4.large and M4.large when the workload changes (and less memory is required) and therefore achieve a higher Perf/$. Finally, by using a heterogeneous cluster of the three VM types as well as jointly tuning the application configuration, we achieve the best Perf/$ and the lowest latency among all techniques. To test scalability, we increase the number of servers to 12 (Fig. 13) and note that the normalized performance of each system stays approximately constant.

4.9 Tolerance to Prediction Errors

We investigate how tolerant OPTIMUSCLOUD is to errors in both predictors—performance (throughput) and workload. We add synthetic noise to the output of each predictor separately and then show how does the benefit of OPTIMUSCLOUD change with the amount of synthetic noise for the HPC workload. The percentage of noise is represented as a uniform random variable that is added to (or subtracted from) the output of the predictor. For performance prediction,

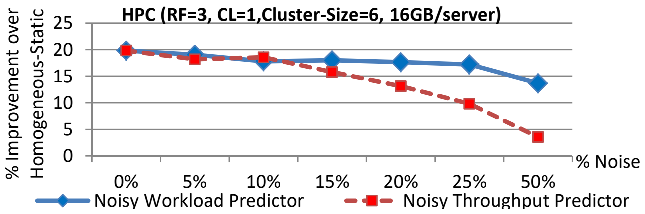

Figure 14: Impact of noisy predictions on* OptimusCloud*'s improvement over best Homogeneous-Static configurations

the noise is added to the overall throughput/$ predicted by our multi-server model. For workload prediction, the noise is added to the number of requests/sec in addition to the workload change duration. As shown in Fig.14, OptimusCloud's improvement over Homogeneous-Static decreases with increasing levels of noise, as the selected configurations deviate from the best configurations. We note that OptimusCloud is more sensitive to errors in the throughput predictor compared to errors in the workload predictor, which is demonstrated in the steeper downward slope in the noisy throughput predictor curve. The reason for this high sensitivity is that OptimusCloud uses the throughput predictor to select the best configuration and with increasing levels of noise, the selected configuration more frequently deviates from the optimal. As discussed earlier, a slight deviation from the optimal configuration may cause a significant reduction in Perf/$. On the other hand, slight errors in workload prediction causes OptimusCloud to reconfigure earlier or later than it optimally should. However, this has less impact on performance as long as it still switches to the best configuration.

5 Related Work

Configuration tuning for datastores: Several works [6, 31] target online configuration tuning for replicated or geo-replicated datastores. [27, 56] perform online reconfiguration for NoSQL datastores. None of these works address how to optimize for cost-performance benefits by exploiting different cloud VM/instance types. A large body of work focused on the best logical or physical design for static workloads in DBMS [3,12,13,18,29,51,52,61], which are orthogonal to our work. OtterTune [62], BerkeleyDB [60], and iTuned [24] only optimize DBMS configuration, while OptimusCloud optimizes both NoSQL configuration and the cluster on which it runs. Pocket [33] optimizes the storage servers for ephemeral data analytics jobs in contrast to handling long-running jobs that are OptimusCloud's focus. While OptimusCloud can also optimize storage, we choose to restrict our storage servers to elastic block storage (EBS) that are separate from the VMs and thus retain data durability.

Performance predictions: Ernest [63] predicts performance of data analytics applications through system modeling. DBSeer [46] uses linear models to predict resource utilization (e.g. Disk I/O). Myria [49, 66] gives personalized SLAs by predicting query execution times for specific workloads. Recent works [42, 43, 45] improve utilization by *learning* workload characteristics. [44] handles prediction errors for unseen workloads. [23] uses queuing models. Rafiki [40] uses a surrogate model to predict performance of NoSQL datastores. No prior work predicts performance for heterogeneous clusters.

Cache Hit-Rate Maximization: Several works target maximizing cache hit-rates and improving end-to-end latency, either for a single application [14] or multi-tenant deployments [15]. However, neither VM configurations nor heterogeneous cluster configurations are considered to optimize performance/$. [9, 65] propose new cache eviction policies that can be implemented in Redis and then selected by OptimusCloud for the appropriate workloads.

6 Discussion

Impact on consistency: OptimusCloud exploits the fact that in typical NoSQL deployments, RF>CL as availability and low-latency are favored over consistency [22, 47, 57]. The higher the difference between RF and CL, the smaller the subset of servers that needs reconfiguration, therefore the higher the gain of OptimusCloud over baselines (Figure 10). For users whose primary goal is consistency and want to use a high value for CL, one option is to also increase RF and leverage the high gain of OptimusCloud. However, increasing RF also increases the total number of copies stored in the cluster, which might negatively impact the cluster's write performance in exchange for higher availability.

Compatibility with other key-value stores: OptimusCloud's design assumes that the underlying key-value store implements a protocol to identify and select the fastest replica(s) given a new query. Cassandra achieves this using its dynamic snitching policy, while other popular systems have similar protocols (e.g., Elasticsearch achieves this by its Adaptive Replica Selection policy [25]). If this feature is not implemented in the system, a simple solution is for OptimusCloud to provide the system with the ordered list of replicas, using OptimusCloud 's performance predictor.

7 Conclusion

For cost-optimal performance of a distributed NoSQL cloud database, it is critical to jointly tune NoSQL and cloud configurations. OptimusCloud provides the insight that it is optimal to create heterogeneous configurations and for this, it determines at runtime the *minimum number of servers* to reconfigure. Using a novel concept of Complete Sets, OptimusCloud provides a technique to search through the large search space brought out by heterogeneity. Configurations found by OptimusCloud outperform those by prior works, CherryPick, Selecta, and SOPHIA, in both Perf/$ and tail latency, across two NoSQL DBMSs, Cassandra and Redis, and all experimental conditions.

Serverless in the Wild: Characterizing and Optimizing the Serverless Workload at a Large Cloud Provider

Mohammad Shahrad, Rodrigo Fonseca, Íñigo Goiri, Gohar Chaudhry, Paul Batum,
Jason Cooke, Eduardo Laureano, Colby Tresness, Mark Russinovich, and Ricardo Bianchini *

Microsoft Azure and Microsoft Research

Abstract

Function as a Service (FaaS) has been gaining popularity as a way to deploy computations to serverless backends in the cloud. This paradigm shifts the complexity of allocating and provisioning resources to the cloud provider, which has to provide the illusion of always-available resources (*i.e.*, fast function invocations without cold starts) at the lowest possible resource cost. Doing so requires the provider to deeply understand the characteristics of the FaaS workload. Unfortunately, there has been little to no public information on these characteristics. Thus, in this paper, we first characterize the entire production FaaS workload of Azure Functions. We show for example that most functions are invoked very infrequently, but there is an 8-order-of-magnitude range of invocation frequencies. Using observations from our characterization, we then propose a practical resource management policy that significantly reduces the number of function cold starts, while spending fewer resources than state-of-the-practice policies.

1 Introduction

Function as a Service (FaaS) is a software paradigm that is becoming increasingly popular. Multiple cloud providers offer FaaS [5, 17, 21, 28] as the interface to usage-driven, stateless (serverless) backend services. FaaS offers an intuitive, event-based interface for developing cloud-based applications. In contrast with the traditional cloud interface, in FaaS, users do not explicitly provision or configure virtual machines (VMs) or containers. FaaS users do not pay for resources they do not use either. Instead, users simply upload the code of their functions to the cloud; functions get executed when "triggered" or "invoked" by events, such as the receipt of a message (*e.g.*, an HTTP request) or a timer going off. The provider is then responsible for provisioning the needed resources (*e.g.*, a container in which to execute each function), providing high function performance, and billing users just for their actual function executions (*e.g.*, in increments of 100 milliseconds).

Obviously, providers seek to achieve high function performance at the lowest possible resource cost. There are three main aspects to how fast functions can execute and the resources they consume. First, function execution requires having the needed code (*e.g.*, user code, language runtime libraries) in memory. A function can be started quickly when the code is already in memory (warm start) and does not have to be brought in from persistent storage (cold start). Second, keeping the resources required by all functions in memory at all times may be prohibitively expensive for the provider, especially if function executions are short and infrequent. Ideally, the provider wants to give the illusion that all functions are always warm, while spending resources as if they were always cold. Third, functions may have widely varying resource needs and invocation frequencies from multiple triggers. These characteristics severely complicate any attempts to predict invocations for reducing resource usage. For example, the wide range of invocation frequencies suggests that keeping resources in memory may work well for some functions but not others. With respect to triggers, HTTP triggers may produce invocations at irregular intervals that are difficult to predict, whereas timers are regular.

These observations make it clear that providing high function performance at low cost requires a deep understanding of the characteristics of the FaaS workload. Unfortunately, there has been no public information on the characteristics of production workloads. Prior work [3, 15, 24, 25, 27, 44] has focused on either (1) running benchmark functions to assess performance and/or reverse-engineer how providers manage resources; or (2) implementing prototype systems to run benchmark functions. In contrast, what is needed is a comprehensive characterization of the users' *real* FaaS workloads on a *production* platform from the provider's perspective.

Characterizing production workloads. To fill this gap, in this paper, we first characterize the entire production FaaS workload of Azure Functions [28]. We characterize the real functions and their trigger types, invocation frequencies and patterns, and resource needs. The characterization produces many interesting observations. For example, it shows that most functions are invoked very infrequently, but the most popular functions are invoked 8 orders of magnitude more frequently than the least popular ones. It also shows that functions exhibit a variety of triggers, producing invocation patterns that are often difficult to predict. In terms of resource needs, the characterization shows a 4x range of function memory usage and that 50% of functions run in less than 1 second.

Researchers can use the distributions of the workload characteristics we study to create realistic traces for their work.

[*] Shahrad is affiliated with Princeton University, but was at MSR during this work. Laureano and Tresness are now with Facebook and D. E. Shaw.

Alternatively, they can use the sanitized *production traces* we are making available with this paper [31].

Managing cold-start invocations. Using observations from our characterization, we also propose a practical resource management policy for reducing the number of cold start executions while consuming no more resources than the large cloud providers' current policies. Specifically, AWS and Azure use a fixed "keep-alive" policy that retains the resources in memory for 10 and 20 minutes after a function execution, respectively [39, 40]. Though this policy is simple and practical, it disregards the functions' actual invocation frequency and patterns, and thus behaves poorly and wastes resources.

In contrast, our policy (1) uses a different keep-alive value for each user's workload, according to its actual invocation frequency and pattern; and (2) enables the provider in many cases to pre-warm a function execution just before its invocation happens (making it a warm start). Our policy leverages a small histogram that keeps track of the recent function inter-invocation times. For workloads that exhibit clear invocation patterns, the histogram makes clear how much keep-alive is beneficial and when the pre-warming should take place. For workloads that do not, our policy reverts back to the fixed keep-alive policy. As the histogram must be small, for any workloads that cannot be captured by the histogram but exhibit predictable invocation patterns, our policy uses time-series analysis to predict when to pre-warm.

We implement our policy in simulation and for the Apache OpenWhisk [34] FaaS platform, both driven with real workload traces. Our simulation results show that the policy significantly reduces the number of function cold starts, while spending fewer resources than the fixed keep-alive policy. Our experimental results show that the policy can be easily implemented in real systems with minimal overheads. In fact, we describe our recent production implementation in Azure Functions in the end of the paper.

Contributions. In summary, our main contributions are:

- A detailed characterization of the entire production FaaS workload at a large cloud provider;
- A new policy for reducing the number of cold start function executions at a low resource provisioning cost;
- Extensive simulation and experimental results based on real traces showing the benefits of the policy;
- An overview of our implementation in Azure Functions;
- A large sanitized dataset containing production FaaS traces.

2 Background

Abstraction. In FaaS, the user uploads code to the cloud, and the provider enables a handle (*e.g.*, a URL) for the code to be run. The choices of which resources to allocate, when to allocate them, and for how long to retain them, still have to be made, but they are shifted to the cloud provider.

Triggers. Functions can be invoked in response to several event types, called triggers [6, 29]. For clarity, in this paper we group Azure's many triggers into 7 classes: HTTP, Event, Queue, Timer, Orchestration, Storage, and others. Event triggers include Azure Event Hub and Azure Event Grid, and are used for discrete or serial events, with individual or batch processing. Queue-triggered functions respond to message insertion in a number of message queueing solutions, such as Azure Service Bus and Kafka. Timer triggers are similar to cron jobs, and cause function invocations at pre-determined, regular intervals. We grouped all triggers related to Azure Durable Functions [30] as Orchestration. One can use these triggers to create native, complex function chaining and orchestration. Finally, we grouped database and filesystem triggers as Storage. These fire in response to changes in the underlying data, and include Azure Blob Storage and Redis.

Applications. In Azure Functions, functions are logically grouped in applications, *i.e.* an application may encompass multiple functions. The application concept helps organize the software and in packaging. *The application, not the function, is the unit of scheduling and resource allocation*.

Cold starts. A *cold start* invocation occurs when a function is triggered, but its application is not yet loaded in memory. When this happens, the platform instantiates a "worker" [1] for the application, loads all the required runtime and libraries, and calls the function. This process can take a long time relative to the function execution [44]. There are strategies to reduce the time taken by each cold start, such as keeping pre-allocated VMs or containers, instantiated virtual network interfaces [32], or pre-loaded runtimes that can be specialized on-demand [18]. In this paper, we focus on the complementary and orthogonal goal of reducing the number of cold starts.

Concurrency and elasticity. A running instance of an application can respond to a configurable number of concurrent invocations of its functions. The number depends on the nature of the function, and its resource needs. Cold starts can also happen if there is a spike in the load to an application, and new instances have to be allocated quickly. Given full-server instances and our real FaaS workload, only a tiny percentage (<1%) of applications would experience this type of cold start. For this reason, we do not consider it in this paper.

Cold start management policy. A key aspect of FaaS is the trade-off between reducing cold starts by keeping instances warm, and the resources (*e.g.*, VMs, memory) they need.

Most FaaS providers use a fixed keep-alive policy for all applications, where application instances are kept loaded in memory for a fixed amount of time after a function execution [39, 40]. This is also the case for most open-source implementations (*e.g.*, OpenWhisk uses a 10-minute period).

This policy is simple to implement and maintain, but does not consider the wide variety of application behaviors our characterization unearths. Thus, it can have many cold starts while wasting resources for many applications. Moreover, it is easy to identify by external users, who sometimes invoke their applications frequently enough (perhaps with dummy

[1] In some systems, a worker is a container, but in others it can be a VM.

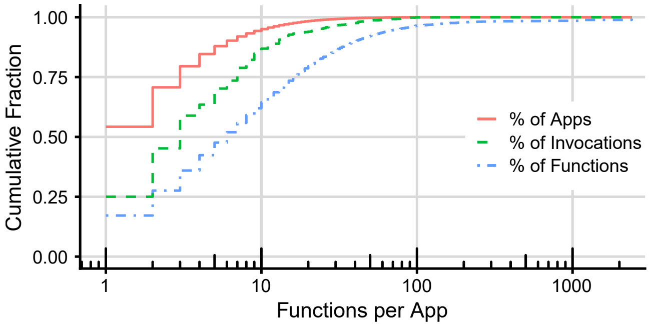

Figure 1: Distribution of the number of functions per app.

invocations) to keep them warm. This practice amplifies the resource waste issue. In this paper, we design a better policy.

3 FaaS Workloads

We characterize the FaaS workloads seen by Azure Functions, focusing on characteristics that are intrinsic to the applications and functions (*e.g.*, their arrival pattern), and not on the characteristics that relate to the underlying platform (*e.g.*, where functions are scheduled). Throughout the characterization, we highlight interesting observations and their implications for cold starts and resource management.

3.1 Data Collection

We collected data on all function invocations across Azure's entire infrastructure between July 15th and July 28th, 2019. We collected four related data sets:

1. Invocation counts: per function, in 1-minute bins;
2. Trigger per function;
3. Execution time per function: average, minimum, maximum, and count of samples, for each 30-second interval, recorded per worker; and
4. Memory usage per application: sampled every 5 seconds by the runtime and averaged, for each worker, each minute. Average, minimum, maximum, and count of samples, for allocated and resident memory.

With this paper, we are releasing a subset of our traces at https://github.com/Azure/AzurePublicDataset.

Limitations. Given the extreme scale of Azure Functions, the invocation counts are binned in 1-minute intervals, *i.e.* our dataset does not allow the precise reconstruction of interarrival times that are smaller than one minute. For this paper, this granularity is sufficient.

For the execution time, we also do not have the complete time distribution across all invocations. However, from the many samples of average time, and corresponding counts, we keep a set of weighted percentiles, where the weight of an entry is the number of samples. For example, if we see an average time of 100ms over 45 samples, the resulting percentiles are equivalent to those computed over a distribution where 100ms are replicated 45 times. The quality of the approximation to the true distribution depends on the number of samples in each bin, the smaller the better. We similarly obtain weighted percentiles for memory usage.

Trigger	%Functions	%Invocations
HTTP	55.0	35.9
Queue	15.2	33.5
Event	2.2	24.7
Orchestration	6.9	2.3
Timer	15.6	2.0
Storage	2.8	0.7
Others	2.2	1.0

Figure 2: Functions and invocations per trigger type.

For confidentiality reasons, we cannot disclose some absolute numbers, such as total number of functions and invocations. Nevertheless, our characterization is useful for understanding a full FaaS workload, and for researchers and practitioners to generate realistic FaaS workloads.

3.2 Functions, Applications, and Triggers

Functions and applications. Figure 1 shows the CDF of the number of functions per application (top curve). We observe that 54% of the applications only have one function, and 95% of the applications have at most 10 functions. About 0.04% of the applications have more than 100 functions.

The other two curves show the fraction of invocations, and functions, corresponding to applications with up to a certain number of functions. For example, we see that 50% of the invocations come from applications with at most 3 functions, and 50% of the functions are part of applications with at most 6 functions. Though we found a weak positive correlation between the number of functions in an application and the median number of invocations of those applications, the number of functions in an application is not a useful signal in resource management.

We took a closer look at the 10 applications with the most functions. Only 4 had more than 1k functions: these, and 3 others, had a pattern of auto-generated function names triggered by timers or HTTP, which suggests that they were being used for large automated testing. Of the remaining 3 applications, two were using Azure Durable Functions for orchestrating multiple functions, and one seems to be an API application, where each function corresponds to one route in a large Web or REST application. We plan to do a broader and more comprehensive study of application patterns in future work.

Triggers and applications. Figure 2 shows the fraction of all functions, and all invocations, per type of trigger. HTTP is the most popular in both dimensions. Event triggers correspond to only 2.2% of the functions, but to 24.7% of the invocations, due to their automated, and very high, invocation rates. Queue triggers also have proportionally more invocations than functions (33.5% vs 15.2%). The opposite happens with timer triggers. There are many functions triggered by timers (15.6%), but they correspond to only 2% of the invocations, due to the relatively low rate they fire in: 95% of the timer-triggered functions in our dataset were triggered at most once per minute, on average.

Trigger Type	% Apps
HTTP (H)	64.07
Timer (T)	29.15
Queue (Q)	23.70
Storage (S)	6.83
Event (E)	5.79
Orchestration (O)	3.09
Others (o)	6.28

(a) Apps with ≥ 1 of each trigger.

Trigger Types	Fraction of Apps (%)	Cum. Frac. (%)
H	43.27	43.27
T	13.36	56.63
Q	9.47	66.10
HT	4.59	70.69
HQ	4.22	74.92
E	3.01	77.92
S	2.80	80.73
TQ	2.57	83.30
HTQ	2.48	85.78
Ho	1.69	87.48
HS	1.05	88.53
HO	1.03	89.56

(b) Popular trigger combinations.

Figure 3: Trigger types in applications.

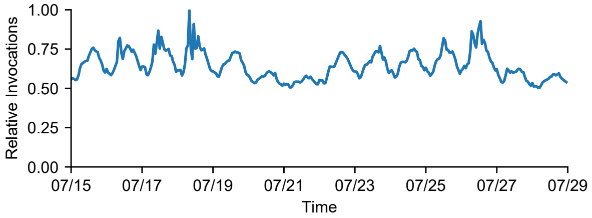

Figure 4: Invocations per hour, normalized to the peak.

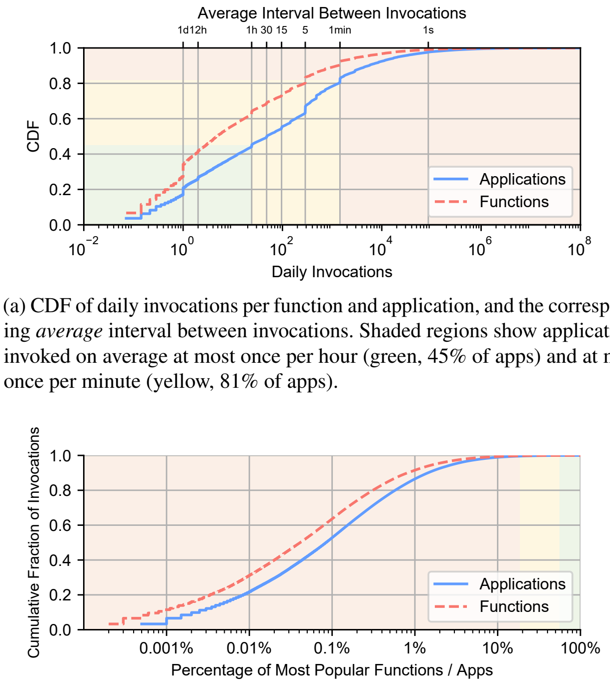
Figure 3 shows how applications combine functions with different trigger types. In Figure 3(a), we show the applications with at least one trigger of the given type. We find that 64% of the applications have at least one HTTP trigger, and 29% of the applications have at least one timer trigger. As applications can have multiple triggers, the fractions sum to more than 100%. In Figure 3(b), we partition the applications by their combinations of triggers. 43% of the applications have *only* HTTP triggers, and 13% of the apps have *only* timer triggers. Combining the two tables, we find that 15.8% of the applications have timers and at least one other trigger type. For predicting invocations, as we discuss later, while timers are very predictable, 86% of the applications have either no timers or timers combined with other triggers.

3.3 Invocation Patterns

We now look at dynamic function and application invocations. Figure 4 shows the volume of invocations per hour, across the entire platform, relative to the peak hourly load on July 18th. There are clear diurnal and weekly patterns (July 20th, 21st, 27th, and 28th are weekend days), and a constant baseline of roughly 50% of the invocations that does not show variation. Though we did not investigate this specifically, there can be several causes, *e.g.* a combination of human and machine-generated traffic, plain high-volume applications, or the overlapping of callers in different time zones.

Figure 5(a) shows the CDF of the average number of invocations per day, for a representative sample of both functions and applications. The invocations for an application are the sum over all its functions. First, we see that the number of invocations per day varies by over 8 orders of magnitude for functions and applications, making the resources the provider has to dedicate to each application also highly variable.



(a) CDF of daily invocations per function and application, and the corresponding *average* interval between invocations. Shaded regions show applications invoked on average at most once per hour (green, 45% of apps) and at most once per minute (yellow, 81% of apps).

(b) Fraction of total function invocations by the fraction of the most popular functions and applications. Same colors as in Figure 5(a).

Figure 5: Invocations per application and per function for a representative sample of the dataset.

The second observation with strong implications for resource allocation is that the vast majority of applications and functions are invoked, on average, very infrequently. The green- and yellow-shaded areas in the graph show, respectively, that 45% of the applications are invoked once per hour or less on average, and 81% of the applications are invoked once per minute or less on average. This suggests that the cost of keeping these applications warm, relative to their total execution (billable) time, can be prohibitively high.

Figure 5(b) shows the other side of the workload skewness, by looking at the cumulative fraction of invocations due to the most popular functions and applications in the sample. The shaded areas correspond to the same applications as in Figure 5(a). The applications in the orange-shaded area are the 18.6% most popular, those invoked on average at least once per minute. They represent 99.6% of all function invocations.

The invocation rates provide information on the average inter-arrival time (IAT) of function and application invocations, but not on the distribution of these IATs. If the next invocation time of a function can be predicted, the platform can avoid cold starts by pre-warming the application right before it is to be invoked, and save resources by shutting it

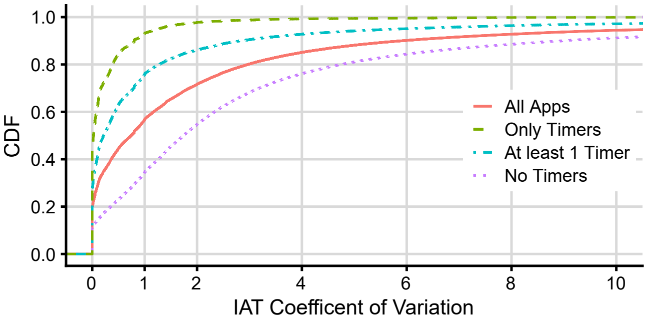


Figure 6: CV of the IATs for subsets of applications.

down right after execution.

Inter-arrival time variability. To gain insight into the IAT distributions of applications, we look at the coefficient of variation (CV) of each application. The CV (standard deviation divided by the mean) provides a measure of the variability in the IATs. We would expect timer-triggered functions to have periodic arrivals, with a CV of 0. Human-generated invocations should approximately follow a Poisson arrival process, with an exponential (memoryless) distribution of IATs [16]. These would ideally yield a CV of 1. CVs greater than 1 suggest significant variability.

Figure 6 shows the distribution of the CV across all applications, as well as for subsets of applications with and without timers. It shows that the real IAT distributions are more complex than the simply periodic or memoryless ones. For example, only ∼50% of the applications with only timer-triggered functions have a CV of 0. Multiple timers with different periods and/or phases will increase the CV. For applications with at least one timer, this fraction is less than 30%, and across all applications the fraction is ∼20%. Interestingly, ∼10% of applications with no timers have CV close to 0, which means they are quite periodic, and should be predictable. This could be due to, for example, external callers (e.g., sensors or IoT devices) that operate periodically. On the other hand, only a small fraction of applications has a CV close to 1, meaning that simple Poisson arrivals are not the norm. These results show that there is a significant fraction of applications that should have fairly predictable IATs, even if they do not have timer triggers. At the same time, these numbers suggest that for many applications predicting IATs is not trivial.

3.4 Function Execution Times

Another aspect of the workload is the function execution time, *i.e.* the time functions take to execute *after they are ready to run*. In other words, these numbers do not include the cold start times. Cold start times depend on the infrastructure to a large extent, and have been characterized in other studies [44].

Figure 7 shows the distribution of average, minimum, and maximum execution times of all function executions on July 15th, 2019. The distributions for other days are similar. The graph also shows a very good log-normal fit (via MLE) to the distribution of the averages, with log mean -0.38 and σ 2.36. We observe that 50% of the functions execute for less than 1s on average, and 50% of the functions have maximum execution time shorter than ∼3s; 90% of the functions take at most 60s, and 96% of functions take less than 60s on average.

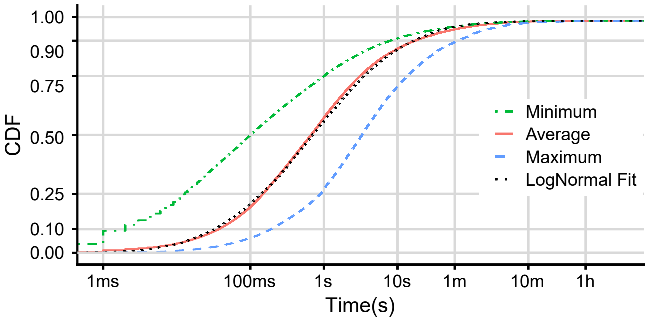

Figure 7: Distribution of function execution times. Min, avg, and max are separate CDFs, and use independent sorting.

The main implication is that the function execution times are at the same order of magnitude as the cold start times reported for major providers [44]. *This makes avoiding and/or optimizing cold starts extremely important for the overall performance of a FaaS offering.*

Another interesting observation is that, overall, functions in this FaaS workload are very short compared to other cloud workloads. For example, data from Azure [12] shows that 63% of all VM allocations last longer than 15 minutes, and only less than 8% of the VMs last less 5 minutes or less. This implies that FaaS imposes much more stringent requirements on the provider to stand-up resources quickly.

Idle times. As we discuss in Section 4, an important aspect of the workload for managing cold starts is idle time (IT), defined as the time between the end of a function's execution and its next invocation. IT relates to IAT and execution time. For most applications, the average execution time is at least 2 orders of magnitude smaller than the average IAT. We verified for the applications in the yellow region in Figure 5(a) – 81% of the applications invoked at most once per minute on average – that indeed the IT and IAT distributions are extremely similar.

Potential correlations. Different triggers had average function execution times differing by about 10×, between 200ms and 2s at the median, but all with the same shape for the distributions. One outlier was a class of orchestration functions with median average execution times of ∼30ms, as they simply dispatch and coordinate other functions.

3.5 Memory Usage

We finally look at the memory demands of applications. Recall that the application is the unit of memory allocation in the platform we study. Figure 8 shows the memory demand distribution, across all applications running on July 15th, 2019. We present three curves drawn from the memory data: 1st percentile, average, and maximum allocated memory for the application. We also plot a reasonably good Burr distribution fit (with parameters $c = 11.652$, $k = 0.221$, and $\lambda = 107.083$) for the average. Allocated memory is the amount of virtual

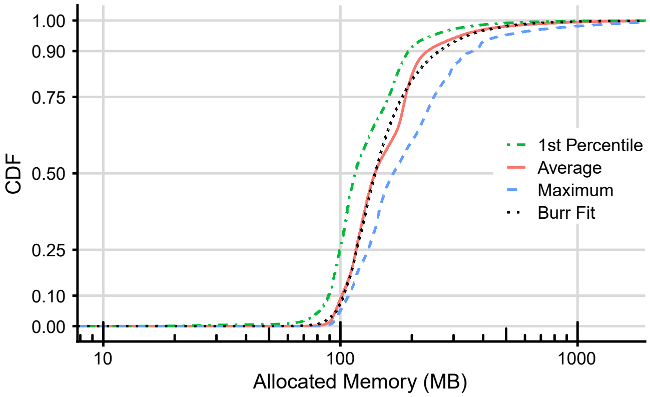

Figure 8: Distribution of allocated memory per application.

memory reserved for the application, and may not necessarily be all resident in physical memory. Here, we use the 1st percentile because there was a problem with the measurement of the minimum, which made that data not usable. Despite the short duration of each function execution, applications tend to remain resident for longer. The distributions for other days in the dataset are very similar.

Looking at the distribution of the maximum allocated memory, 90% of the applications never consume more than 400MB, and 50% of the applications allocate at most 170MB. Overall, there is a 4× variation in the first 90% of applications, meaning that memory is an important factor in warmup, allocation, and keep-alive decisions for FaaS.

Potential correlations. We found no strong correlation between invocation frequency and memory allocation or between memory allocation and function execution times.

3.6 Main Takeaways

From the point of view of cold starts and resource allocation, we now reiterate our three main observations. First, the vast majority of functions execute on the order of a few seconds – 75% of them have a maximum execution time of 10 seconds – so execution times are on the same order as the time it takes to start functions cold. Thus, it is critical to reduce the number of cold starts or make cold starts substantially faster. Eliminating a cold start is the same as making it infinitely fast.

Second, the vast majority of applications are invoked infrequently – 81% of them average at most one invocation per minute. At the same time, less than 20% of the applications are responsible for 99.6% of all invocations. Thus, it is expensive, in terms of memory footprint, to keep the applications that receive infrequent invocations resident at all times.

Third, many applications show wide variability in their IATs – 40% of them have a CV of their IATs higher than 1 – so the task of predicting the next invocation can be challenging, especially for applications that are invoked infrequently.

4 Managing Cold Starts in FaaS

We use insights from our characterization to design an adaptive resource management policy, called *hybrid histogram policy*. The goal is to reduce the number of cold start invocations with minimum resource waste. We refer to a *policy* as a set of rules that govern two parameters *for each application*:

— *Pre-warming window.* The time the policy waits, since the last execution, before it loads the application image expecting the next invocation. A pre-warming window = 0 means that the policy does not unload the application after one of its functions executes. Aggressive pre-warming (a large window) reduces resource usage but may also cause cold starts, in case the next invocation occurs sooner than expected.

— *Keep-alive window.* The time during which an application's image is kept alive after (1) it has been loaded to memory (pre-warming window ≥ 0) or (2) a function execution (pre-warming window = 0). (Note that our definition for this window differs from the keep-alive parameter in fixed keep-alive policies, which is the same for all applications and only starts at the end of function executions.) Longer windows have the potential to reduce cold starts by increasing the chances of an invocation falling into this window. However, this may also waste resources, *i.e.* leave them idle, in case the next invocation does not happen soon after loading.

A *no-unloading policy* would keep every application image loaded in memory all the time (*i.e.*, infinite keep-alive window and pre-warming window = 0). This policy would get no cold starts but would be too expensive to operate.

4.1 Design Challenges

Designing a *practical policy* poses several challenges:

1. **Hard-to-predict invocations.** As Figure 3 shows, many applications are triggered by timers. A timer-aware policy could leverage this information to pre-warm applications right before the next invocation. However, predicting the next invocation is challenging for other triggers.
2. **Heterogeneous applications.** As Figure 5 shows, the invocation frequency and pattern vary substantially across applications. A one-size-fits-all fixed policy is certain to be a poor choice for many applications. A better policy should adapt to each application dynamically.
3. **Applications with infrequent invocations.** Some applications are invoked very infrequently, so an adaptive policy would take some time to learn their invocation patterns. The same applies for applications that it sees for the first time.
4. **Tracking overhead.** Adapting the policy to each application means tracking each application individually. For this reason, the cost to track the information for each application should be small. For example, we need to consider the size of the data structures that will keep this state.
5. **Execution overhead.** Since function executions can be very short (*i.e.*, more than 50% of executions take less than 1 second), running the policy and updating its state need to be fast. This is especially critical considering providers charge users only during their function execution times (*e.g.*, based on CPU, memory). For instance, we cannot take 100 ms to update a policy for each 10 ms-long execution. Due

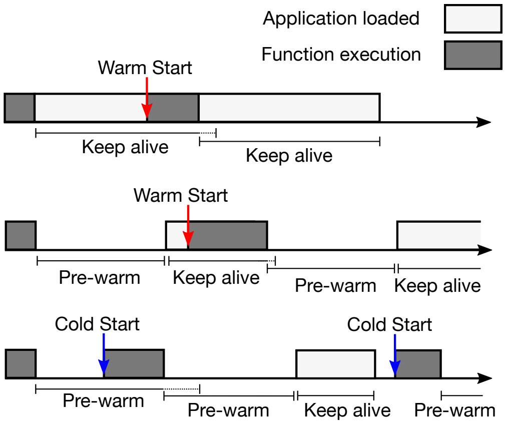

Figure 9: Timelines showing a warm start with keep alives and no pre-warming (top); a warm start following a pre-warm (middle); and two cold starts, before a pre-warm, and after a keep alive (bottom).

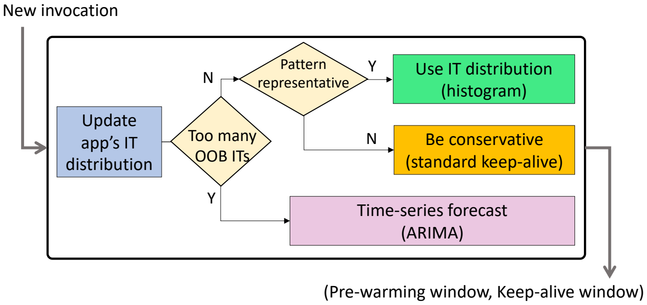
to these overheads, expensive prediction techniques, such as time-series analysis, cannot be used for all applications.

4.2 Hybrid Histogram Policy

Overview. Our hybrid histogram policy addresses all the above challenges. To address challenges #1 and #2, our policy adjusts to the invocation frequencies and patterns of each individual application. It identifies the application's invocation pattern, removes/unloads the application right after each function execution ends, reloads/pre-warms the application right before a potential next invocation (after a "pre-warming window" elapses), and keeps it alive for a period (until a "keep-alive window" elapses). The pre-warming window starts after each function execution, and the keep-alive window starts after each pre-warming. If the pre-warming window is 0, we do not unload the application after an execution, and the end of the execution still starts a new keep-alive window. We explain how exactly we compute the length of these windows below.

Figure 9 shows the pre-warming and keep-alive windows in three scenarios. In the top scenario, the pre-warming window is 0, and an invocation that happens before the keep-alive window ends is a warm start. The end of the execution starts a new keep-alive window. In the middle, the next invocation is a warm start, as the application is re-loaded after a pre-warming window. The end of the execution starts a new pre-warming window. In the bottom scenario, there are two cold starts: the first resulting from an invocation arriving before the pre-warming window elapsed, and the second from an invocation arriving after the keep-alive period elapsed.

The policy comprises three main components: (1) a range-limited histogram for capturing each application's "idle" times (ITs); (2) a standard keep-alive approach for when the histogram is not representative, *i.e.* there are too few ITs or the IT behavior is changing (again, note that this differs from a fixed keep-alive policy); and (3) a time-series forecast component for when the histogram does not capture most ITs. Figure 10 overviews our policy and its components. Ultimately, the policy defines the pre-warming and keep-alive windows for each application. Next, we describe each component in turn.



New invocation
Update app's IT distribution
Too many OOB ITs
N
Pattern representative
Y
Use IT distribution (histogram)
N
Be conservative (standard keep-alive)
Y
Time-series forecast (ARIMA)
(Pre-warming window, Keep-alive window)

Figure 10: Overview of the hybrid histogram policy.

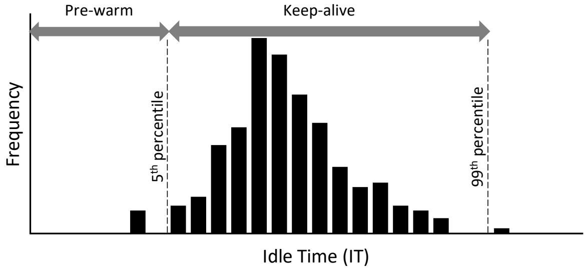


Figure 11: Example application idle time (IT) distribution used to select pre-warming times and keep-alive windows.

Range-limited histogram. To address challenges #4 and #5, the centerpiece of our policy is a compact histogram data structure that tracks the IT distribution for each application. Each entry/bin of the histogram counts the number of ITs of the corresponding length that have occurred. We use 1-minute bins, which strikes a good balance between metadata size and the resolution needed for policy actions. Keep-alive time scales are in orders of minutes for FaaS platforms. We use the same scale for pre-warming. In addition, the histogram tracks ITs of up to a configurable duration (*e.g.*, 4 hours). Any ITs longer than this are considered "out of bounds" (OOBs).

Given the ITs that are within bounds, our policy identifies the head and tail of the IT distribution. We use the head to select the pre-warming window for the application, and the tail to select the keep-alive window. To exclude outliers, we set the head and tail by default to the 5th- and 99th-percentiles of the IT distribution. (When one of these percentiles falls within a bin, we "round" it to the next lower value for the head or the next higher value for the tail.) These two configurable thresholds strike a balance between managing cold starts and resource costs. Figure 11 shows the histogram for a sample application, and the head and tail markers. To give the policy a little room for error, our implementation uses a 10% "margin" by default, *i.e.* it reduces the pre-warming window by 10% and increases the keep-alive window by 10%.

Figure 12 shows nine real IT distributions over a week. The three histograms in the left column show cases where both head and tail cutoffs are easy to identify. These distributions produce the ideal situation: long pre-warm windows and short

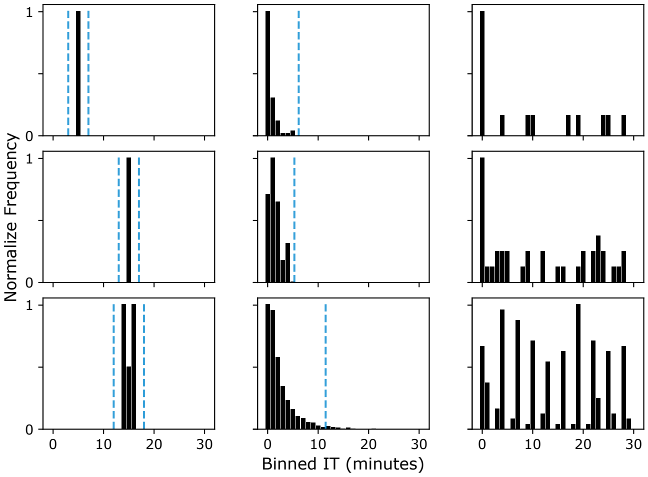

Figure 12: Nine normalized IT distributions from real FaaS workloads over a week.

keep-alive windows. The center cases show no head cutoff as the head marker rounded down to 0. In these cases, the pre-warming window is 0 and the policy does not kill the application after a function execution.

Standard keep-alive when the pattern is uncertain. The histogram might not be representative of an application's behavior when (1) it has not observed enough ITs for the application, or (2) when the application is transitioning to a different IT regime (*e.g.*, change from a consistent pattern to an entirely new one). When the histogram is not representative, we revert to a standard keep-alive approach: pre-warming window = 0 and keep-alive window = range of the histogram (*e.g.*, 4 hours). This conservative choice of keep-alive window seeks to minimize the number of cold starts while the histogram is learning a new pattern. Our policy reverts back to using the histogram when it becomes representative (again).

We decide whether a histogram is representative by computing the CV of its bin counts. A histogram that has a single bin with a high count and all others 0 would have a high CV, whereas a histogram where all bins have the same value would have CV = 0. The histogram is most effective in the former case, where there is a large concentration of ITs (left and center of Figure 12). It is not as effective when ITs are spread widely (right of Figure 12). Thus, if the CV is lower than a threshold, we use the standard keep-alive approach. To track the CV efficiently, we use Welford's online algorithm [45].

Time-series analysis when histogram is not large enough. A compact histogram cannot represent ITs larger than its range. Thus, applications with very infrequent invocations (challenge #3) may exhibit many out-of-bounds ITs. For these applications, our policy uses time-series analysis to predict the next IT. Specifically, we use ARIMA modeling [11].

With an IT prediction, our policy sets the pre-warm window to elapse just before the next invocation and a short keep-alive window. In more detail, we used the `auto_arima` implementation from the `pmdarima` package [2], which automatically searches for the ARIMA parameters (p,d,q) that produce the best fit. As applications using ARIMA are invoked very infrequently, we update the model for each of them after every invocation. To give the prediction some room more inaccuracy, we include a (configurable) margin of 15%. For example, if the predicted IT is 5 hours, we set the pre-warming window to 4.25 hours (5 hours minus 15%) and the keep-alive window to 1.5 hours (15% of 5 hours in each side of the IT prediction).

Justification. Like other FaaS cold start policies, our policy eagerly frees up memory when it is not needed. An alternative would have been to leverage standard (lazy) caching policies, which free up cache space only on-demand. Section 7 explains the differences between these types of policies that justify our approach. Our policy uses a standard keep-alive with a long window, when it does not have accurate IT data about the application, to conservatively prevent cold starts. A shorter window would lower cost but would incur more cold starts. We prefer our approach because it often quickly reduces memory usage greatly, after the histogram becomes active for the application. Instead of using a histogram, we could attempt to predict the next invocation or idle time using time-series analysis or other prediction models. We experimented with some models, including ARIMA, but found them to be inaccurate or excessively expensive for the bulk of invocations. The histogram is accurate, compact, and fast to update. So, we rely on ARIMA only for the applications that cannot be represented with a compact histogram. Producing an ARIMA model is expensive, but can be off the critical path. Moreover, these applications involve only a small percentage of invocations, so computation needs are kept small. Nevertheless, we can easily replace ARIMA with another model.

4.3 Implementation in Apache OpenWhisk

We implement our policy in Apache OpenWhisk [34], which is the open-source FaaS platform that powers IBM's Cloud Functions [21]. It is written in Scala.

OpenWhisk architecture. Figure 13 shows the architecture of OpenWhisk [35]. It exposes a REST interface (implemented using Nginx) for users to interact with the FaaS platform. A user can create new functions (*actions* in OpenWhisk terminology), submit new invocations (*activations* in OpenWhisk terminology), or query their status. Here, we focus on function invocation and container management. Invocation requests are forwarded to the Controller component, who decides which Invoker should execute each function instance. This logic is implemented in the Load Balancer, which considers the health and available capacity of the Invokers, as well as the history of prior executions. The Controller sends the function invocation request to the selected Invoker via the distributed messaging component (implemented using Kafka). The Invoker receives the invocation request, starts the function in a Docker container, and manages its runtime (including when to stop the container). By default, each Invoker implements a fixed 10-minute keep-alive policy, and informs the

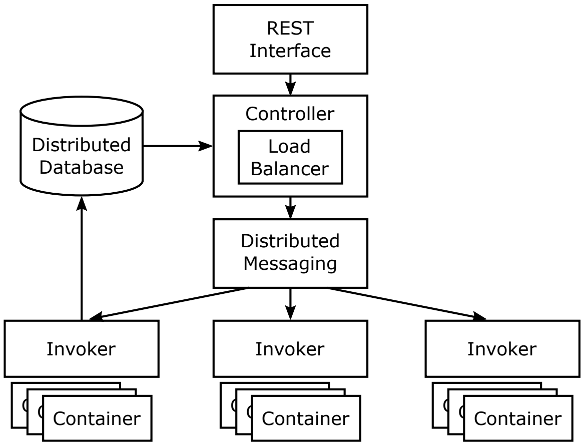

Figure 13: OpenWhisk architecture.

Controller when it unloads a container.

Implementing our policy. We modify the following OpenWhisk components to implement the hybrid policy:

1. **Controller:** Since all invocations pass through the Load Balancer, it is the ideal place to manage histograms and other metadata required for the hybrid policy. We add new logic to the Load Balancer to implement the hybrid policy and to update the keep-alive and pre-warm parameters after each invocation. We also modify the Load Balancer to publish the pre-warming messages.
2. **API:** We send the latest keep-alive parameter for a function to the corresponding Invoker alongside the invocation request. To do this, we add a field to the *ActivationMessage* API, specifying the keep-alive duration in minutes.
3. **Invoker:** The Invoker unloads Docker containers that have timed-out in the *ContainerProxy* module. We modify this module to unload containers based on the keep-alive parameter received from *ActivationMessage*.

5 Evaluation

5.1 Methodology

Simulator. Evaluating our policy requires (1) long executions to assess applications with infrequent invocations, and (2) exploring a large space of configurations. To limit the evaluation time, we use simulations. We build a simulator that allows us to compare various policies using real invocation traces.

The simulator generates an array of invocation times for each unique application. It then infers whether each invocation would be a cold start. By default, the first invocation is always assumed to be a cold start. The simulator keeps track of when each application image is loaded and aggregates the wasted memory time for the application, *i.e.* the time when the application's image was kept in memory without actually executing any functions. We conservatively simulate function execution times equal to 0 to quantify the worst-case wasted resource time. We do not have memory usage data for all applications, so we also simulate that applications use the same amount and focus on the wasted memory time.

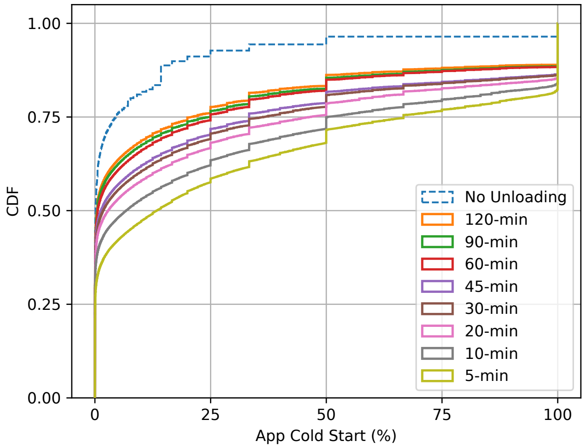

Figure 14: Cold start behavior of the fixed keep-alive policy, as a function of the keep-alive length.

Real experiments. To show that our policy can be easily implemented in real systems with minimal overheads, we use our OpenWhisk implementation (Section 4.3). Our setup consists of 19 VMs. One VM with 8 cores and 8GB of memory hosts containers for the Controller and other main components, including Nginx and Kafka. Each of the remaining 18 VMs has 2 cores and 4GB of memory, hosting an Invoker to actually run the functions in Docker containers.

Workloads. As input to our simulations, we use the first week of the trace from Section 3. For the real experiments, we use a scaled-down version of the trace. We randomly select applications with mid-range popularity. As we run the full system, we limit each OpenWhisk execution to only 8 hours. As we show in Section 5.3, *the experimental and simulation results show the same trends in both cold start and memory consumption behaviors.*

5.2 Simulation Results

Understanding the fixed keep-alive policy. We start evaluating the policy used by most providers: the fixed keep-alive policy. We first assess how the length of the keep-alive affects the cold starts. Figure 14 shows the distribution of cold start percentage experienced by all applications for various lengths. For comparison, we also include a *No unloading* policy, which corresponds to each application only experiencing the initial cold start. Even the *No unloading* policy has ∼3.5% of applications with 100% cold starts; these applications have only one invocation in the entire week.

We see significant cold start reduction going from a 10-minute keep-alive to 1-hour. The 75th-percentile application experiences cold starts 50.3% of the time for the 10-minute keep-alive. This number goes down to 25% for 1-hour. The cold start improvement is more pronounced in the last quartile of the distribution, since applications with infrequent invocations are those that benefit the most. From now on, we will focus on this metric (*i.e.*, 75th-percentile) to report cold starts.

While a longer keep-alive reduces cold starts significantly,

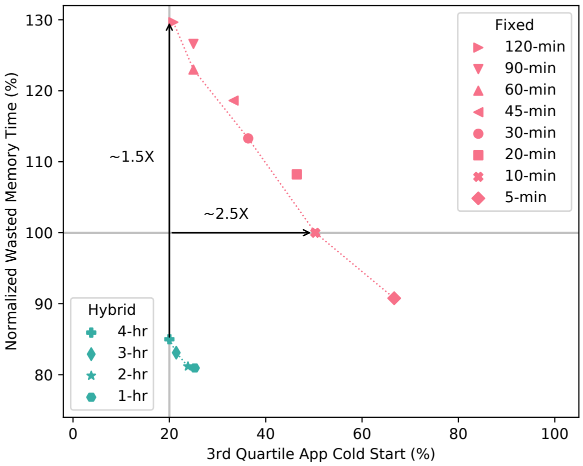

Figure 15: Trade-off between cold starts and wasted memory time for the fixed keep-alive policy and our hybrid policy.

it also increases the resources wasted significantly. The red markers in Figure 15 show the trade-off between cold starts and memory wasted, where we normalize the wasted memory time to the 10-minute keep-alive. The red curve near the red markers approximates the Pareto curve. The figure shows, for example, that a fixed 2-hour keep-alive has almost 30% higher wasted memory time than the 10-minute baseline. An optimal policy would deliver the lowest cold starts with minimum cost. We rely on these Pareto curves to evaluate the policies.

Impact of using a histogram. We now start to evaluate our hybrid policy with the impact of the histogram and its range. The green markers in Figure 15 show the cold start percentage and wasted memory time of our histogram for various ranges. The figure shows how our policy reduces the cold starts significantly with lower memory waste. In fact, the 10-minute fixed keep-alive policy involves ~2.5x more cold starts at the 75th-percentile while using the same amount of memory as our histogram with a range of 4 hours. From a different perspective, the fixed 2-hour keep-alive policy provides roughly the same percentage of cold starts as the 4-hour histogram range, but consumes about 50% more resources. Overall, the hybrid policies form a parallel, more optimal Pareto frontier (green curve) than the fixed policies (red curve).

Impact of the histogram cutoff percentiles. Our policy uses two cutoff percentiles to exclude outliers in the head and tail of the IT distribution. Figure 16 shows the sensitivity study that we used to determine suitable cutoff values. The figure shows that, by setting the head and tail cutoffs to the 5th- and 99th-percentiles of the IT distribution (labeled *Hybrid[5,99]* in the figure), the cold start percentage does not degrade noticeably whereas the wasted memory time goes down by 15%, compared to the case with no cutoff (*Hybrid[0,100]*).

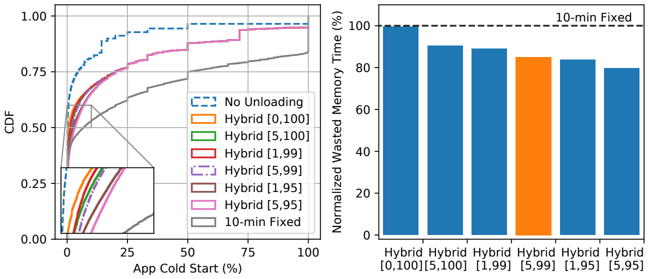

Figure 16: Wasted memory time can be significantly reduced by excluding outliers from the IT distribution.

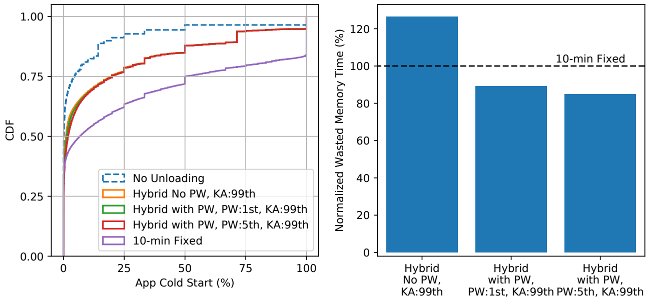

Figure 17: Pre-warming reduces the wasted memory time significantly. The cost is slight increase in cold starts.

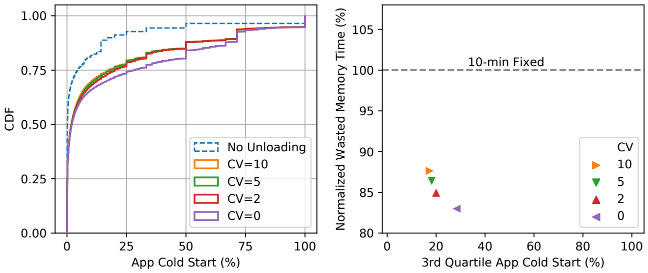

Figure 18: Trade-off between cold starts and memory wasted, as a function of the CV threshold, using a 4-hour range.

Impact of unloading and pre-warming. Complementing our adaptive keep-alive with pre-warming allows unloading of an application right after execution and pre-warming right before the next invocation. This reduces the wasted memory time of application images. Figure 17 shows this, where using similar keep-alive (KA) configurations with and without pre-warming (PW) has significantly different wasted memory time. The cost, however, is adding a small number of cold starts from unexpected invocations. We can control this trade-off by adjusting the histogram head cutoff percentile.

Impact of checking the histogram representativeness. Our policy checks whether the histogram is representative before using it. If the histogram is not representative (*i.e.*, the CV of its bin counts is lower than a threshold), it uses a standard keep-alive approach where applications stay loaded for the same length as the histogram range. We study the impact of different CV thresholds in Figure 18. The figure shows the application cold start distributions (left) and the Pareto frontier (right). We see significant gains using a small CV threshold larger than 0. We opt for CV=2 as our default threshold. Increasing the CV further has negligible cold start reduction with higher resource costs.

Impact of using time-series analysis. Another feature of our hybrid policy is to use ARIMA modeling for applications

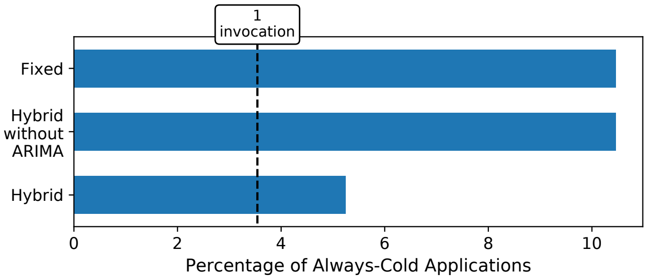

Figure 19: Percentage of applications that always experience cold starts, as a function of policy.

that have many ITs outside the range of the histogram. To evaluate its impact, we now focus on the percentage of applications that show 100% cold starts. Figure 19 shows this percentage when using (1) the fixed keep-alive policy, (2) the hybrid policy without ARIMA, and (3) the full hybrid policy (including ARIMA). All of them use 4 hours for the fixed keep-alive and the histogram range. During the week-long simulation window, 0.64% of invocations were handled by ARIMA, and 9.3% of applications used ARIMA at least once. Using ARIMA reduces the percentage of applications that experience 100% cold starts by about 50%, *i.e.* from 10.5% to 5.2% of all applications. A significant portion of these applications have only one invocation during the entire week and no predictive model can help them. Excluding these applications, the same reduction becomes 75%, *i.e.* from 6.9% to 1.7% of all applications. This shows that ARIMA provides benefits for applications that cannot benefit from a fixed keep-alive or a histogram-based policy.

Summary. Our hybrid policy can reduce the number of cold starts significantly while minimizing the memory cost. We achieve these positive results despite having deliberately designed our policy for simplicity and practicality: (1) histogram bins have a resolution of 1-minute, (2) histograms have a maximum range, (3) they do not require any pre-processing or complicated model updates, and (4) when the histogram does not work well, we resort to simple and effective alternatives.

5.3 Experimental results

We ran two experiments with 68 randomly selected mid-range popularity applications from our workload on our 19-VM OpenWhisk deployment: one experiment with the default 10-minute fixed keep-alive policy of OpenWhisk, and another with our hybrid policy and a 4-hour histogram range. Each experiment ran for 8 hours. During the 8-hour period, there are a total of 12,383 function invocations. We use FaaSProfiler [1, 38] to automate trace replay and result analysis.

Figure 20 compares the cold start behavior of the hybrid and 10-minute fixed keep-alive policies. The significant cold start reductions follow the *same trend as our simulations* (left graph of Figure 16). On average and across the 18 Invoker VMs, the hybrid policy reduced memory consumption of worker containers by 15.6%, which is also *consistent with our simulation results* (right graph of Figure 16). Moreover, the hybrid policy reduced the average and 99-percentile function execution time 32.5% and 82.4%, respectively. This is due to a secondary effect in OpenWhisk, where the language runtime bootstrap time is eliminated for warm containers.

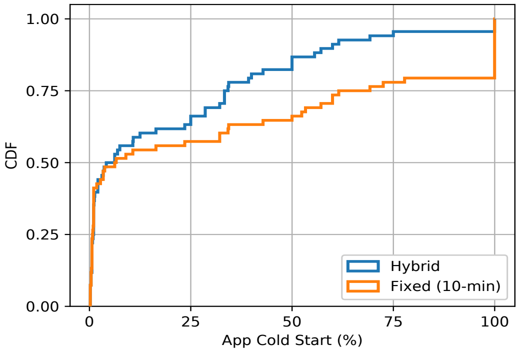

Figure 20: Cold start behavior of fixed keep-alive and hybrid policies in OpenWhisk.

Policy overhead. We measure the (1) additional latency induced by our implementation and (2) the impact of our policy on the scalability of the OpenWhisk controller. The Scala code that implements our policy in the Controller adds an average of only $835.7\mu s$ ($\sigma = 245.5\mu s$) to the end-to-end latency. This overhead is negligible compared to the existing latency of OpenWhisk components: the (in-memory) language runtime initiation takes $O(10ms)$ and the container initiation takes $O(100ms)$ for cold containers [38]. For the uncommon cases where ARIMA is required (0.7% of invocations), the initial forecast involves building the model, which takes an average of 26.9ms, whereas subsequent forecasts take an average of 5.3ms. Since ARIMA works for applications that would normally experience cold starts, these overheads represent a relatively small cost compared to the cold start overhead.

In terms of scalability, CPU utilization is the limiting factor for the Controller. Our policy adds only a 4-6% higher utilization for a range of benchmarking request rates (10rps to 300rps), compared to OpenWhisk's default policy.

6 Production Implementation

We have implemented our policy in Azure Functions for HTTP-triggered applications; its main elements will be rolling out to production in stages starting this month. Here, we overview the implementation.

Azure Functions has a controller that communicates with function-execution workers through HTTP, and a database for persisting system state. The controller gets asynchronous updates from the workers at fixed intervals; we use these to populate the histogram. We keep the histogram in memory (bucket of 240 integers per application, or 960 bytes) and do hourly backups to the database. We start a new histogram per day in the database so we can track changes in application's invocation pattern, and remove histograms older than 2 weeks. We can potentially use these daily histograms in a weighted fashion to give more importance to recent records.

When an application changes state from executing to idle, we use the aggregated histogram to compute its pre-warm interval and schedule an event for that time (minus 90 seconds). Pre-warming loads function dependencies and performs JIT where applicable. Some steps, like JIT of the function code, happen when the actual invocation comes in as the function's code cannot be executed as part of warmup to preserve execution semantics. Each worker maintains the keep-alive duration separately, depending on how long it has been idle for. We make all policy decisions asynchronously, off the critical path to minimize the latency impact on the invocation. This includes updating the in-memory histogram, backing up the histogram to the database, scheduling pre-warming events, and controlling the workers' keep alive intervals.

7 Related Work

There is a fast-increasing number of studies on different aspects of serverless computing. The most relevant for our paper are those that characterize FaaS platforms and applications, and those that propose and optimize FaaS serving systems.

FaaS characterization. A few studies [7, 15, 24–26, 44] have characterized the main commercial FaaS providers, *but only from the perspective of external users.* They typically reverse-engineer aspects of FaaS offerings, by running benchmark functions to collect various externally visible metrics. Our characterization is orthogonal to these works, as we provide a longitudinal characterization of the entire workload of a large cloud provider from the provider's perspective. *Our characterization is the first of its kind.*

Another class of studies looks at the ways developers are using FaaS offerings, by looking at public application repositories [41]. While valuable, this approach cannot offer insights on the aggregate workload seen by a provider.

Optimizing FaaS serving. Another set of relevant work considers optimizing different aspects of FaaS systems. Van Eyk *et al.* [42] identify performance-related challenges, including scheduling policies that minimize cold starts. They also identify the lack of execution traces from real FaaS platforms as a major obstacle to addressing the challenges they identified.

For optimizing each cold start, Mohan *et al.* [32] find that pre-allocating virtual network interfaces that are later bound to new function containers can significantly reduce cold start times. SOCK [33] proposes to optimize the loading of Python functions in OpenLambda by smart caching of sets of libraries, and by using lightweight isolation mechanisms for functions. SAND [3] uses application-level sandboxing to prevent the cold start latency for subsequent function invocations within an application. Azure Functions warms all functions within an application together; thus this was not a concern for us. Replayable Execution [43] proposes checkpointing and sharing of memory among containers to speed up the startup times of a JVM-based FaaS system. Kaffes *et al.* [22] propose a centralized core-granular scheduler. *Our work on reducing the number of cold starts and resource usage by predicting function invocations is orthogonal to these improvements.*

Other studies also use prediction to optimize different aspects. Work in [19, 20] proposes a policy for deciding on function multi-tenancy, based on a predictive model of resource demands of each function. Without discussing design details, EMARS [37] proposes using predictive modeling for allocation of memory to serverless functions. Kesidis [23] proposes to use the prediction of the resource demands of functions to enable the provider to overbook functions on containers. In contrast, we track invocation patterns and use this knowledge to reduce cold starts and memory waste.

Cache management. Finally, one might think that the problem of managing cold starts is similar to managing caches of variable-sized objects, such as Web page caches and others [4, 8, 36]. However, there are two fundamental differences. First, FaaS frameworks are often implemented on top of services that charge by the time resources are allocated (*e.g.*, each application is packaged as a container and deployed to a container service). Thus, cold start policies proactively unload applications/functions from memory, instead of waiting for other applications/functions to need the space. Our policy is closest to a class of TTL-based caches where new accesses reset the TTL [9, 10]. These works did not consider temporal prefetching, the equivalent of our pre-warming. Other caching work did consider it, but with capacity-based replacements [46]. Second, most caching algorithms to date have focused on aggregate performance metrics [13, 14], such as the weighted sum or average of per-object miss ratios. In contrast, we tailor our cold start management to each application to maximize individual customer satisfaction.

8 Conclusion

In this paper, we characterized the entire production FaaS workload of Azure Functions. The characterization unearthed several key observations for cold start and resource management. Based on them, we proposed a practical policy for reducing the number of cold starts at a low resource cost. We evaluated the policy using both simulations and a real implementation, and real workload traces. Our results showed that the policy can achieve the same number of cold starts at much lower resource cost, or keep the same resource cost but reduce the number of cold starts significantly. Finally, we overviewed our policy's implementation in Azure Functions. We released sanitized traces from our characterization data at [31].

Abstract

The Chameleon testbed is a case study in adapting the cloud paradigm for computer science research. In this paper, we explain how this adaptation was achieved, evaluate it from the perspective of supporting the most experiments for the most users, and make a case that utilizing mainstream technology in research testbeds can increase efficiency without compromising on functionality. We also highlight the opportunity inherent in the shared digital artifacts generated by testbeds and give an overview of the efforts we've made to develop it to foster reproducibility.

1 Introduction

The primary goal of computer science (CS) experimental testbeds is to support CS systems research by inventing and operating a scientific instrument on which such research can be conducted. Like in any other experimental science, such instrument is a critical tool: while we can conceive of all sorts of experiments, in practice we can carry out only those that are supported by an instrument that allows us to deploy, capture, and record relevant phenomena. The objective of experiment support can be considered along two dimensions: supporting the broadest possible set of experiments for the largest possible set of experimenters. The factors that influence the former include providing state-of-the-art hardware at appropriate scales and sufficiently expressive interfaces for allocating and configuring that hardware (i.e., deploying experiments). The latter is influenced by the cost of per user and per experiment support, but also the usability and familiarity of interfaces that lower the entry barrier for most users.

In this paper, we describe Chameleon, a testbed for CS research and education, and evaluate it from the perspective of the two dimensions outlined above. Chameleon gives users access to a broad array of state-of-the-art hardware, supports deep reconfigurability and experimentation at scale as well as isolation, preventing one experiment from impacting another. Since its public availability date in July 2015, Chameleon has supported 4,000+ users working on 600+ projects.

Unlike traditional CS experimental systems such as Grid'5000 [1], Emulab/CloudLab [2, 3], or GENI [4], which have generally been configured by technologies developed in-house, Chameleon adapted the OpenStack mainstream open-source cloud technology to provide its capabilities. This has a range of practical benefits, such as familiar interfaces for users and operators (or workforce development potential for those not familiar with OpenStack, as they acquire transferable skills), the opportunity to leverage the contributions from a large development community, and the potential to contribute back to that community in turn and thus influence infrastructure used by many users worldwide. Beyond practical benefits, configuring an experimental platform as a cloud also provides a direct answer in the debate over whether CS systems research can be supported on clouds, including potentially commercial clouds. More importantly, it also provides a means of influencing that debate through direct mainstream contributions, i.e., describing how a cloud needs to be configured to support this type of research. A secondary contribution of our paper is thus an articulation of a mainstream cloud configuration that yields a platform suitable for systems research.

Perhaps the most important lesson learned from Chameleon was that testbeds generate a wealth of experimental digital artifacts compatible with the testbed – such as images, orchestration templates, or more recently, computational notebooks – that can be used to re-play experiments. Testbeds are thus "readers" for digital representations of experiments. This creates an opportunity for developing a sharing ecosystem in which users can easily share and replicate each other's experiments and thereby another dimension in which a testbed can support research. This dimension is influenced by how easily experiments can be expressed in a shareable and replicable form – and then how easily they can be discovered and published. We introduced these mechanisms in Chameleon over the last year; while they have been around for too short a time to provide a comprehensive evaluation, we will discuss both their structure and potential.

2 Chameleon in a Nutshell

The Chameleon testbed consists of two operating sites: one at University of Chicago (UC) and the other at Texas Advanced Computing Center (TACC). Our approach to hardware seeks to balance scale (i.e., support for HPC and Big Data experiments) and diversity. Scale was achieved via investment in 12 Haswell racks (2 at UC, 10 at TACC) containing a mix of compute and storage nodes, one with IB interconnect. More recently, they were augmented by 3 SkyLake racks (2 at UC, 1 at TACC) and 1 CascadeLake rack at TACC. The SkyLake racks are equipped with Corsa switches enabling experimentation with Software Defined Networks (SDN). The sites are connected by a 100G network supporting experimentation with large flows. This investment in scale is supplemented by smaller clusters of nodes supporting specialized experiment types: they include four types of GPUs (M40s, K80s, P100s, and P100 with NVLINK), FPGAs, low-power nodes (ARMs, Atoms, and low-power Xeons), and memory hierarchy nodes equipped with almost a TB of RAM memory, and a range of NVMes, SDDs, and HDDs. Over 4 PB in global storage capability is additionally distributed across the sites. About a year ago a Chameleon Associate Site (contributed on a voluntary basis) was added at Northwestern with a modest allocation of nodes equipped with 100G cards, expanding Chameleon's ability to support experiments with large networking flows. A fine-grained and rigorously up-to-date description of hardware can be obtained from the Chameleon Resource Discovery services [5].

Chameleon's capabilities are designed to allow experimenters to allocate and configure these resources at multiple entry levels: users can make allocations expressed as model-based constraints, allocate by node type, or point to a specific node, either on-demand or via advance reservations. Allocatable resources range over nodes, networks, and IP addresses. Resource configuration is supported at bare metal level and supports custom kernel boot. The latter is achieved via the support of whole-disk images, which include a kernel, a partition map, and a bootloader. Reimaging takes places as a sequence of booting to a provisioning ramdisk via PXE, image transfer to node's disk via iSCSI, and a local boot. This allows kernel developers to replace the kernel as needed for experimentation; they can also use serial console access at boot time for debugging and snapshotting to save the revised image. In addition, Chameleon supports network stitching and SDN experimentation via the recently introduced Bring Your Own Controller (BYOC) [6] abstraction built on top of the Corsa DP2000 series OpenFlow switches. Users can create SDN networks that are isolated from each other and the testbed management networks by dynamically provisioned virtual forwarding contexts (VFCs), each with its own controller and subset of ports/VLANs, that are then connected to the nodes and external circuits reserved by the user.

Configuration can also be carried out at multiple entry levels: users can reimage individual nodes and then configure their experiments manually, use orchestration capabilities to render complex (potentially distributed) experiments that can be automatically and repeatedly deployed, or use Jupyter notebooks in combination with one or both of these mechanisms. Monitoring is supported partly by OpenStack Gnocci service that has been augmented to provide capabilities such as e.g., fine-grained power monitoring. The CHameleon Infrastructure (CHI), which implements these capabilities, is built primarily on top of the mainstream open-source OpenStack platform [7] (with extensions and contributions from our team), but also integrates resource representation, versioning and management tools from the Grid'5000 project [1], and network management tools from the ExoGENI [8] project. The implementation of CHI has been described in detail in [9].

Chameleon projects are given allocations of 20,000 SUs (one SU is a node hour) for six months; this aims to strike a balance between what might represent a reasonable amount of time needed to obtain a result (a very variable measure!) and 1% of 6 months' capacity of the initial testbed deployment (i.e., if everybody was using their allocation at the same time the testbed could support no more than 100 projects in that amount of time). Allocations can be recharged (more SUs) or renewed (longer time). In addition, user's leases on the system (i.e., the length of time for which resources can be allocated) are limited to at most 7 days; these can also be extended either programmatically or via interactions with Chameleon operators.

Figure 1 provides a rough summary of Chameleon's growth in hardware and utilization, as well as users and projects. Over the almost four and a half years of its operational life Chameleon has supported 4,331 users across 655 unique projects representing a broad array of research and educational uses. The growth of Chameleon usage has been steady since the project start, with about 7 new projects per month in the first years of operations, accelerating to eleven new projects per month in 2019. Incremental hardware investments have been keeping up with that growth. We also observe a similar trend to that already reported by [3] where usage is lower during summer and winter breaks and peaks during the semester and important conferences such as the supercomputing conference series.

3 Most Experiments for Most Experimenters

We now evaluate the key decisions made in Chameleon from the perspective of supporting the most experiments for the most experimenters. To evaluate the former, we will look at whether the hardware and capabilities we provide are sufficient to support experiments in our community; for the latter we will look at quantitative measures such as the numbers of users and experiments the tested can simultaneously support and the types of projects it attracted.

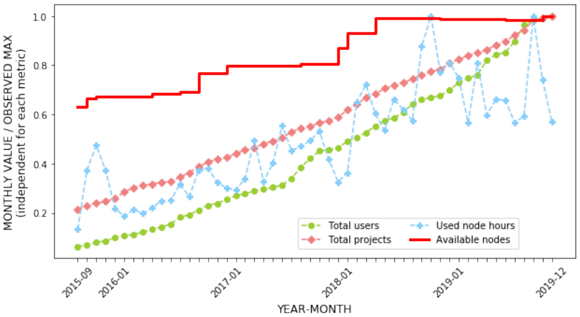

Figure 1: Increasing usage and capacity of the testbed over time. Monthly values are normalized to the maximum observed value over time. Scalings are independent for each metric.

3.1 Experiments

In this section we describe and evaluate both our strategy for hardware configuration and the technical decisions we made to provide access to this hardware such that it supports the broadest possible set of experiments. Unless we specify otherwise, the data reflects period between 09/01/15 to 12/31/19.

3.1.1 Hardware

Where resources are limited (as they inevitably are in academic testbeds) it is important that hardware investments strike a balance between scale, i.e., support for large-scale experimentation, such as HPC, and diversity, i.e., support for a broad range of resources on which different research questions can be tried. Given these considerations, our hardware investment strategy was to build up scale at the beginning of the project (the original 12 rack Haswell deployment) and then introduce diversity gradually with an eye towards the types of projects that were requested the most, and the type of resources that were utilized the most. We also held back a "strategic reserve" of hardware investment to develop the testbed as innovative hardware solutions emerged.

To understand how well we satisfy the need for scale we looked at the size of lease requests for the testbed in general, and the large Haswell partition in particular. By far the most leases on the testbed are requests for a single node, constituting 67.19% of testbed leases (63.24% of Haswell leases) with only 5% of requests exceeding 10 nodes (11% for Haswell). The largest lease on the testbed was 120 nodes. Overall, this means that our investment in scale did indeed broaden the set of supported experiments while also allowing us to support more simultaneous leases.

To understand how well we support the need for diverse hardware types, we show in Figure 2 node availability against the percentage of time that it was available, first for the overall time since resource installation, and then during the busiest and least busy month as measured by highest and least utilization of the testbed as a whole (Cascade Lake was installed very recently and is not shown). By far the most used resource types are the four GPU types, with the two newer GPUs (GPU P100) more in demand than the two older ones (GPU K80 and M40), followed closely by the memory hierarchy nodes. On the other end of the spectrum, ARMs, Atoms, and low-power Xeons—targeting specialized power experiments—are used the least. The large-scale resources, Haswells and Skylakes, as well as the FPGAs, occupy the middle.

While these categorizations are roughly consistent across specific time periods and overall, some important details are different. For example, the availability of the GPU P100 NVLINK is less in both most and least used month than the overall availability graph would suggest; this is due in significant part to the fact that resources are typically much less utilized immediately after they are introduced as the knowledge of their availability has yet to be absorbed. In general, periodic usage patterns might fluctuate due to specific conference deadlines or teaching/workshop use.

One lesson learned from our experiences is the need for adaptation. Overall, introducing diversity to the testbed gradually allowed us to make changes to respond to community demand, shaped by the evolving nature of the research needs. For example, based on the response to our early K80 and M40 deployments driven by emergent interest in machine learning, and combined with less demand for a low-power processors, we re-budgeted some of our planned investment between those categories and also invested our "strategic reserve" into more GPUs. This meant that we were able to provide ample support for low-power experimentation while keeping up with emergent demands. Because of periodic fluctuations it is hard to formulate recommendations on when such change should be considered; based on our experiences it is likely to occur when usage moves to the area of the graph between the large-scale and memory hierarchy resources.

3.1.2 Capabilities

Resource Description. Much of the usefulness of the testbed relies on the manner in which users gain access to hardware. To do that, users have to describe the resources they need. Commercial clouds offer a variety of "instances", sometimes with vaguely described properties (e.g., "high I/O bandwidth"). Experimental testbeds allow users to choose a specific hardware type and sometimes seek to ensure that all servers of the same type have comparable performance [3,10]. In contrast, we take the view that performance variability is a fact of life and often a research topic in itself. Our approach therefore is to allow users to choose resources on a range of levels: from a model description expressed as a set of constraints (e.g., "memory of at least X" or "X nodes situated on the same rack"), through describing hardware type (e.g., a Skylake node), or by referring to a specific node.

Analyzing Chameleon lease requests made between 09/16

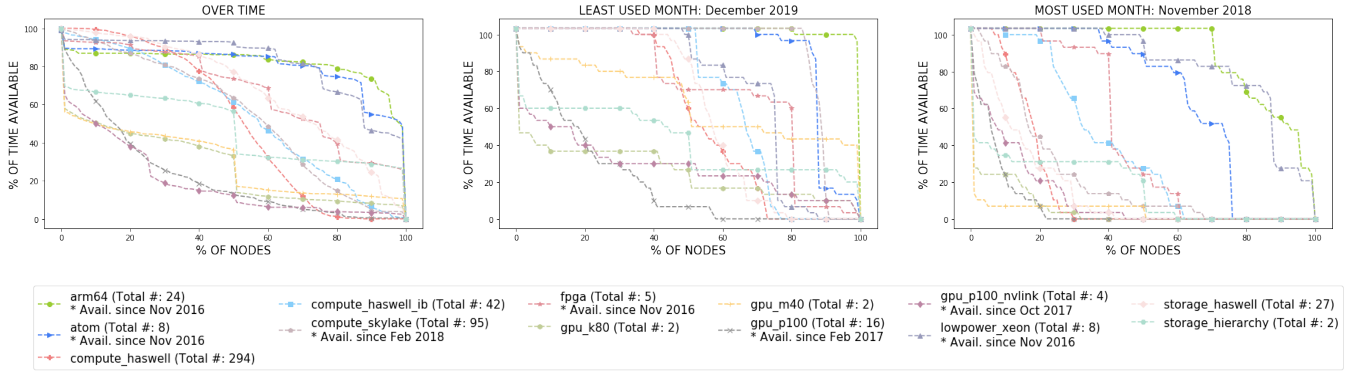

Figure 2: The usage of Chameleon hardware types expressed as resource availability plotted against the percentage of time in which it was available for (a) overall availability since resource installation, (b) the least and (c) most utilized month.

and 11/19, we find that the majority (89.24%) were created using a single constraint (the rest are leases using either no constraint or multiple constraints; 9.5% and 1.26%, respectively). Of the single constraint leases, 90.18% were created by specifying the hardware type and only 3.38% specify node uid (a specific node). However, when we look at single-constraint leases that are created more than 7 days in advance, the percent of leases with node type constraint drops to 59.91%, while the percent of leases with uid increases to 18.45%, which shows that users who need a specific node are willing to wait for it rather than replace it with something else.

Overall, a hardware type is clearly the most requested quality. Specific nodes are requested relatively infrequently, though some experimenters do need them and model-based descriptions based on high-level constraints are rare. While it is often tempting to think that a model-based description is the ideal, the following anecdote illustrates the limitations of this approach. Using a model-based request ("memory greater than X"), one of our users was assigned an ARM node; this led to a difficulty since although this was a correct match for the experimental model, the user's tooling did not work on ARMs. In subsequent conversation with our support staff the user was advised to browse our discovery services, found the Chameleon memory hierarchy nodes, and concluded that with those nodes he would be able to design a more ambitious experiment. We derive two lessons from this: first, models are not all that is needed for determining the right experimental resources (logistical concerns need to be taken into account as well); second, resource discovery phase is an essential part of an the experimental workflow and critical to taking full advantage of the testbed.

Allocatable Resources. Another matter of interaction with the testbed consists of being able to obtain resources in a timely manner. Commercial clouds use the metaphor of an "endless resource" always available on-demand – in practice no resource is of course endless even in commercial clouds (e.g., the current initial limit at AWS is 256 VCPUs [11]) – though some are sufficiently large. Thus, the ability to gracefully deal with availability limitations is important, particularly in academic clouds where we try to maximize small scale resource investment.

To provide such ability we introduced the abstraction of an allocatable resource described in [12]. In brief, an allocatable resource allows users to manage a resource allocation in terms of both time and resource assigned to the allocation (i.e., when an allocation starts and ends, and well as how many nodes belong to it). In particular, the ability to manage the start time is sometimes referred to as "advance reservations" and is a generalization of on-demand availability provided by commercial clouds (i.e., on-demand is an advance reservation with start time set to "now"). The resources can be of various types and can be managed to fulfill different conditions; in Chameleon currently the managed allocatable resources consist of nodes, VLANs, and public IP addresses. The implementation of this capability and its contribution to OpenStack was initiated by the Chameleon team.

As [12] demonstrates, allocatable resources, and advance reservations in particular, are useful in providing access to scarce resources: the scarcer the resource, the more likely users are to make an advance reservation to ensure availability, and the longer in advance this reservation is likely to be made. In figure 3, we provide a more detailed demonstration of this concept: we scatter plot all leases made for three types of resources: Haswell compute nodes at TACC (largest partition), Skylake compute nodes at UC (largest partition), and our GPU P100 cluster (16 nodes), noting the number of nodes requested and the reservation lead time.

We see that the GPU P100 nodes (one of the most utilized resources per Figure 3) have by far the longest advance reservation lead times even though only very few users reserve more than one node. On the other hand, Haswell@TACC, used for experiments at scale, show a significantly higher proportion of leases with multiple nodes (with the max being 85). While many of them are created with some lead time, it was

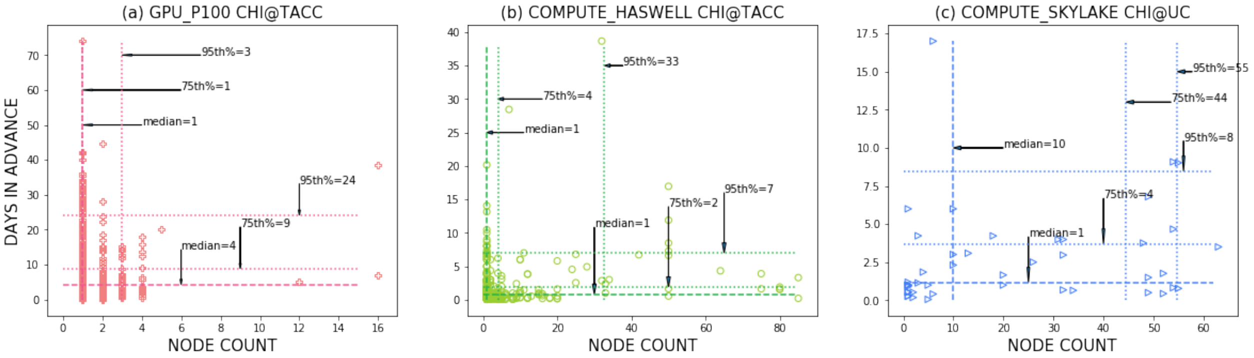

Figure 3: Node counts vs. advance reservation lead time of advanced leases for (a) GPU_P100, (b) Haswell, and (c) Skylake

possible to create some large leases on-demand; they are correlated to summer use (low utilization) and no leases with size in the 95th percentile were available after 2016 as the testbed became popular. This trend is even more pronounced when looking at the Skylake nodes, which are a scarcer resource than Haswells (64 versus 278 for largest partition) but also support experiments at scale. Advance reservations are thus useful in managing two types of resource scarcity: very scarce resources (e.g., GPU P100) will require high lead times, but relatively abundant resources (e.g., Haswells) can become scarce if a large reservation is requested.

The end time of a resource reservation can also be extended programmatically, although according to our policies this can only take place within 48 hours of lease expiration and of course only if the resource is not reserved by another user (a policy exception can also be requested via the help desk.). This last consideration limits the practical usefulness of this feature in the case of scarce resources, as it is likely that they will have been reserved by the time the extension window becomes active. For this reason, programmatic extension requests have only been successful in relatively few cases in practice, e.g., during the last year at UC only 5.4% leases got extended in this way; though half of them more than once.

Separation of allocation and configuration. Unlike commercial clouds where resource allocation and image deployment are one operation, Chameleon separates them to allow users to map different images to an allocation. This capability proved relatively popular with experimenters: 22.07% of the allocations had more than one instance deployed, and roughly half of those (9.17% of all the allocations) had more than one unique instance (i.e., associated with a different image) deployed; the average number of instances deployed within one allocation is 1.45 (with max being 12) and of unique instances is 1.12 (with max being 10).

Networking. Network isolation is an important property in that it allows non-standard IP configuration, potentially disruptive services, or security experiments that analyse or intentionally attack other nodes on the isolated network. Similarly to many of the base Chameleon features, we implemented this via standard OpenStack services; within each geographic site, users can create Chameleon networks that are isolated within unrestricted VLANs (i.e., no firewalls) and logically connect any number and type of nodes.

Chameleon's "Bring Your Own Controller" (BYOC) [6] capability extends these isolated networks by providing direct user control of network flows and configuration via a standard or customized OpenFlow 1.3 controller. Though OpenStack did not support BYOC out of the box, its modular design enabled us to implement the feature as a custom Neutron plugin, which enables users to specify the IP and port of the user's OpenFlow controller (whether provisioned on Chameleon or externally). Chameleon uses Corsa DP2000 series switches to dynamically create isolated OpenFlow 1.3 network slices in hardware operating at full performance (10 Gbps node ports and a 100 Gbps uplink); this is in contrast to an approach which provides coarse control of whole OpenFlow switches from a static pool of hardware as implemented by CloudLab. BYOC enables many experiments from basic hands-on educational experiences with OpenFlow to advanced networking experiments that optimize performance of network traffic or identify and remedy security breaches by analysing low-level traffic behavior. Despite the fact that BYOC networking is new and targeted at highly specialized and advanced users, there have been already been 11 unique projects (representing 4% of active projects over the time period) that have deployed OpenFlow experiments on the Chicago site alone.

Networking experiments on Chameleon are not limited to the Chameleon testbed alone. Users can create dedicated layer 2 circuits between Chameleon networks and external facilities such as ExoGENI, campus laboratories, public clouds, and other Chameleon sites; creating dynamic connections of this type is often called "stitching" [4]. ExoGENI provides a dynamic stitching service that connects a wide collection of participating facilities, including Chameleon. Chameleon users can create isolated stitched links between their networks (including BYOC networks) and ExoGENI and can extend those links across ExoGENI to remote facilities. In addition, multiple stitched links can be connected to a single Chameleon network, enabling user-controlled wide-area multi-path routing experiments. To date, 22 unique projects (representing 8% of active projects over the feature's life time) that rely on network stitching have created 920 stitched links between remote facilities using ExoGENI.

Orchestration. Once a lease is created, users can configure it using Chameleon provided images, create their own (often, but not always, derived from Chameleon provided images), or use complex appliances [13], representing concepts such as a cluster, a cloud, or a networking experiment, that can be deployed "with one click" and then repeated in future deployments, similar to CloudLab profiles [3]. These experiments are configured using images in conjunction with Heat orchestration templates [14] that define how to deploy and contextualize [15] them to create the desired integrated environment and processes. Using Heat, an active Chameleon topology can be modified (by e.g., adding or removing nodes, altering MTUs on the network, or changing a post-boot step for a particular node) through changes to the underlying Heat template; the orchestration system applies the delta without forcing re-creation of the entire topology. The choice to decouple allocation and configuration made this functionality easier: because a set of resources is allocated explicitly to a user for a time period, any topological or software/firmware configuration can vary without breaking the researcher's assumptions about the underlying hardware.

Consistent with our decision to make the testbed available at various levels of access, the use of orchestration is optional for Chameleon users. Using orchestration/Heat provides repeatability at the cost of an additional up-front investment (i.e., developing an orchestration template) and thus tends to be used in later stages of a project when experimental configuration is settled on. Since users often develop orchestration templates by modifying existing ones, the Chameleon project provides 3 complex appliances (images+Heat template) and another 14 individually-supported complex appliances are hosted on our appliance catalog; the most popular are MPI bare-metal cluster (MPICH3), Ryu OpenFlow Controller, and OpenFlow - QuickStart appliance. To date, 81 Chameleon projects have used Heat, among those 20 were in systems, 17 in education, and 12 in networking, with the rest ranging over a variety of topics including security, power management, and others. The usage data since 10/16 when this feature was introduced show a steady upward trend in orchestrated deployments: 94 (2017), 155 (2018), and 405 (2019), though more recently users were increasingly using Jupyter notebooks or scripting for orchestration. Overall, while orchestration is an advanced feature and thus the uptake is slow, it is proving a useful tool to express a range of experiments.

Configuring complex experiments, even when automated via orchestration, can still take significant time, as packages need to be installed, configuration scripts run, and tests executed. Thus, while separating allocation and configuration proved a successful decision, users often ask for functionality that effectively recombines these actions, i.e., automatically triggers the deployment of an orchestrated experiment when a user's advance reservation comes into effect. To provide it, we introduced the automated deployment feature [16] in 01/19 that automatically triggers the deployment of experiments orchestrated with Heat. So far it has been little used while still being often requested; this likely points to the need for more energetic education efforts as well potentially to the need of extending this capability to other orchestration methods, in particular the increasingly popular Jupyter-based approach.

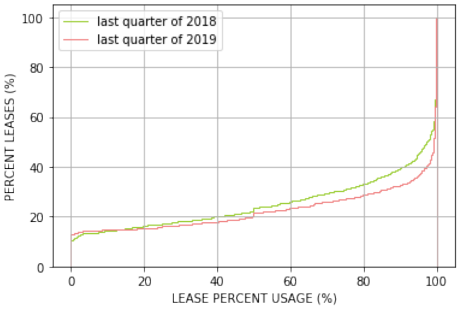

Figure 4: The cumulative distribution functions (CDFs) of lease percent usage for the last quarter of 2018 and 2019.

Managing User Behavior. Perhaps the most significant challenge of operating Chameleon, common to all academic cloud resources, is ensuring fair sharing of the resource. Unlike in HPC datacenters, where actual resource use is tied to the submission of a specific program (such that if the program fails the resource grant is withdrawn), access to cloud resources is given out on an open-ended basis. Commercial clouds create incentive to use no more than is needed by charging for the duration of access. Academic clouds, such as Chameleon, seek to provide a similar incentive via allocation policies (see Section 2); this is generally less successful since users can recharge or renew their allocation relatively easily. In fact, we found this measure to be inadequate on its own early in the project as users created leases to "put a hold" on resources that then went unused, significantly reducing testbed capacity for others. This led us to introduce the (extensible) 7 day lease limit described earlier which improved fair sharing at the cost of imposing extra overhead on experiments that legitimately need more than 7 days. However, we still see leases on the testbed that merely hold resources without using them.

To manage this situation, we introduced a policy whereby users are expected to start using their lease within a certain amount of time from deployment. This policy is enforced by a "lease reaper" (deployed in 09/19) that monitors the use of a lease, sends a reminder to users not using their leases, and terminates them if still unused after a certain period of time.

Figure 4 shows a comparison of lease usage for the last quarter of 2018 and last quarter of 2019 (before and after the lease reaper was introduced). While it is natural that resources in a lease may be unutilized for some time (e.g., between deployment of different images), we see that in 2018 (without lease reaper) a large percentage of leases is underutilizing resources to a significant extent. However, in 2019 (with lease reaper) the situation improved: it went from 40.79% to 45.95% fully-used leases and from 66.92% to 71.19% 80%-used leases. More sophisticated ways of ascertaining if a lease is actually being used are likely to tighten the gap between allocated and used leases further, but at the same time become open to "gaming" by users emulating lease usage via artificial means, reducing their effectiveness. Thus, striking the right balance of incentive and access to promote fair sharing in academic environments is still an open question.

Summary. On the whole, we found that the key design decisions we took, whether by introducing new hardware or new capabilities, led to expanding the set of experiments available to our user community, and were thus quickly embraced. While we still receive new feature requests, they are increasingly smaller and come less often. At the same time, a significant lesson learned in the process of operating Chameleon is that no research testbed is ever complete because the set of desired experiments is constantly expanding. As the research frontier advances emergent research opportunities create the need for new scientific instruments – or new features in existing scientific instruments – to support their exploration. While setting aside a strategic reserve in hardware served us well, the extent to which this phenomenon drove development was surprising: not only did we need to adapt the system to leverage new opportunities in hardware (such as e.g., providing the BYOC capability on top of the Corsa switches), we needed to develop abstractions (such as e.g., the allocatable resources) to integrate those extensions in the experimental workflow. The most significant types of experiments that Chameleon does not support yet are thus in emergent topics – for example, on the intersection of Internet of Things (IoT) and cloud computing as well as machine learning.

3.2 Experimenters

Supporting as many users as possible will be influenced by two factors: how many users a testbed can sustain by managing the cost of users and experiments and how many users it can attract by adapting itself to the needs of different communities; this section will discuss how well Chameleon was able to achieve both.

Isolation and Automation. Providing an appropriate level of isolation captures an important trade-off: it should be fine-grained enough to divide the testbed efficiently between multiple experiments – but also coarse-grained enough to satisfy the isolation needs of a specific experiment. Since the granularity often goes with the level of isolation a specific mechanism provides [12] we must be careful to not sacrifice the required level of isolation; at the same time we want to serve as many users as possible. In Chameleon, we navigate this trade-off by configuring the bulk of the testbed with CHI while setting aside two racks (originally three) provided as a standard OpenStack/KVM cloud. This finer-grained system isolation that this alternative cloud provides means that multiple user VMs can be deployed on one node instead of allocating a whole bare metal node (though it does not provide the performance isolation that a bare metal offers). Because of this efficiency, we were also able to offer a different policy: users can make open-ended deployments on the KVM partition while CHI (bare metal) leases are limited as to 7 days at most. Last but not least, it is more suited to less-experienced users.

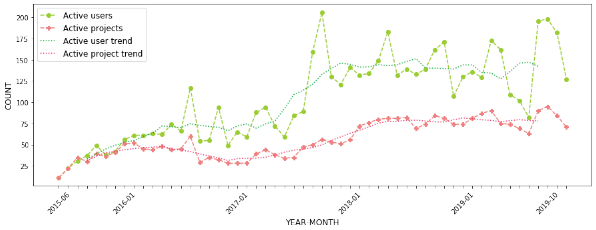

Figure 5: The numbers of active users and projects over time. The trend lines average the number of users/projects over 6 month period.

Our data indicate that 209 Chameleon projects (22.94% of all Chameleon projects) used our KVM partition at least once. Among those projects, 12.92% are projects in CS education. About 26.16% of our total number of users used the partition, most of them assigned to an educational project. Most VMs (71.52%) are deployed for an hour or less and only 3.18% leverage the ability to claim testbed resources for more than one week. The median daily count of deployed VMs is 344 (with max/min of 1490/29); each of those would have likely occupied a bare metal node otherwise. All those statistics point to significant educational use; given the number of users and projects overall this seems a good investment for what currently constitutes only 16% of our total Haswell system and even smaller fraction of the overall testbed.

Supporting Volume. While isolation method determines the unit of sharing, the largest factor in the ability to support as many users as possible is automation since it lowers the per-user and per-experiment cost. We noted earlier that Chameleon is a production testbed, i.e., a testbed that supports production services that yield individual/breakable testbeds. Consistent with this definition, we define Chameleon testbed functions as only those experiments that are accessible to users in an automated manner (while we also support experiments requiring manual intervention from operators and special requests, we consider them support functions, not testbed functions). We now examine indicators of how much user volume the testbed can support.

We first asked how many active users the testbed supported

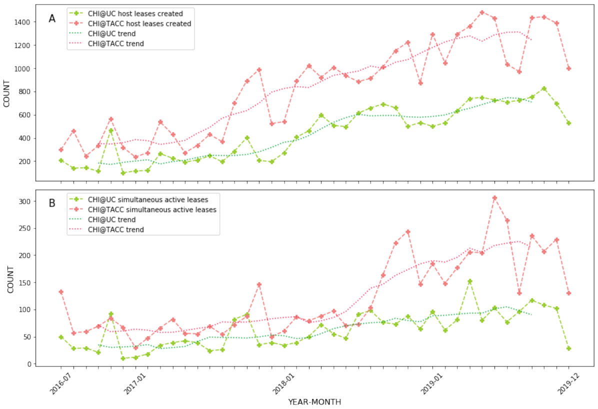

Figure 6: (A) Total leases created each month. (B) Maximum simultaneous active leases by month. The trend lines average the number of leases over 6 month period.

overtime. We see that numbers of active users follow the general pattern of slow and busy months (semesters versus breaks) that we have already seen in Figure 5. However, although we saw that the cumulative number of users was rising, it is interesting to note that the average number of active users and projects grew significantly about two years after the testbed has became available (fall of 2017). It is hard to pinpoint this to any one reason but possibilities include a lag that it takes for a new testbed to become established, the incremental introduction of features that broadened the set of supported experiments, and our first Chameleon User Meeting held just before the trend increase. At peaks, the testbed supported about 200 active users; this is twice as much as the lower bound that our allocation policy is based on (Section 2); luckily not all users are living up to their allocations!

We then asked how many leases and simultaneous leases users were able to create on a per month basis. The result for unique leases is shown in Figure 6 (A). We see that the trends are consistent with the number of active users reflecting the usage patterns in a similar way and picking up around the same time, though the growth trend is still continuing. The result for simultaneous leases (i.e., for each month, we found the max number of leases happening at the same time) is shown in Figure 6 (B); we see that the testbed has sustained up to 300 simultaneous ongoing experiments, but the trends picked up about a year later than trends for active users and experiment counts; it is clear that the testbed is now becoming more saturated.

Support Cost. Another metric important in the discussion of any testbed is support costs, specifically the time effort required by the team. Chameleon users have submitted 3,167 technical help desk tickets, averaging roughly 13 tickets every week and less than 1 ticket per user. On average users receive a reply within 15 hours and their issue is completely resolved within 2 weeks. These trended down over time: in 2019 the average response time was 16 hours, while the resolution time was 6 days. The costliest tickets concern hardware failures, which are often difficult to diagnose and/or require ordering new parts and performing maintenance. Cutting-edge or nonstandard hardware and firmware also pose problems for support staff, as documentation might not be extensive (or even exist) and having expertise at hand is unlikely. In all cases, an ounce of prevention is worth a pound of cure: we have deployed or implemented an operational model integrating early detection (e.g., daily/hourly "happy path" tests of common user flows, live-monitoring with Prometheus [17], and a catalogue of alertable issues and resolution steps) and automated remediation (in the form of "hammers", i.e., bots that periodically check for and fix irregularities in testbed usage and performance). We additionally automate most common operator tasks, such as building new base images, deploying patches or configuration changes to the control plane, and taking nodes in or out of maintenance. Details of Chameleon operations has been published in [18].

Another indicator of cost in a system where users are given significant privileges is the cost of security management. We employ a range of standard security practices designed to make the system more secure: project PIs are vetted and assume responsibility for users on their projects; we provide base images configured and maintained by our team with reasonable security defaults and SSH key pairs for authentication; the management network is isolated from tenant networks; and we use intrusion detection system (IDS) alerts across the entire deployment. Since the system went public we've had a number of security incidents; most are caused by users either unknowingly or deliberately shirking best practices, e.g., using images with a known administrative password or using outdated software with known exploits – the latter sometimes to be compatible with benchmarks and other research software. The most typical types of exploits result in activities such as distributed denial of service (DDoS) attacks (~40% incidents) or bitcoin mining (~36% incidents). Those are typically identified via IDS systems operated on sites and trigger well-defined security procedures in response usually involving user/PI cooperation. So far, we've only had one incident involving malicious users in the first quarter of 2020 which shows that our PI vetting methods work well on the whole. Considering the nature of attacks to date the greatest improvement would probably be effected by more user training in techniques such as setting up bastion host for when insecure researchware has to be used as well as general training in operational security.

Community. Chameleon users come from 168 different institutions, the vast majority of which are US colleges and universities from 40 states and Puerto Rico, including 11 minority serving institutions. While most of the research projects we support are in computer science, 54 identify themselves as being from outside of computing disciplines, primarily in life sciences, astronomy and other fields. By analyzing project abstracts we see that roughly 12% of all projects relate to cybersecurity, 20% are involved in machine learning, 10% are in edge computing or IoT applications, 5% are doing research work relating to containers (scheduling, virtualization, or performance), 2% are investigating software-defined networking. Several hundred grants are reported by users as the source of funding; the vast majority of these are from NSF, and within those the vast majority are spread among all divisions within CISE. About 5% of grants are supported by the DOE, DARPA, or the Air Force Office of Sponsored Research. A handful of projects are supported by industry, and several more have international support.

Publications are a complicated metric to track as they tend to be a lagging indicator; many happen after the allocation is complete, when there are few incentives for users to report them to the project. Further, the primary way we capture publication counts is through self-reporting when users seek a renewal of their allocation; while this is an incomplete method it still represents a useful lower bound. Through 2019, users have self-reported about 275 publications relating to their work on Chameleon, with many projects still active. There are 75 referred journal articles among these, with close to 200 conference publications. The spread of publications is fairly wide, with no clear concentrations in particular conferences or journals. As would be expected for a testbed, growth over time is dramatic and lagging: of the 75 journal papers, only 3 were published in the first project year, 8 in the second, 10 in the third, 23 in the fourth, and 31 have been published so far in the fifth year with several months remaining.

In addition to research usage, there is substantial educational use of the system. 45 projects support classroom instruction, often multiple classes over multiple semesters; all but four of these projects support courses in CS departments at 41 different schools. In total, the education projects have used about 9% of the total time available on Chameleon to date (roughly 675,000 node-hours), and they represent about 9% of the total projects – so an average classroom project uses about 15,000 node-hours, matching the usage of a typical research project.

One measure of the satisfaction of the user community is persistence. Projects are initially allocated time on the system for 6 months, and at the end of the year they must seek a renewal or extension. Of the projects that have reached the end of their initial year of allocation, about three-quarters of all projects have sought to renew their allocations, indicating that they find value in the use of the system. Many projects seek multiple renewals – in fact thirty-three of the original projects from the first year have been renewed multiple times and counting!

4 Building a Testbed on Top of Mainstream Cloud Implementation

When the Chameleon project started, we were presented with the unique opportunity of building the testbed on top of the then maturing cloud infrastructure: the first version of the OpenStack Ironic component [19], implementing bare metal reconfiguration (which we knew would be an indispensable capability of the system) has been released a few months prior to the project start, and while not yet an official part of the system has already been used in some bare metal deployments. The chance to base a testbed for cloud computing research on a mainstream open source implementation held out many possibilities, but will it be enough to support all the experiments that needed to be supported in the way they needed to be supported? After thorough evaluation of the system and development of a few alternative risk-mitigating strategies we decided that capabilities we needed were there—or were within reach in that they could be developed by our team. This section presents an analysis of the advantages and cost of taking this approach.

One practical benefit of using OpenStack is that it provides familiar interfaces to users and operators. The 2018 OpenStack User Survey [20] (most recent) included 858 OpenStack deployments across 441 organizations and 63 countries; of those organizations, 13% were categorized as academic or research-oriented. Those include major scientific institutions such as CERN [21], NeCTAR [22], and NASA JPL [23], and a formal Scientific Special Interest Group (SIG) [24] for OpenStack's use in science domains has existed since 2016 [25]. Since the introduction of the OpenStack Administrator certification three years ago, 3,000 individuals in 77 countries have taken the test [26]. All this not only creates a base of familiarity with OpenStack for users and operators – but also ensures that such familiarity is a transferable skill and thus valuable for workforce development. Finally, the Net Promoter Score [27] of 41 reported by the survey (up from 25 in 2017) indicates that the OpenStack environment continues to improve in terms of usability and that users enjoy the experience overall.

Another benefit of working with a mainstream platform is the ability to leverage and adapt the work of a large community which helps keep our development and operations costs down. Over 8,400 individuals have contributed code to OpenStack, with 1,000-2,500 contributors participating in each major release [28]. Leveraging their contributions, over the lifetime of the project we were able to offer our community new key features such as whole disk image boot, multi-tenant networking, serial console integration, support for non-x86 architectures, and user-customizable firewalls—simply by upgrading to a new OpenStack version. Future capabilities already possible due to upstream contributions include self-service BIOS customization and detachable remote storage; both have been common user requests. From the operator's perspective, deploying and managing Chameleon was made simpler and more reliable by the Kolla project, which provides a packaging of OpenStack as Docker containers [29] and a set of highly-configurable Ansible provisioning scripts [30] to orchestrate the setup and maintenance of the deployment. Further, ~6,000 individuals have been involved in reviewing all code changes [31]: thus, by using a mainstream infrastructure we also benefit from a built-in large-scale quality control mechanism. No less valuable has been the access to the existing documentation and support systems within the community: the openstack-discuss mailing list [32] sees between 500-1000 messages each month, the OpenStack Q&A forum [33] has over 18,000 answered questions, and on many occasions we were able to get a workarounds or patches for bugs within days simply by filing a ticket to the official tracker.

The flip side of leveraging contributions of others is the opportunity to contribute to and shape a mainstream infrastructure. On a practical level, this magnifies our investment in the infrastructure and our broader impacts as any new features and additions we make to OpenStack are also impacting communities beyond the testbed. Because its hardware resources have always been constrained relative to the demands of its user community, Chameleon required a system for allocating and managing resources (including advance reservations), which our team implemented by reviving and significantly improving the OpenStack Blazar project. This attracted the interest of others and we were subsequently able to partner on development with contributors from NTT (Japan) and DOCOMO Euro-Labs (Germany) who use the component in Software Defined Networking applications. As a result of this collaboration, Blazar became an official top-level OpenStack component in 09/17 and has been included in each OpenStack releases since Queens. Other significant new features developed by the Chameleon team include bare metal snapshotting and enablement of slice creation via integration with ExoGENI stitching implementation; in addition, we made many smaller contributions in the form of bug fixes and patches.

These advantages are offset by some costs. Since it solves a complex problem, OpenStack is complex; thus operating, and in particular extending it, requires both development skills and deep expertise in the underlying systems and concepts, putting pressure on operator hours and level of skill. The most problematic manifestation of this complexity in our experience used to be OpenStack upgrades; this has improved significantly with tools that aid operators in these tasks, such as the aforementioned Kolla project. The size and structure of the open source community imposes its own overhead and requires commitments both in process and in time: patches must be reviewed, meetings must be attended, changes must be formally proposed and approved, and documentation and tests must be written. These commitments are the price of admission to an open-source community that, in our experience, ultimately returns the investment many times over in the form of support, debugging, development, and partnership.

Looking beyond practical benefits, building on top of a mainstream infrastructure helps settle a point of intellectual interest in that it provides a direct answer to the question: can clouds support CS system experimentation? While different clouds will of course be configured differently, Chameleon represents a configuration that satisfies this condition; we describe this configuration in this paper but it is also expressed in practical form via code, recipes, and settings that are publicly available and suitable for replication whether in academia or commercially. Like the Chameleon interfaces we support, that recipe has multiple "entry points": users may elect to simply install OpenStack with our contributions—they may elect to replicate the Chameleon configuration in every detail—or they may choose something in between. We facilitate this by providing a packaging of Chameleon Infrastructure (CHI) that contains not only OpenStack but also extensions including Grid'5000 and ExoGENI additions, as well as an operational model we developed that makes clouds of this type cost-effective to provide. This packaging, called CHI-in-a-Box [34], has recently been installed at Northwestern University and augmented Chameleon capabilities by providing modest but unique networking hardware.

5 Fostering Replicability and Sharing

Perhaps the most important lesson learned from Chameleon is that testbeds provide not only a platform for instruments but also generate shareable digital artifacts such as images, orchestration templates, datasets, tools, notebooks, and others. Those artifacts typically represent either a complete experiment or an important part of one and can be used to reenact it on the testbed on which it was created. For example, over the lifetime of the Chameleon testbed, users created 120,000 disk images and 31,000 orchestration templates that can be used for such purpose. This presents an opportunity: since the generated artifacts can be used to repeat experiments, sharing them should allow others to repeat experiments, introduce variation, or extend experiments more easily. We posit that fostering that sharing will contribute to the overall goal of providing a scientific instrument to advance CS systems research by both reducing time to discovery and providing a more fertile ground for sharing of ideas. The question arises how specifically experiments should be represented and structured—and then how specifically they should be shared.

Chameleon has supported a variety of mechanisms to aid repeatability over its lifetime. First, the Chameleon hardware is versioned, which allows users to easily identify any changes which would introduce variation. Users can also version the images they configure, and publish them in a catalog. Since this still requires a user to keep track of which appliances were deployed on which testbed version, we introduced a system, called Chameleon's Experiment Précis [35], which captures all the distributed events generated by a user in the testbed, and presents him or her with a summary (a précis) of their experiment. Then, working with an accurate and impartial record of their work, the user can filter or preview the events to include only the relevant ones. The précis data can be used to generate a description of the experiment in English, or potentially an actionable description of the experiment in the form of orchestration templates or commands that will reproduce the experiment. Generating Heat orchestration templates in this way is in fact the objective of an OpenStack Flame [36] tool. Overall, the Experiment Précis is somewhat analogous to a shell's "history" command with the critical difference that it captures distributed rather than local events – though its output is less "actionable".

This raises the question of what an actionable representation of an experiment should ideally look like. Orchestration systems such as profiles in CloudLab or Heat in Chameleon require adhering to a strict machine-readable syntax, often formulating that syntax in a declarative text file, or providing a layer of indirection that allows the user to work in a higher-order language. Furthermore, these systems are transactional, either fulfilling the topology or not, making complex configurations difficult to develop and iterate upon. Proposed workflow systems [37] experience similar challenges [38]. They fundamental problem from the user perspective in these cases is that a user must invest extra time to make an experiment reproducible. This leads to the "reproducibility dilemma": the user needs to choose whether to invest time into making an experiment replicable or continuing with other research. Ideally, a system that represents an experiment would allow the experimenter to develop it gradually and interactively reflecting the often meandering creative process, support experimental "story-telling" for human as opposed to just machine users, and—true to our philosophy—be an open source project in mainstream use.

In researching solutions to this problem, we considered computational notebooks such as Wolfram Mathematica [39] and Jupyter Notebooks [40], which combine expository text, executable code, and presentation of results in one human-readable, interactive document. Jupyter's newfound ubiquity across the research landscape and its extensible architecture provided fertile ground for exploration; to leverage it, we integrated Jupyter and Chameleon with the intent to reduce the gap between designing an experiment and sharing it. As a result, users can log in to Chameleon Jupyter server with their testbed credentials; these credentials are implicitly bound to the user's isolated Jupyter Notebook server, allowing the user to call Chameleon APIs (via the CLI interface or Python APIs) directly within their notebook's code blocks. This allows a notebook to completely re-create a pre-existing testbed topology. We additionally mounted Chameleon's object store as a virtual drive in the Jupyter application to allow shared storage and therefore collaboration between users. The user's Jupyter server comes pre-installed with several libraries that aid interfacing with an experiment on Chameleon [41] (e.g., creating a lease and launching an instance and then executing commands remotely via SSH). As we've improved the Jupyter interface to Chameleon it has seen an increasing share of testbed usage; over the last year 10% of our monthly active users have been using Jupyter as their interface to the system.

While the notebook may be an appropriate way to package an experiment without disrupting the flow of research, the challenge of properly disseminating and discovering these artifacts remains. At the end of 2019, we implemented the first version of a Sharing Portal [42] to allow users to publish and discover these notebook-based artifacts. Users can publish a set of files directly from the Jupyter interface via a custom UI extension; the files are compacted into an archive and published to CERN's Zenodo [43] for long-term storage, where they are also assigned a DOI for citation. The Sharing Portal then maintains a reference to the published artifact along with helpful metadata such as tags and documentation. Other Chameleon users can search for artifacts within the portal and "re-play" them on Chameleon with one click: an ephemeral Jupyter server tied to the artifact is dynamically provisioned, including additional software dependencies defined by the publisher. Users can version their artifacts by publishing a new set of files and creating a new version (and DOI) on Zenodo. Though too early in its lifetime to provide a quantitative analysis of its impact, we expect to continue investing in this area going forward.

6 Related work

Some of our design decisions in Chameleon were informed by our earlier work on experimental testbeds including FutureGrid [44,45] and ExoGENI [8], as well as our long standing close collaboration with Grid'5000 [1]. In particular, we are indebted to the latter two projects for not only providing insight but also specific capabilities that were directly integrated into the testbed; the stitching capabilities in the case of ExoGENI and the resource representation and related tooling in the case of Grid'5000. At the same time, Chameleon represents a significantly different approach from any of them in many ways, most prominently in that it is configured for cloud computing research (unlike ExoGENI), supports bare metal reconfiguration (unlike FutureGrid), and is based on a mainstream infrastructure (unlike Grid'5000).

We additionally leverage the experience gained by the rich history of CS testbeds, ranging from those specializing in networking (PlanetLab [46], GENI [4], Emulab [2], OneLab [47], CENI [48]) and wireless/IoT (ORBIT [49], FIT [50], CityLab [51]) to systems (CloudLab [3]) and security (DeterLab [52]); Chameleon complements these systems in that it largely focuses on a different area of research and thus supports different types of experiments. The most similar testbed to Chameleon is CloudLab (itself another NSFFutureCloud testbed). We differ from CloudLab primarily in specific design decisions we made in building the system, many of which are described in this paper as well as in our early emphasis on reproducibility and sharing by integration of tools like Experiment Précis and Jupyter notebooks. The most significant difference however is that we built Chameleon on top of a mainstream cloud infrastructure for reasons described above.

Clouds are being increasingly used in science and many of them elect to use OpenStack, e.g., Jetstream [53], Aristotle [54], Comet [55], Bridges [56], and NeCTAR [22] all represent different configurations of the system. The most significant difference from Chameleon is that these are relatively standard cloud configurations, designed primarily to support domain science applications rather than CS experimentation, and differ from Chameleon significantly on key features such as bare metal reconfiguration. However, there are significant commonalities on the operations side ensuring that we are able to leverage their contributions, with the OpenStack SIG being one avenue of communication. An interesting recent addition is the CloudBank project [57], which will provide tools, training, and credits for CS research on virtualized commercial clouds; since we provide similar services via our KVM cloud, we look forward to working with this project.

Reproducibility of CS experiments [58] is another area in which our contributions relate to other work in the field. Several projects have used Jupyter notebooks as a mechanism for encapsulating and reproducing research [59, 60]. Managed "Notebook-as-a-Service" platforms e.g., CodeOcean [61], WholeTale [62], and Nextjournal [63] have further elevated the profile and utility of Jupyter for this purpose. Workflow solutions such as Popper [37] aim to aid reproducibility in a different way and are more relevant to our efforts on Experiment Précis. Chameleon differs from all of these examples in that it integrates reproducibility tools in the context of a testbed, allowing users to leverage a commonality of platform to replicate not only the process of experimentation, but also the requisite hardware configurations and topologies.

7 Conclusions

Chameleon represents a unique testbed in that it expresses the capabilities needed for CS research in terms of mainstream cloud functionality. This is an important step to understand how such capabilities may be supported more ubiquitously, with more discernment, and in a more cost-effective manner. This paper discusses the specific design decisions, extensions, and configurations that we chose in order to do so, and evaluates them within a framework that seeks to establish how they influenced the set of supported experiments and how they influenced the community of users the testbed was able to support. Our contribution is accompanied by software that was contributed or integrated with a mainstream open-source cloud implementation (OpenStack) so that a cloud of this type – or its evolutions or variations – can be supported by anyone.

The most important part of our experience is the insight that though originally created to support the most experiments for the most experimenters, testbeds have also become both a generator and an essential platform for sharing digital representations of experiments. While our understanding of digital sharing ecosystem still evolves, and is likely to evolve for some time, we proposed some approaches that our user community has found useful and we look forward to contributing to this area in the future.

Acknowledgments

Results presented in this paper were obtained using the Chameleon testbed supported by the National Science Foundation. This material is based upon work supported by the U.S. Department of Energy, Office of Science, under contract number DE-AC02-06CH11357.

Availability

Traces from Chameleon CHI and KVM have been publically available at [64, 65] for the last couple of years and used in a variety of resource management publications. Not all the data used in this paper is reflected in those traces though we are currently discussing revisions to both the content and format. All the code described here is open source.

Abstract

In a large software system such as the Linux kernel, there is a continual need for large-scale changes across many source files, triggered by new needs or refined design decisions. In this paper, we propose to ease such changes by suggesting transformation rules to developers, inferred automatically from a collection of examples. Our approach can help automate large-scale changes as well as help understand existing large-scale changes, by highlighting the various cases that the developer who performed the changes has taken into account. We have implemented our approach as a tool, Spinfer. We evaluate Spinfer on a range of challenging large-scale changes from the Linux kernel and obtain rules that achieve 86% precision and 69% recall on average.

1 Introduction

The Linux kernel is present today in all kinds of computing environments, from smartphones to supercomputers, including both the latest hardware and "ancient" systems. This multiplicity of targets with widely varying needs has implied that the code base has grown steadily over the Linux kernel's 28-year history, reaching 18M lines of code in Linux v5.4 (Nov. 2019). The complexity of designing an operating system kernel and the need to continually take into account new requirements has implied that the design of internal interfaces must be revisited, triggering the need for repetitive changes among the users of these interfaces that may affect an entire subsystem, or even the entire source tree. The size and number of the needed changes can discourage developers from performing them, and can introduce errors. Furthermore, when code is incompletely transformed, the volume of the performed changes can obscure the conditions that later developers who want to complete the change should take into account.

Since 2008, the automatic C code transformation tool Coccinelle [12] has been part of the Linux kernel developer toolbox for automating large-scale changes in kernel code. Coccinelle provides a notion of semantic patch allowing kernel developers to write transformation rules using a patch-like [16] (i.e., diff-like) syntax, enhanced with metavariables to represent common but unspecified subterms and notation for reasoning about control-flow paths. Given a semantic patch, Coccinelle applies the rules automatically across the code base. Today, Coccinelle is widely adopted by the Linux community: semantic patches are part of the Linux kernel source tree, are invokable from the kernel build infrastructure, and are regularly run by Intel's Linux kernel 0-day build-testing service [10]. Semantic patches have been written by kernel developers to make timers more secure [5], prepare the Linux kernel for the overflow of 32-bit time values in 2038 [6], reduce code size [27], etc.

Kernel developers use Coccinelle by first writing a semantic patch to perform a desired change, then applying it to the code base using Coccinelle and manually checking the resulting patch, and finally submitting the resulting patch for review and integration, according to the standard kernel development process [28]. Semantic patches have also been recognized as providing a precise means of communication about changes; developers include semantic patches in the commit logs of large-scale changes, and maintainers ask for them if they are not present, showing that semantic patches are considered to be valuable in the review and subsequent maintenance process. Still, there remain large-scale changes in the Linux kernel commit history where Coccinelle has not been used. Through discussions with Linux kernel developers we have learned that some know that Coccinelle would be helpful to them but, as they do not use it often, they do not remember the syntax. They also report that this realization often comes after performing a few manual changes. Furthermore, Coccinelle does not help developers understand existing large-scale changes, if no semantic patch is provided.

To better help developers, we propose to *infer semantic patches from existing change examples*, represented by a collection of files from before and after a change has been applied. Semantic patch inference can help developers understand previous changes without looking at hundreds of change instances. Semantic patch inference can also help developers with little Coccinelle knowledge use semantic patches if they are willing to make a few instances of the change manually.

Inferring semantic patches from real Linux kernel code changes, however, raises some challenges. The Linux kernel is written in C, which is a low-level language. Individual functionalities may be implemented as multiple C statements connected by control-flow and data-flow constraints. These constraints must be captured from the change examples and validated in the code to transform. A single kernel interface may expose multiple functions and data structures that can be used in various ways, any or all of which may be affected by a change. Inference must thus be able to cope with multiple change variants. Finally changes that are relevant to many files may be tangled with *noise*, *i.e.*, changes that are specific to a particular file, and thus are not worth automating. Semantic patch inference should be able to ignore such changes.

In this paper, we propose an approach to semantic patch inference that scales to the needs of systems code, such as the Linux kernel. Starting with the intraprocedural control-flow graphs of the original and changed functions found in the examples, our approach iteratively identifies code fragments having a common structure and common control-flow relationships across the examples, and merges them into a rule proposition. During this iterative merging process, rules are split as inconsistencies appear. Our approach is able to infer semantic patches from examples that overlap, that implement a family of transformations, and that may include noise. We have implemented our approach as a tool, *Spinfer*, targeting semantic-patch inference for the Linux kernel. Spinfer-inferred semantic patches can be read and understood, reviewed, and automatically applied to the Linux kernel.

The contributions of this paper are as follows:

- We propose a taxonomy of challenges that must be handled by transformation-rule inference tools and assess recent work and our proposed approach according to this taxonomy.
- We propose an approach to automatic inference of semantic patches that takes control and data-flow, multiple change instances, multiple change variants and unrelated changes into account. We provide an implementation of this approach for C code in the tool Spinfer.
- We evaluate Spinfer on a large set of 80 changes, affecting thousands of files drawn from recent Linux kernel versions, against semantic patches written by a Coccinelle expert. Generated semantic patches achieve on average 86% precision and 69% recall.

The rest of this paper is organized as follows. Section 2 presents some motivation for our work, our taxonomy and the most closely related work. Section 3 presents our approach and its implementation in Spinfer. Section 4 evaluates Spinfer on 80 recent sets of changes to the Linux kernel. Finally, Section 5 presents other related work and Section 6 concludes.

2 Background and Motivation

We first present an example of a large-scale change from the Linux kernel development history. Based on the challenges identified in this example, we then propose a taxonomy of challenges for transformation-rule inference. We then assess related approaches in terms of this taxonomy.

2.1 Motivating example

Linux kernel timers were originally initialized by a multi-step process, involving a call to **`init_timer`** to initialize a timer structure and two assignments to initialize the fields **`function`** and **`data`**, describing what to do when the timer expires. In Linux 2.6.15, released in 2006, **`setup_timer`** was introduced to combine these operations and thus simplify the source code. Elimination of **`init_timer`** got off to a slow start, with 73 changes in 2008 and then little activity until 2014. In 2014-2016 there were 43, 93, and 37 changes per year, respectively. The remaining 267 calls were removed in 2017, when it was also recognized that incremental initialization using **`init_timer`** represents a security hole.[1]

Figure 1 illustrates some instances of the **`init_timer`** change.[2] We examine these instances in terms of the challenges they pose for semantic patch inference.

Control-flow. The change typically involves removing three statements, *i.e.*, the call and the two field initializations. These three statements are typically part of some larger block of code, and thus do not correspond to an independent subtree of an Abstract Syntax Tree (AST). They are not always contiguous either (**`nicstar.c`**).

Data-flow. The change involves keeping the same expression for the **`init_timer`** and **`setup_timer`** first argument, and for the structure used in the **`data`** and **`function`** field initialization.

Multiple variants. While the examples basically perform the same operations, at a detailed level there are a number of variations. For example, the first two examples initialize both the **`function`** and **`data`** fields, but in the opposite order. Semantic-patch inference should be able to proceed in the face of these variants and generate the needed rules. The last example presents yet another variant that does not initialize the **`data`** field at all, retaining the default value of 0. This variant poses a further challenge, as it overlaps with the other variants, in that all of the examples remove an **`init_timer`** call and the initialization of the **`function`** field. Semantic-patch inference has to *carefully order* the resulting rules such that a rule setting the third argument of **`setup_timer`**, representing the timer data, to **`0UL`** does not apply to code where a value for the **`data`** field is specified.

- ntimer.function = nmi_wdt_timer;
+ setup_timer(&ntimer, nmi_wdt_timer, 0UL);
```

Figure 1: Variants of the **`init_timer`** change

Multiple instances. Another form of variation in the examples is the number of instances of a given change. Most of the examples initialize only one timer, but **`hostap_hw.c`** initializes two. To concisely describe the overall change, it is better to obtain a rule for a single timer that applies to this code twice, rather than obtaining a rule specific for this case.

Noise. Change examples can also contain extraneous changes from which it is not useful to infer semantic patches. A single patch may, for example, change a function definition and update the uses of the function accordingly. The change to the definition is a one-time operation, so it is not useful to automate. Another possibility is the presence of other changes, such as minor refactorings. While research on application software has found that the latter tangled changes are frequent [9], the Linux kernel documentation requires that developers separate their changes into one change per patch [28], and thus we expect tangled changes to be a minor issue in our setting in practice.

2.2 Taxonomy

Based on the above examples and study of other large-scale changes in the Linux kernel, we have created a taxonomy, shown in Table 1, of challenges for transformation-rule inference. This taxonomy can be used to characterize particular change examples and to compare transformation-rule inference approaches.

Table 1: Taxonomy of challenges for transformation inference

***C*: Control-flow dependencies**
0. *No* control-flow dependencies between changed terms
1. *Intraprocedural dependencies* between changed terms
2. Intraprocedural dependencies between changed and *unchanged terms*
3. Some terms must *not* appear within relevant control-flow paths
4. *Interprocedural* control-flow dependencies between changed and unchanged terms
***D*: Data-flow dependencies**
0. *No* data-flow dependencies between changed terms
1. Data-flow dependencies between changed terms
2. Data-flow dependencies between changed and unchanged terms
***I*: Change instances per function**
0. One instance
1. Multiple instances
2. Overlapping instances
***V*: Change variants**
0. One variant
1. Multiple variants
2. Multiple variants with specific order
***N*: Noise (errors and unrelated changes)**
0. *No* noise
1. Contains noise

The taxonomy considers the relationship between changed terms in a single change instance (C and D), the ways in which multiple change instances can appear within a single function (I), and the possibility of change variants (V) and unrelated changes (N, noise). For control-flow dependencies, the taxonomy entries range from no dependencies (C_0) to changes that requires intraprocedural dependencies to changed terms (C_1) to changes that involve dependencies between both changed and unchanged terms across multiple functions (C_4). For data-flow dependencies, the taxonomy entries range from no dependencies (D_0) to data dependencies between both changed and unchanged terms (D_2). For multiple change instances, the taxonomy entries range from one instance per function (I_0) to overlapping instances (I_2). For multiple variants, the taxonomy entries range from one variant at all change instances (V_0) to multiple variants that have to be considered in a specific order (V_2). For noise, the taxonomy entries have either the absence of noise (N_0) or presence of noise (N_1). Spinfer targets C_1, D_2, I_2, V_2, N_1 (control-flow and data-flow constraints, potentially overlapping change instances, multiple order-dependent change variants, and the possibility of noise in the examples).

2.3 Existing tools

A number of tools have previously been developed to infer transformation rules or update API uses automatically. Most of these tools target user-level applications written in object-oriented languages, typically Java, while we target an operating system kernel written in C. While these different kinds of code bases raise different challenges, all of the issues we identify with existing tools also apply to our setting.

Individual examples. Sydit [17], A4 [11], Meditor [30], AppEvolve [7], and GenPat [8] generate transformation rules from individual change examples. All of these approaches except GenPat abstract over the examples by abstracting over variables. In practice, change examples mix generic computations and computations that are specific to a particular application. Abstracting over variables is not always sufficient to abstract away these application-specific computations. Such approaches thus obtain low recall on anything but the simplest examples. GenPat [8] bases abstraction decisions on the frequency of various terms in code repositories such as GitHub. As GenPat's abstraction strategy is based on the properties of a large code corpus rather than on the change itself, it may infer transformations that are too generic, transforming code that should not be changed, thus reducing precision. The evaluation presented in the work on GenPat reflects these issues.

Approaches that abstract from individual examples may perform incorrect transformations if the examples are not given to the tool in the right order. For example, in the **`init_timer`** example, if **`nmi.c`** is provided as an example first, then all timer initialization code will be incorrectly updated with the data value 0, even if another data value is provided. AppEvolve addresses this issue by computing a common core of the provided examples, and attempting to apply the generated rules in order of their distance from this common core. The rule generated from the **`nmi.c`** example, however, is smaller than the others, and would thus be tested first by such a strategy. AppEvolve additionally proposes to use testing to validate the changed code, but the Linux kernel does not provide a comprehensive suite of easy-to-run high coverage test cases.

Several of these tools are also not able to identify change application sites. For example, Sydit requires the user to specify the affected function, while AppEvolve requires the user to specify the affected file name and line number. Manually specifying change sites is not practical for a code base the size of the Linux kernel.

In terms of the taxonomy, Sydit, A4, Meditor and GenPat target C_0, D_2, I_1, V_2, N_0; AppEvolve targets C_0, D_2, I_1, V_2, N_1 but requires preliminary manual rewriting of the change examples [29].

Multiple examples. Lase [18], Refazer [23], and Spdiff [1, 2] learn from multiple examples, identifying how to abstract over these examples based on the commonalities and differences between them.

Based on a set of change examples, Lase represents modifications as a sequence of AST edits and solves the Largest Common Subsequence Problem to find a transformation rule. This method implies that Lase cannot learn from examples containing unrelated changes or multiple variants, as we have seen for **`init_timer`**. Moreover these edit subsequences do not capture control-flow constraints and thus can generate incorrect changes, as illustrated below. In terms of the taxonomy Lase targets C_0, D_2, I_0, V_0, N_0

Refazer represents a transformation as a list of rewrite rules in a domain-specific language. It clusters changes from multiple examples and then infers one rule for each cluster. Like Lase this list of rewrite rules does not incorporate control-flow constraints and thus can generate incorrect changes. In terms of the taxonomy Refazer targets C_0, D_2, I_2, V_1, N_0.

Spdiff abstracts over common changes across the examples, incrementally extending a pattern until obtaining a rule that safely describes the complete change, taking control-flow constraints into account. It targets the Linux kernel and produces Coccinelle semantic patches. In terms of the taxonomy Spdiff targets C_2, D_2, I_2, V_0, N_0, however when tested on all of our examples it produced no correct results. For even simple function call replacements, we found that Spdiff spends much time on finding more complex but actually incorrect solutions.

We can note that, with the exception of Spdiff, all existing tools do not handle control-flow relationships between changed terms. To illustrate the impact of control flow, we have performed an experiment on Linux kernel-like code using Lase[3] (the distributed implementation of Refazer only supports restricted subsets of Python and C#, making it difficult to test in practice). Consider the following Linux kernel change example:[4]

```
- tport = kmalloc(sizeof(struct ti_port), GFP_KERNEL);
+ tport = kzalloc(sizeof(struct ti_port), GFP_KERNEL);
  if (tport == NULL) {
    dev_err(&dev->dev, "%s - out of memory\n", ...);
    status = -ENOMEM;
    goto free_tports;
  }
- memset(tport, 0, sizeof(struct ti_port));
```

Thus, from examples such as this one, Lase infers a rule that makes the following incorrect changes:

```
  if (a)
-   x = kmalloc(sizeof(*x), GFP_KERNEL);
+   x = kzalloc(sizeof(*x), GFP_KERNEL);
  else
-   memset(x, 0, sizeof(*x));
```

[3] Lase targets Java. We use C in the presented examples for consistency with the rest of the paper.

[4] Commit 7ac9da10af7f

and

```
- x = kmalloc(sizeof(*x), GFP_KERNEL);
+ y = kzalloc(sizeof(*y), GFP_KERNEL);
  y = kmalloc(sizeof(*x), GFP_KERNEL);
- memset(y, 0, sizeof(*y));
  memset(x, 0, sizeof(*x));
```

The first case shows that the inferred rule does not check that the **memset** affects the result of the call to **kmalloc** in the same control-flow path, thus performing an incorrect transformation. The second case shows that the inferred rule modifies the wrong **memset**, *i.e.*, the one affecting **y** rather than the one affecting **x**, and, worse, rearranges the variables so that **x** is no longer initialized. LASE only updates the first match in each function, and thus the second call to **kmalloc** is left unchanged. The former example may be unlikely for the specific functions of **kmalloc** and **memset**, but there is an instance analogous to the latter example in the Linux kernel history.[5]

Our approach. Given the difficulty of choosing an appropriate degree of abstraction from only one example, and given the availability of multiple examples of the use of most interfaces in the Linux kernel, our approach relies on multiple examples. Our approach is able to infer and express both control-flow and data-flow relationships that must be respected between fragments of code that are to be transformed. It adapts to variations in the examples to produce multiple rules and tolerates noise. Finally it produces transformation rules in a readable notation that is close to C code and is familiar to Linux kernel developers.

To the best of our knowledge, our approach is the only one capable of handling all these challenges at the same time and requires no rewriting of example code, making it suitable for systems code transformations.

3 Approach and Tool Design

In this section, we first give an overview of our approach, and then present the various steps used by our tool Spinfer to realize this approach. Spinfer is implemented as 10.6K lines of OCaml code. For parsing C code and mining control-flow relationships, it reuses the infrastructure of Coccinelle [12].

3.1 Overview

Our goal is to produce Coccinelle transformation rules based on a set of provided change examples, consisting of pairs of functions from *Before* and *After* the change. To motivate the steps of our approach, we first consider a semantic patch, composed of 4 rules, that a Coccinelle expert might write based on the **init_timer** examples illustrated in Section 2:

```
@@expression T,F,D;@@    @@expression T,F,D;@@
- init_timer(&T);         - init_timer(&T);
+ setup_timer(&T, F, D);+ setup_timer(&T, F, D);
  ...                       ...
- T.data = D;             - T.function = F;
- T.function = F;         - T.data = D;

@@expression T,F,D;@@    @@expression T,F;@@
- T.function = F;        - init_timer(&T);
- T.data = D;            + setup_timer(&T, F, 0UL);
  ...                      ...
- init_timer(&T);        - T.function = F;
+ setup_timer(&T, F, D);
```

The semantic patch consists of four transformation rules for the four different patterns of changes that occur in the examples. Each rule initially declares some *metavariables*, representing abstracted subterms, and then describes the changes as a sequence of lines of code patterns annotated with **-** and **+**, indicating code to remove and add, respectively. "..." represents a control-flow path, connecting the code matched by the pattern before the "..." to the pattern after the "...". Coccinelle applies a semantic patch to C source code in terms of the C source code's control-flow graph (CFG). A CFG as used by Coccinelle contains a node for each semicolon-terminated statement in the function, as well as for each if header, while header, etc. Coccinelle matches each rule of a semantic patch against the CFG of each function in a C file. When a match is found, Coccinelle transforms the code found in each matched CFG node according to the **-** and **+** annotations. More details about Coccinelle's semantic patch language SmPL are presented elsewhere [3].

We can observe that these four transformation rules share some constituents:

- Removal of a call to **init_timer**: **init_timer(&T);**
- Removal of a **data** field initialization: **T.data = D;**
- Removal of a **function** field initialization: **T.function = F;**
- Addition of the call **setup_timer(&T, F, D);**

We call these constituents *abstract fragments*, as they are fragments of a semantic change and each of them has a particular role in that change. Identifying a semantic patch as an assembly of small abstract fragments can help to solve the challenges highlighted in the introduction. In this view:

- Control-flow dependencies are the rules to assemble fragments together.
- Data-flow dependencies are the rules to match metavariables together.
- Variants are different assemblies of abstract fragments.
- Errors and noise are very unpopular abstract fragments.

[5] Commit 87755c0b3af6.

One can thus resolve these challenges by identifying the abstract fragments to consider and by determining how to assemble them together.

Following this observation, our approach focuses on finding abstract semantic patch fragments that will be assembled into one or more semantic patch rules. Each rule will match one of the variants illustrated by the examples. We have implemented this approach as a tool named Spinfer.

Starting from a set of *examples*, consisting of pairs of files before and after some changes, Spinfer constructs a set of transformation rules describing the changes. For this, Spinfer first identifies sets of common removed or added terms across the examples, then generalizes the terms in each set into a pattern that matches all of the terms in the set, and finally integrates these patterns into transformation rules that respect both the control-flow and data constraints exhibited by the examples, splitting the rules if necessary when inconsistencies appear.

Spinfer is organized as follows:

1. Identification of abstract fragments: Spinfer first clusters subterms from the examples having a similar structure and generalizes each cluster into an abstract fragment that matches all the terms in the cluster.

2. Assembling the rule-graphs: Spinfer then combines the abstracted fragments into a *semantic patch rule-graph*, a representation of a transformation rule as a graph, where nodes represent fragments to add and remove, and where edges are determined by control-flow dependencies exhibited in the associated examples.

3. Splitting: When assembling fails or when Spinfer detects data-flow inconsistencies, Spinfer splits existing rule-graphs into more specific ones.

4. Rule ordering: Finally, Spinfer orders the generated rules, removing redundant ones, to maximize precision and recall while minimizing the number of rules for the final semantic patch.

3.2 Identification of abstract fragments

The goal is to cluster nodes sharing similar subterms to form abstract fragments. Given that we have no a priori knowledge of the change variants illustrated by our examples, we must make an arbitrary decision about the granularity at which to investigate their subterms. Concretely, we choose the granularity of individual statements in a straightline code sequence, as well as function headers and headers of conditionals and iterators. An example from the **`init_timer`** code would be **`init_timer(&device->timer);`**. Such terms have the desirable property of being complete statements and expressions, with simple control-flow relationships between them. We refer to these terms as *nodes* as they will later correspond to the nodes of the control-flow graphs (CFGs) that we use to validate the control-flow constraints.

Spinfer then proceeds with an initial clustering of the CFG-nodes to be removed and added according to the examples. This clustering is independent of control-flow information, and is refined by control-flow constraints in the subsequent step. Each cluster will be represented by the smallest abstraction that matches all members in the cluster, known as the anti-unifier [21,22] of the cluster. Clustering code fragments using anti-unification has already been used in REVISAR [24] and CodeDigger [4]. However these approaches give the same weights to all anti-unifiers, regardless of their popularity, which cannot help to discriminate noise from relevant nodes. Spinfer overcomes this limitation by using techniques from text mining.

Node weighting: To facilitate clustering and noise detection, we want to give higher weight to anti-unifiers that are likely to form correct abstract fragments, and lower weight to anti-unifiers that are either too specific, manifested as rarely occurring across the set of examples, or too generic, manifested as occurring frequently within a single example, to describe the change. This goal is very similar to the goal of the *term frequency – inverse document frequency (TF-IDF)* [26] process used in text mining to highlight words that particularly characterize the meaning of a given document in a corpus. Spinfer requires the inverse notion, i.e., anti-unifiers that are common to many documents (i.e., functions), but do not occur too frequently in any given document.

Concretely, Spinfer uses a process that we call *function frequency – inverse term frequency (FF-ITF)*. In FF-ITF terms are anti-unifiers and a term weight increases with the number of functions that contains nodes matching this term (function frequency), and decreases with the number of nodes matching this term which appear in the same function (inverse term frequency).

The first step is to count how many times each anti-unifier appears. To do so, Spinfer first represents each node as a set of anti-unifiers that can match this node, from very abstract ones, that are likely to be shared by several nodes, to very concrete ones; we only consider anti-unifiers that at least abstract over local variables. Then given an anti-unifier $\mathcal{A}$, a set of functions F and a particular function $f \in F$ that contains the set of nodes N_f, our weight $w_{\mathcal{A},f}$ is:

$$\mathrm{FF}_{\mathcal{A}} = \frac{|\{f' \in F : \mathcal{A} \in f'\}|}{|F|}$$

$$\mathrm{ITF}_{\mathcal{A},f} = \log \frac{|N_f|}{|\{n \in N_f : \mathcal{A} \in n\}| + 1}$$

$$w_{\mathcal{A},f} = \mathrm{FF}_{\mathcal{A}} \times \mathrm{ITF}_{\mathcal{A},f}$$

This weight function is closely related to the one used in TF-IDF. We illustrate why this weight function works with an example on the **`init_timer(&ntimer);`** code fragment. We consider here only the 3 following anti-unifiers: (1) **`Expr;`**, (2) **`init_timer(&ntimer);`** and (3) **`init_timer(&Expr);`**. (1) is too generic and matches every statement, consequently it will have high function frequency but a very low inverse term frequency. Conversely (2) is too specific and probably matches only one node, so it will have a low function frequency but a high inverse term frequency. (3) matches **`init_timer`** function calls and nothing else, making it a good candidate to form correct abstract fragment. It will have both a high function frequency and a high inverse term frequency, which will result in a higher weight than (1) and (2).

Noise detection: The result of the node weighting gives a set of weighted anti-unifiers for every modified node of each example. The next step is to separate noise from relevant nodes. As noise is composed of very unpopular code fragments, all its anti-unifiers are either too generic or have very low function frequency, and as a consequence, have low weights. On the contrary relevant nodes have at least one anti-unifier with a high weight. Thus it is possible to distinguish noise nodes from relevant nodes by looking at the weight of their highest weighted anti-unifier.

To decide if a node is relevant, Spinfer compares the weight of the node's highest weighted anti-unifier to the average of the weights of the highest weighted anti-unifier of each node. If it is below a certain distance from this average, the node is considered to be noise. We have performed a separate experiment on the noise detection and looked for the distance at which we could mark nodes as noise without producing false positives. We found the ideal distance to be slightly less than 3 standard deviations.

Nodes marked as noise are dropped from further processing by Spinfer.

Clustering: In this step, we want to group together nodes that share a common high-weighted anti-unifier. For this Spinfer, proceeds with the clustering of the nodes not identified as noise. Spinfer first assigns to each node a characteristic vector encoding the weights of all anti-unifiers for this node. Our approach uses agglomerative hierarchical clustering with complete linkage, described by Zhao *et al.* [31], on our characteristic vectors. This approach has already been used for document classification in conjunction with TF-IDF weighting [31].

The number of clusters is determined using the best average *Silhouette score* [25], a score estimating the quality of the clustering, for all possible numbers of clusters. After this procedure we obtain groups of nodes that are very similar, and that will be transformed to abstract fragments in the next step.

Cluster (code and CFG-Diff node)	Abstraction

`init_timer(&device->timer);`
`init_timer(&ns_timer);`
	`init_timer(&X0);`

`device->timer.function =`
`    dasd_device_timeout;`
`ns_timer.function = ns_poll;`
	`X0.function = X1;`

`device->timer.data =`
`    (unsigned long) device;`
`ns_timer.data = 0UL;`
	`X0.data = X1;`

Figure 2: *Before* clusters and anti-unifiers from the **`init_timer`** examples. **`X0`** and **`X1`** are metavariables.

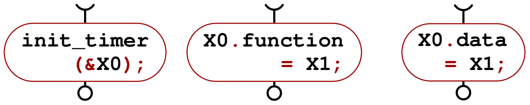

Figure 3: **`init_timer`** *Before* fragments

We illustrate this procedure with the **`init_timer`** change. In each of our **`init_timer`** examples, three nodes are removed and one node is added. The clusters are shown on the left side of Figure 2. Each element of a cluster is annotated with the example from which it comes and its position in that example.

For each cluster, Spinfer then create its anti-unifier, that retains the common parts of the terms in the cluster, and abstracts the subterms that are not common to all of the terms as *metavariables*, *i.e.*, elements that can match any term. The right side of Figure 2 shows the anti-unifier for each cluster.

Anti-unifiers represent sets of similar terms, but do not provide any control-flow information. In order to prepare for the next step, which constructs a semantic patch rule proposition based on control-flow constraints, Spinfer next expands each anti-unifier into the fragment of a control-flow graph that the anti-unifier's constituent node fragments represent, called an abstract fragment. An abstract fragment is composed of at least one node that contains the abstracted pattern, and a non-empty list of pairs of entry and exit points. Multi-node abstract fragments are created for complex control-flow structures such as conditionals and loops. Figure 3 shows some fragments for our **`init_timer`** example.

3.3 Assembling the semantic patch rule-graph

In order to address the first semantic patch inference challenge of capturing control-flow constraints, Spinfer relies on the notion of *dominance* [15] in CFGs. A node A *dominates* a node B in a directed graph $\mathcal{G}$ if every path from the entry node of $\mathcal{G}$ to B goes through A. A is then a dominator of B. Similarly, a node B *postdominates* a node A if every path from A to an exit node of $\mathcal{G}$ goes through B. B is then a postdominator of A. This notion generalizes straightforwardly to sets of nodes. Dominance characterizes the semantics of Coccinelle's "`...`" operator. A pattern of the form A ... B matches a fragment of C code if the set of terms matching

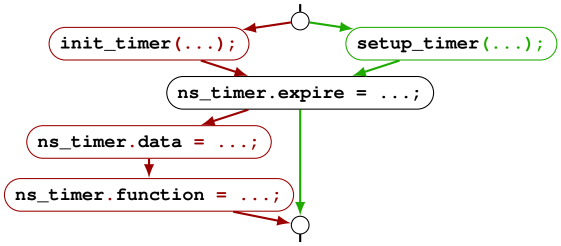

Figure 4: CFG-Diff for the `nicstar.c` `init_timer` change

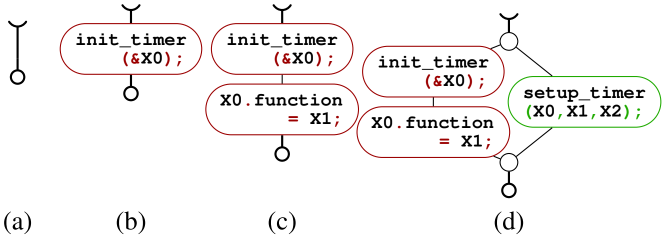

Figure 5: Steps in semantic patch-rule-graph construction

B postdominate the term matching *A*, meaning that from the code matching *A*, all outgoing paths reach code matching *B*.

Spinfer first constructs the control-flow graph (CFG) of each changed function in the examples, before and after the change. Each pair of before and after CFGs is then merged into a single CFG, referred to as a CFG-Diff. In the CFG-Diff, removed nodes from the before CFG are colored *Before* (red/-dark grey) and added nodes from the after CFG are colored *After* (green/light grey). An extract of the CFG-Diff for the `nicstar.c` change is shown in Figure 4.

To construct a semantic patch rule, Spinfer first constructs a *semantic patch rule-graph*, incrementally adding first *Before* fragments and then *After* fragments as long as the dominance relations in the semantic patch rule-graph respect the dominance relations in the example CFGs associated with the fragments.

We present the semantic patch-rule-graph construction algorithm in terms of the `init_timer` example. Spinfer starts with an empty semantic patch rule-graph, consisting of two special nodes, a global entry node and a global exit node, and a directed edge from the global entry node to the global exit node (Figure 5(a), the half-circle is the global entry node and the full circle is the global exit node). By convention, the global entry node dominates every node and every node postdominates it, and the global exit node postdominates every node and every node dominates it.

For our example, out of the available fragments (Figure 3), suppose that Spinfer first chooses the one representing the `init_timer` calls. This fragment can be added straightforwardly (Figure 5(b)) because the start node and the end node dominate and postdominate every node, respectively. Next, Spinfer may add the fragment representing the initialization of the timer's `function` field, below the node representing the `init_timer` call. Indeed, in both *Before* CFGs, the call to `init_timer` dominates the `function` field initialization, either because of a direct connection between them, or because of a control-flow path consisting of straightline code between them. The `function` field initialization likewise postdominates the `init_timer` call. The resulting semantic patch rule-graph is shown in Figure 5(c).

We defer the treatment of the initialization of the `data` field to Section 3.4, and turn to the integration of the *After* fragment, *i.e.*, the abstracted call to `setup_timer`. While the addition of the *Before* fragments relies on dominance relations between the fragment and the nodes already in the semantic patch rule-graph, this is not always possible for *After* nodes. Indeed, there exist no dominance relations between the *Before* and *After* nodes. When an addition is in fact a replacement, we observe that the *After* node and the *Before* node it is replacing share common context (non-modified) predecessors and successors (see Figure 4). Moreover, this context does dominate/postdominate both the deletion and the addition. Spinfer exploits this property to insert *After* fragments. For this, Spinfer replaces each entry and exit pair of the *After* fragment by the nearest context predecessors and successors, if any, and checks the domination properties on these context nodes instead. If the properties hold then the fragment is inserted. The context used is replaced by *Merge* nodes, that are omitted in the final semantic patch.

3.4 Splitting the semantic patch rule-graph

Assembling the semantic patch rule-graph can fail, due to inconsistencies. This situation occurs when there are multiple change variants in the examples, our third semantic patch inference challenge. One possible inconsistency is incompatible domination properties, representing inconsistent control flow. Another is the inability to map metavariables to terms in a way that allows the added code to be constructed from the removed code, representing a form of inconsistent data flow. Spinfer splits the semantic patch rule-graph and reduces the genericity of metavariables to address these issues.

Control-flow inconsistencies. Trying to insert the `data` field initialization fragment into the rule-graph shown in Figure 5(c), reveals a control-flow inconsistency: `dasd.c` initializes the `data` field after the `function` field, while `nicstar.c` initializes it before. To proceed, Spinfer chooses an element of the `data` field initialization cluster, say the one from `dasd.c`, and splits the cluster into one cluster of the instances that respect the same control-flow constraints and another cluster for the remaining instances. The latter is deferred for later integration. At the same time, Spinfer splits the semantic patch-rule graph into one copy derived from the graphs whose `data` field initialization respects the same control flow constraints as the `dasd.c` initialization and another copy for the rest. The latter rule-graph copy is likewise pushed onto a stack for later treatment.

After splitting the cluster and the semantic patch rule-graph, Spinfer can add the fragment representing `data` field initializations that are consistent with `dasd.c` into the rule-graph below the `function` field initialization, and then proceed to the integration of the *After* fragment, as described previously. With this rule-graph complete, Spinfer then proceeds to the next rule-graph on the stack and the remaining fragments.

A semantic patch rule-graph split may lead to a situation, as we have here, where a rule-graph represents only a single example. In this case, Spinfer leaves the generated semantic patch rule abstract, according to the metavariables motivated by the clustering, to allow the generated semantic patch rule to match code from other files. This extra abstraction, however, may lead to false positives, if the rule is so generic that it matches parts of the code that should not be transformed. In a final step, Spinfer validates the complete generated semantic patch on the complete example files, which may contain a great deal of code other than that of the functions the rule was learned from. If this validation shows that a rule causes false positives, Spinfer specializes the rule according to the specific code fragments that motivated its construction, resulting in a safer, but potentially less widely applicable, semantic patch rule.

Data-flow inconsistencies. A semantic patch rule needs to be able to construct the *After* code from the information found in the *Before* code, to carry out the intended change. Thus, in a completed semantic patch rule-graph, Spinfer reassigns the metavariables, `X0`, `X1`, etc. (see Figure 2), that were local to each fragment, in a way that is consistent across the proposed semantic patch rule. It may occur that no consistent assignment is possible, and some metavariables may remain in the *After* fragments that are not instantiated by the *Before* fragments.

As an example, suppose we add the fourth example of Figure 1 to our set of fragments. This example has no `data` field initialization, and thus it will cause a split from the others, producing a separate semantic patch rule-graph. This rule-graph will indicate removal of the abstract fragment `init_timer(&X0);` and removal of the subsequent fragment `X0.function = X1;`, and the addition of the fragment `setup_timer(X0,X1,X2);`. `X2`, however, represents `0UL`, which is not represented by any of the metavariables of the removed code. In this situation, Spinfer agglomeratively considers subsets of the examples contributing to the semantic patch rule-graph, to determine whether respecializing the metavariables to the contents of the considered subsets can produce a consistent metavariable assignment. In our case, there is only one associated example, and Spinfer eliminates `X2` entirely, replacing it with `0UL` in the generated semantic patch.

3.5 Rule ordering

Finally Spinfer pretty prints each semantic patch rule-graph into a rule, and then orders the rules to form a single semantic patch. This last step is important because graph splitting can produce rules that subsume other rules or rules that must be executed in a certain order to limit the number of false positives. For instance, for the `init_timer` example, a rule matching the `nmi.c` variant must be executed after all other rules that could have consumed the missing `data` field.

To solve these issues Spinfer first looks for semantic patch rules that subsume other rules. Let R_1 and R_2 be two rules and let TP_1 and TP_2 be the sets of true positives and FP_1 and FP_2 the sets of false positives produced by applying R_1 and R_2 respectively, by using Coccinelle on the provided examples. R_1 is said to be subsumed by R_2 if TP_1 is a subset of TP_2 and FP_1 is a superset of FP_2. When Spinfer detects a rule that is subsumed by others it is eliminated from the final semantic patch. Finally, Spinfer orders the remaining semantic patch rules, by looking at the F2 score (a combination of precision and recall that favors high recall) of tentative semantic patches each consisting of a pair of rules. From these results, it does a topological sort to order the complete set of semantic patch rules into a single semantic patch.

4 Evaluation

In this section, we evaluate Spinfer on two datasets composed of real changes from the Linux kernel. We then illustrate a failure case of Spinfer in which it generates an incorrect semantic patch and explain why it was generated this way. With this example, we illustrate how a developer can easily fix a semantic patch to produce a correct one.

4.1 Methodology

Our first dataset is a collection of 40 sets of changes in the Linux kernel, that have been selected to challenge Spinfer, by focusing on the higher levels of the taxonomy. Consequently, it is not intended to be representative of the real taxonomy distribution of Linux kernel changes. The sets include some changes that have been performed using Coccinelle as well as recurring changes found in recent Linux kernel versions v4.16-v4.19, identified using the tool `patchparse` [20]. We refer to this dataset as the *challenging dataset*.

Our second dataset is composed of 40 sets of changes randomly picked from changes to the Linux kernel in 2018. To build this dataset we first identified 175 large-scale changes (changes from one developer affecting at least 10 files) from the changes performed in 2018 and then we randomly selected 40. We refer to this dataset as the *2018 dataset*.

For each dataset we describe the interesting aspects of its taxonomy and we perform two experiments:

The *synthesis experiment* learns semantic patches from the full dataset containing all the files and evaluates the resulting semantic patch on the same set of files. This experiment evaluates the degree to which Spinfer is able to capture the changes found in the examples provided to it. It is relevant to the user who wants to understand a previously performed change. Without Spinfer, such a user has to read through the entire patch and collect all of the different kinds of changes performed, with no way to validate his understanding. Spinfer does both the inference and validation automatically.

The *transformation experiment*, on the other hand, learns semantic patches from a reduced dataset composed of the first 10 changed files, as indicated by the commit author date (ties between files in the same commit are broken randomly), or half of the full dataset if the full dataset contains fewer than 20 files. This experiment evaluates the resulting semantic patch on the portion of the dataset that does *not* include the set of files from which the rules were learned. This experiment is relevant to the user who wants to change new code by bootstrapping a semantic patch.

We recall that Spinfer targets the whole taxonomy, except in terms of control flow where it targets only C_0 and C_1, but not the higher levels. Since not all examples are in Spinfer's targets in terms of the taxonomy, for each experiment we separate the analysis of the results according to whether the examples are in Spinfer's scope or not.

We use classic metrics that are applied for evaluation of program transformation tools: *precision*, *i.e.*, the percentage of changes obtained by applying the inferred semantic patch that are identical to the expected changes in the examples, and *recall*, *i.e.*, the percentage of expected changes in the examples that are obtained by applying the inferred semantic patch. To address the issue of *noise* we compare the changes performed by the semantic patch generated by Spinfer against those performed by a human-written semantic patch created by a Coccinelle expert. In this way, we benefit from the intuition of the human expert to filter out noise. As there are many ways to write a semantic patch for the same change, we do not directly compare the syntax of the generated semantic patch against the human-written one, and instead focus on the results of applying the semantic patch itself.

4.2 Experiments on the *challenging dataset*

The taxonomy of the changes for the *challenging dataset* is shown in Figure 6. The majority of transformations in this dataset require taking into account both control-flow and data-flow relationships, with 21 examples requiring at least control-flow dependencies on unchanged terms (C_2), which is outside of the scope of Spinfer (C_0 or C_1). Three quarters of the transformations have multiple variants including one quarter with variants that need to be performed in a specific order, features that are targeted by Spinfer.

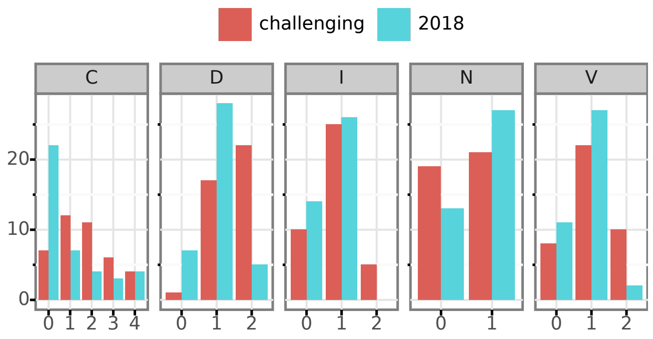

Figure 6: Taxonomy of the two datasets

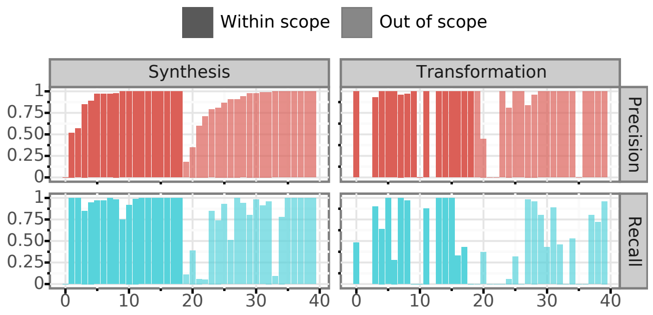

Figure 7: CFG-nodes metrics for the *challenging dataset*

To evaluate Spinfer in terms of the correctness of the transformation. We look at the ratio of correctly modified CFG-nodes, either successfully deleted, or added to the correct location in the CFG of the example. As Spinfer prints around one line of semantic patch per modified node, this roughly translates to the ratio of correct lines in the generated semantic patch. Figure 7 gives the recall and precision for the node modifications produced by the generated semantic patches, with each bar corresponding to one set of changes. The lighter color of the bars on the right indicates that the examples are not in Spinfer target in terms of the taxonomy. Missing values for the transformation experiment at indices 1, 2 and 12 correspond to sets of changes with 2 modified files or fewer. In this case, performing the transformation experiment is not possible as Spinfer needs to learn from at least two files. Other missing values indicate that Spinfer either did not generate anything, or generated a semantic patch that was not applicable to the evaluation dataset. These cases count as having both a recall and a precision of 0.

On average, the semantic patches generated by Spinfer achieve 87% precision and 81% recall for the synthesis experiment, and 86% precision and 49% recall for the transformation experiment. For the part of the examples in Spinfer's scope in terms of the taxonomy, Spinfer obtained 88% precision and 91% recall for the synthesis experiment, and 93% precision and 62% recall for the transformation experiment. Precision and recall are much lower for examples outside Spinfer's scope, averaging 86% precision and 72% recall in

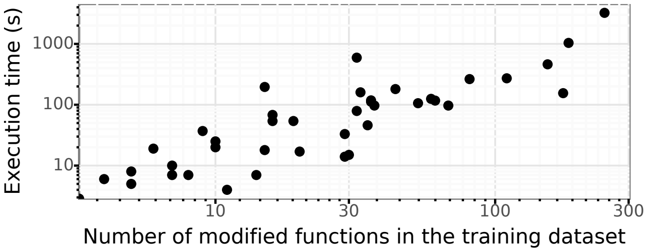

Figure 8: Execution time for the *challenging dataset*

synthesis and 81% precision and 39% recall in transformation.

These results suggest that, for the subset of examples in its scope, Spinfer can be used to infer semantic patches that can perform most of the needed transformations. Also, by carefully examining the produced semantic patches, we believe that most of the non-exhaustive semantic patches in this subset can be modified in a couple of minutes to obtain complete ones. For examples outside Spinfer scope, Spinfer is still able to perform some of the transformations without producing too many false positives.

As shown in Figure 8, Spinfer's execution time is almost linear in the number of modified functions in the training dataset. Spinfer takes less than 50 seconds to infer a semantic patch for examples with 10 or fewer modified functions. We believe that Spinfer's execution time is quite reasonable to be used as a tool to suggest a semantic patch.

4.3 Experiments on the *2018 dataset*

Figure 6 also shows the taxonomy of the changes for the *2018 dataset*. Contrary to the *challenging dataset*, the largest part of the changes in the *2018 dataset* do not require taking complex control flow into account (C_0 and C_1) and thus fit in Spinfer's scope. The kinds of control-flow constraints observed are from one statement to the next, and from one statement to some later statement that is not directly contiguous. Only a few changes require taking into account negative information (C_3), such as verification that a variable is not used in its scope before removing it, or interprocedural information (C_4). However, multiple variants (I_1) and noise (N_1) are very common.

We evaluate the results in the same way as for the *challenging dataset*. Figure 9 gives the recall and precision for the generated semantic patch. For the four C_4 cases in the taxonomy the results are evaluated against the developers' changes directly, rather than against human-written semantic patches, as Coccinelle does not support interprocedural control-flow constraints.

For the *2018 dataset*, the generated semantic patches achieve 85% precision and 83% recall in synthesis, and 87% precision and 62% recall in transformation. Looking only at the examples in the scope of Spinfer, the generated semantic patches obtained 92% precision and 88% recall in synthesis, and 94% precision and 65% recall in transformations, which is very close to the results for the *challenging dataset*. As most of the transformations in our randomly sampled dataset are in Spinfer scope, these results suggest that Spinfer is adapted to real kernel transformation situations, and can generate high quality semantic patches that can be used by kernel developers to perform synthesis or transformation tasks.

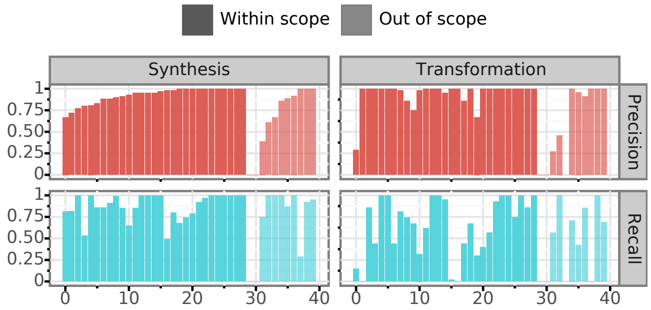

Figure 9: CFG-nodes metrics for the *2018 dataset*

4.4 Analysis of a failure case

We now analyze a typical failure case that gives an intuition for why some examples have a lower recall in transformation than in synthesis.

A case where Spinfer does not generate a high quality semantic patch is for the elimination of the **cpufreq_frequency_table_target** function. For this transformation our human expert wrote the following semantic patch:

```
@@ expression policy, old_freq; @@
- cpufreq_frequency_table_target(policy, old_freq,
-        CPUFREQ_RELATION_H)
+ cpufreq_table_find_index_h(policy, old_freq)

@@ expression policy, old_freq; @@
- cpufreq_frequency_table_target(policy, old_freq,
-        CPUFREQ_RELATION_L)
+ cpufreq_table_find_index_l(policy, old_freq)

@@ expression policy, old_freq; @@
- cpufreq_frequency_table_target(policy, old_freq,
-        CPUFREQ_RELATION_C)
+ cpufreq_table_find_index_c(policy, old_freq)
```

The semantic patch composed of three rules replaces the uses of **cpufreq_frequency_table_target** by specialized **cpufreq_table_find_index** functions. The choice of replacement function depends on the constant used as the third argument of **cpufreq_frequency_table_target**.

For this transformation we launched Spinfer on a learning set of only two files and, in under two seconds, Spinfer generated the following semantic patch composed of two rules:

```
@@ expression E0, E1, E2; @@
- E0 = cpufreq_frequency_table_target(E1, E2,
-        CPUFREQ_RELATION_H);
+ E0 = cpufreq_table_find_index_h(E1, E2);
```

```
@@ expression E0, E1; @@
- E0 = cpufreq_frequency_table_target(&E1, E1.cur,
-        CPUFREQ_RELATION_C);
+ E0 = cpufreq_table_find_index_c(&E1, E1.cur);
```

The generated semantic patch does not cover all the cases, and thus it is incomplete. It illustrates two typical reasons for the failure Spinfer: **variant bias** and **over-specialization**.

Variant bias happens when only a subset of variants is present in the learning set. In this case the learning set contains only instances with **CPUFREQ_RELATION_H** and **CPUFREQ_RELATION_C** constants. Consequently Spinfer did not see the third constant and cannot generate a rule for it. Given this semantic patch, however, a developer can easily find the missing constant and complete the semantic patch with copy-pasting and small edits.

Over-specialization is present here in two forms: all rules are assignments and the second rule contains a mandatory field **cur** for the second parameter of both functions. Both of these constraints are incorrect, but they are generated because they are present in all examples in the learning set and because Spinfer prefers precision over recall. Once again, fixing these issues can be very quick for a Linux kernel developer, once the basic outline of the semantic patch is provided.

We have illustrated two typical reasons for the failure of Spinfer, in which our tool generates an incorrect semantic patch for the testing set. These cases happen because Spinfer somewhat overfits the learning set to prevent false positives. However these kinds of failure can be easily and quickly fixed by developers, by using their knowledge of the kernel or by providing more examples to our tool.

5 Related Work

The most closely related works are Sydit [17], Lase [18], AppEvolve [7], Refazer [23], Meditor [30], A4 [11], and GenPat [8], that were already presented in Section 2.

A novelty of Spinfer is its focus on control-flow graphs. CBCD [14] relies on Program Dependence Graphs (PDGs) to find other instances of a known bug in a code base. CBCD is limited to only one example bug, does not produce a script for matching buggy code, and does not address how to fix bugs. By considering commonalities among multiple examples, Spinfer can learn more general rules. By providing a transformation script, Spinfer makes the result understandable to the user and even allows the user to improve the script or adapt it to other uses. Finally, Spinfer-inferred semantic patches both find code needing transformation and describe how to transform it automatically.

Spinfer requires the existence of patches that illustrate a desired change. When the developer does not know how to make a change, he can search for examples in the commit history. Patchparse [20] finds common changes in commit histories of C code. SysEdMiner [19] finds such changes for Java code. Prequel allows the developer to search for commits that match patterns of removed and added code, making it possible to find examples for specific changes [13]. The output from those tools may be used with Spinfer.

6 Conclusion

This paper proposes an approach to automatically inferring Coccinelle semantic patches from a collection of change examples written in C. Our approach considers similar code fragments and control flows among the changes to identify change patterns and construct transformation rules. Generated semantic patches are easily understandable by developers and can be used both for understanding past changes and to perform large scale transformation, with little to no modifications. We have implemented our approach as a tool named Spinfer, and evaluated it on two sets of 40 real changes from the Linux kernel. Our evaluation shown that Spinfer is capable of handling the majority of the real Linux kernel transformation situations by generating semantic patches with high recall and precision in only a few minutes.

We have also identified a taxonomy of challenges that transformation-rule inference tools for systems code must solve, based on the complexity of the control and data flow, and the number of change instances and variants. Such a taxonomy provides level ground for comparing the capabilities of different transformation-rule inference tools, and Spinfer achieves much safer and more comprehensive results than previous tools with respect to the properties defined in the taxonomy. The taxonomy can also be used to guide the future development of Spinfer and other transformation-rule inference tools. In particular, the next frontier for transformation rule inference is to effectively take into account unmodified terms into control-flow dependencies. Typically, for a large-scale change, each changed function contains many times more unmodified lines than changed lines, and the unmodified lines exhibit much greater variety. A challenge is to identify which of the unmodified lines, if any, are relevant to controlling when a change should be performed.

FuZZan: Efficient Sanitizer Metadata Design for Fuzzing

EPFL

Abstract

Fuzzing is one of the most popular and effective techniques for finding software bugs. To detect triggered bugs, fuzzers leverage a variety of *sanitizers* in practice. Unfortunately, sanitizers target long running experiments—e.g., developer test suites—not fuzzing, where execution time is highly variable ranging from extremely short to long. Design decisions made for developer test suites introduce high overhead on short lived fuzzing executions, decreasing the fuzzer's throughput and thereby reducing effectiveness.

The root cause of this sanitization overhead is the heavy-weight metadata structure that is optimized for frequent metadata operations over long executions. To address this, we design new metadata structures for sanitizers, and propose FuZZan to *automatically* select the optimal metadata structure without any user configuration. Our new metadata structures have the *same* bug detection capabilities as the ones they replace. We implement and apply these ideas to Address Sanitizer (ASan), which is the most popular sanitizer.

Our evaluation shows that on the Google fuzzer test suite, FuZZan improves fuzzing throughput over ASan by 48% starting with Google's provided seeds (52% when starting with empty seeds on the same applications). Due to this improved throughput, FuZZan discovers 13% more unique paths given the same 24 hours and finds bugs 42% faster. Furthermore, FuZZan catches all bugs ASan does; i.e., we have not traded precision for performance. Our findings show that sanitizer performance overhead is avoidable when metadata structures are designed for fuzzing, and that the performance difference will have a meaningful difference in squashing software bugs.

1 Introduction

Fuzzing [33] is a powerful and widely used software security testing technique that uses randomly generated inputs to find bugs. Fuzzing has seen near ubiquitous adoption in industry, and has discovered countless bugs. For example, the state-of-the-art fuzzer American Fuzzy Lop (AFL) has discovered hundreds of bugs in widely-used software [57], while Google has found 16,000 bugs in Chrome and 11,000 bugs in over 160 other open source projects using fuzzing [10]. On its own, fuzzing only discovers a subset of all triggered bugs, e.g., failed assertions or memory errors causing segmentation faults. Bugs that silently corrupt the program's memory state, without causing a crash, are missed. To detect such bugs, fuzzers must be paired with sanitizers that enforce security policies at runtime by turning a silent corruption into a crash. To date, around 34 sanitizers [47] have been prototyped. So far, only the LLVM-based sanitizers ASan, MSan, LeakSan, UBSan, and TSan have seen wide-spread use. For brevity, we use *sanitizers* to refer to such frequently used sanitizers in the rest of the paper.

Unfortunately, sanitizers are designed for developer-driven software testing rather than fuzzing, and are consequently optimized for minimal per-check cost, not startup/teardown of the metadata structure. Consequently, they are based around a shadow-memory data structure wherein the address space is partitioned, and metadata is encoded into the "shadow" memory at a constant offset from program memory. Optimizing for long executions makes sense in the context of developer-driven software testing, which generally verifies correct behavior on expected input, leading to relatively long test execution times. Fuzzing has a more diverse set of inputs that cause both short (i.e., invalid inputs) and long running executions with billions of executions. For example, the Chrome developers use Address Sanitizer (ASan) for their unit tests and long-running integration tests [39]. However, the underlying design decisions that make ASan a highly performant sanitizer for long running tests result in high performance overhead—up to 6.59×—for short executions, as observed in a fuzzing environment[1]. This high overhead reduces throughput, thereby preventing a fuzzer from finding bugs effectively.

We analyze the source of this overhead across a variety of sanitizers, and attribute the cost to heavy-weight metadata structures employed by these sanitizers. For example, Address Sanitizer maps an additional 20TB of memory for each exe-

[1] The average time for a single execution across the first 500,000 tests for the full Google fuzzer test suite is 0.61ms.

cution, Memory Sanitizer (MSan) 72TB, and Thread Sanitizer (TSan) 97TB on a 64-bit platform. The high setup/teardown cost of heavy-weight metadata structures is amortized over the long execution of programs due to the low per-check cost. In contrast, a fuzzing campaign typically consists of massive amounts of short-lived executions, effectively transforming what is a large one-time cost into a large runtime cost. For example, Table 1 indicates that memory management is the main source of overhead for ASan under fuzzing on the Google fuzz test suite, accounting for 40.16% of the total execution time we observe. Memory management is the key bottleneck for using sanitizers with fuzzers, and has to date gone unaddressed.

Instead, increasing the efficiency and efficacy of fuzzing has received significant research attention on two fronts: (i) mechanisms that reduce the overhead of fuzzers [27, 55, 57]; and (ii) mechanisms that reduce the overhead of sanitization on longer running tests and conflicts between sanitizers [25, 37, 38, 52, 54]. These works address fuzzers and sanitizers in isolation, ignoring the core sanitizer design decision to optimize for long running test cases using a heavy-weight metadata structure that limits sanitizer performance in combination with fuzzers. Consequently, optimization of sanitizer memory management for short execution times remains an open challenge, motivated by the need to design sanitizers that are optimal under fuzz testing.

We present FuZZan, which uses a two-pronged approach to optimize sanitizers for short execution times, as seen under fuzzing: (i) two new light-weight metadata structures that trade significantly reduced startup/teardown costs [2] for moderately higher (or equivalent) per access costs and (ii) a dynamic metadata structure switching technique, which dynamically selects the optimal metadata structure during a fuzzing campaign based on the current execution profile of the program; i.e., how often the metadata is accessed. Each of our proposed metadata structures is optimized for different execution patterns; i.e., they have different costs for creating an entry when an object is allocated versus looking up information in the metadata table. By observing the metadata access and memory usage patterns at runtime, FuZZan dynamically switches to the best metadata structure *without* user interaction, and tunes this configuration throughout the fuzzing campaign.

We apply our ideas to ASan, which is the most widely used sanitizer [43, 44, 47]. ASan focuses on memory safety violations—arguably the most dangerous class of bugs, accounting for 70% of vulnerabilities at Microsoft [34]—and has already detected over 10,000 memory safety violations [9, 12, 50] in various applications (e.g., over 3,000 bugs in Chrome in 3 years [50]) and the Linux kernel (e.g., over 1,000 bugs [12, 51]) by using a customized kernel address sanitizer (KASan). We further apply FuZZan to MSan and MOpt-AFL.

FuZZan improves fuzzing throughput over ASan by 52% when starting with empty seeds and 48% when starting with Google's seed corpus, averaged across all applications in the Google fuzzer test suite [11] as part of our input record/replay fuzzing experiment. Due to this improved throughput, FuZZan discovers 13% more unique paths (with an improvement in throughput of 61% compared to ASan) given the standard 24 hour fuzz testing with widely used real-world software and a provided corpus of starting seeds.

Modes	ASan's init time ms (%)	ASan's logging time ms (%)	Memory mgmt. time ms (%)	# page faults
Native	0.00 (0.00%)	0.00 (0.00%)	0.05 (11.49%)	2,569
ASan	0.17 (10.58%)	0.30 (18.86%)	0.63 (40.16%)	11,967

Table 1: Comparison between native and ASan executions with a breakdown of time spent in memory management, and time spent for ASan's initialization and logging. Results are aggregated over 500,000 executions of the full Google fuzzer test suite [11]. Times are shown in milliseconds, and % denotes the ratio to total execution time.

Crucially, FuZZan achieves this without *any* reduction in bug-finding ability. Therefore, FuZZan strictly increases the performance of ASan-enabled fuzzing, resulting in finding the *same* bugs in *less* time than using ASan with the same fuzzer.

Our contributions are:

1. Identifying and analyzing the primary source of overhead when sanitizers are used with fuzzing, and pinpointing the sanitizer design decisions that cause the overhead;

2. Designing and implementing a sanitizer optimization (FuZZan) and applying it to ASan; that is, we design several new metadata structures along with a dynamic metadata structure switching to choose the optimal structure at runtime. We also validate the generality of our design by further applying it to MSan and MOpt-AFL;

3. Evaluating FuZZan on the Google fuzzer test suite and other widely used real-world software and showing that FuZZan effectively improves fuzzing throughput (and therefore discovers more unique bugs or paths given the same amount of time).

2 Background and Analysis

We present an overview of fuzzing overhead and ASan (our target sanitizer). Further, we detail the design conflicts between ASan and fuzzing when used in combination.

2.1 Fuzzing overhead

Given the same input generation capabilities, a fuzzer's throughput (executions per second) is critical to its effectiveness in finding bugs. Greater throughput results in more code

[2] Compared to ASan, our min-shadow memory mode reduces the time that startup/teardown functions spend in the kernel by 62% on the first 500,000 tests across the full Google fuzzer test suite.

and data paths being explored, and thus potentially triggers more bugs. Running a fuzzer imposes some overhead on the program, a major component of which is the repeated execution of the target program's initialization routines. These routines—including program loading, `execve`, and initialization—do not change across test cases, and hence result in repeated and unnecessary startup costs. To reduce this overhead, many fuzzers leverage a *fork server*. A fork server loads and executes the target program to a fully-initialized state, and then clones this process to execute each test case. This ensures that the execution of each test case begins from an initialized state, and removes the overhead associated with the initial startup.

Another technique for reducing process initialization costs is *in-process fuzzing*, such as AFL's persistent mode and libFuzzer. In-process fuzzing wraps each test in one iteration of a loop in one process, thus avoiding starting a new process for each test. However, in-process fuzzing generally requires manual analysis and code changes [13, 58]. Additionally, in-process fuzzing requires the target code to be stateless across executions as all tests share one process environment, otherwise the execution of one test may affect subsequent ones, potentially leading to false positives. Consequently, testers should avoid in-process fuzzing for library code using global variables. Bugs found from in-process fuzzing may not be reproducible as it is not always possible to construct a valid calling context to trigger detected bugs in the target function, and side-effects across multiple function calls may not be captured [32]. Because of these limitations, in-process fuzzing is used on stateless functions in libraries, while the fork server model (i.e., out-of-process fuzzing) remains the most general fuzzing mode for fuzzing programs.

2.2 Address Sanitizer

All sanitizers leverage a customized metadata structure [47]. Out of many different metadata schemes, shadow memory (both direct-mapped or multi-level shadow) is the most widely used [4, 14–16, 29, 30, 42, 45, 48, 49, 56]. ASan enforces memory safety by encoding the accessibility of each byte in shadow memory. Allocated (and therefore accessible) areas are marked and padded with inaccessible red zones. In particular, *direct-mapped shadow memory* encodes the validity of the entire virtual memory space, with every 8-bytes of memory mapping to 1-byte in shadow memory. Shadow memory encodes the state of application memory. The 8-bit value k encodes that the 8-k bytes of the mapped memory are accessible. The corresponding shadow memory address for a byte of memory is at:

$$addr_{shadow} = (addr >> 3) + offset$$

where *addr* is the accessed address. Generally, ASan only inserts redzones to the high address side of each object as the preceding object's redzone suffices for the low address side. ASan also instruments each runtime memory access to check if the accessed memory is in a red zone, and if so faults. ASan's effectiveness in detecting hard-to-catch memory bugs has led to its widespread adoption. It has become best practice [47] to use ASan (or KASan [20], the kernel equivalent) with a fuzzer to improve the bug detection capability.

2.3 Overhead Analysis of Fuzzing with ASan

To understand ASan's overhead with fuzzing, we analyze the Linux kernel functions used during fuzzing campaigns. Table 1 shows the overhead added by ASan, broken out across ASan's logging, ASan's initialization, and memory management. Our experiments measure the ratio of the time spent in the kernel functions compared to the total execution time for a number of target programs.

Note that memory management makes up 40.16% of ASan's total execution time, as opposed to 11.49% for the base case, and that memory management is more than double the overhead of ASan's logging and initialization *combined*. ASan's heavy use of the virtual address space results in 4.66× page faults compared to native execution. Our memory management overhead numbers reflect the time spent by the kernel in the four core page table management functions: (i) `unmap_vmas` (24.6%), (ii) `free_pgtable` (4.7%), (iii) `do_wp_page` (8.2%), and (iv) `sys_mmap` (2.6%).

Notably, `unmap_vmas` and `free_pgtable` correspond to 73% of ASan's measured memory management overhead across the four core page table management functions. The execution time for these two functions (`unmap_vmas` and `free_pgtable`) is 10x higher than when executing without ASan. To break this overhead down, when executing a test under the fork server mode, a fuzzer needs to create a new process for each test. During initialization, ASan reserves memory space (20TB total, including 16TB of shadow memory, and a separate 4TB for the heap on 64-bit platforms) and then poisons the shadow memory for globals and the heap. Accessing these pages incurs additional page faults, and thus page table management overhead in the kernel. Note that the large heap area causes sparse page table entries (PTEs), which increase the number of pages used for the page table and memory management overhead.

Existing techniques to deal efficiently with large allocations do not help here. Lazy page allocation of the large virtual memory area used by ASan does not mitigate memory management overhead in this case, as many of the pages are accessed when shadow memory is poisoned. Poisoning forces a copy even for copy-on-write pages, and thus increases page table management cost. During execution, memory allocations and accesses cause additional shadow memory pages to be used, again with page faults and page table management. When the process exits, the kernel clears all page table entries through `unmap_vmas` and releases memory for the page table (via `free_pgtables`). The cost of these two functions are correlated with the number of physical pages used by the process. As fuzzing leads to repeated, short executions, such bookkeeping introduces considerable memory management overhead. In contrast to these active memory management functions, `sys_mmap` only accounts for 7% memory management overhead of ASan. This is the expense for reserving all virtual memory areas. However, large areas that are actively accessed by ASan incur considerable additional expenses as detailed above.

For completeness, we note that our analysis finds that ASan performs excessive "always-on" logging (18.86%) by default, and that ASan's initial poisoning of global variables (10.58%) is inefficient. Combined, these additional sources of overhead account for 29.44% overhead. We address these engineering shortcomings in our evaluation, but they are neither our core contributions nor the choke point in fuzzing with ASan.

3 FuZZan design

FuZZan has two design goals: (1) define new light-weight metadata structures, and (2) automatically switch between metadata structures depending on the runtime execution profile. In this section, we present how we design each component of FuZZan to achieve both goals, as illustrated in Figure 1.

3.1 FuZZan Metadata Structures

To minimize startup/teardown costs while maintaining reasonable access costs, FuZZan introduces two new metadata structures: (i) a Red Black tree (RB-tree) metadata structure, which has low startup and teardown costs, but has high per-access costs; and (ii) min-shadow memory, which has medium startup/teardown costs and low per-access costs (on par with ASan). Table 2 shows a qualitative comparison of the different metadata schemes that we propose in this section, see Table 4 for quantitative results. The RB-tree is optimal for short executions with few metadata accesses as it emphasizes low startup and teardown costs, while min-shadow memory is best suited for executions with a mid-to-high number of metadata accesses as it has lower per metadata access costs while still avoiding the full startup/teardown overhead imposed by ASan's shadow memory.

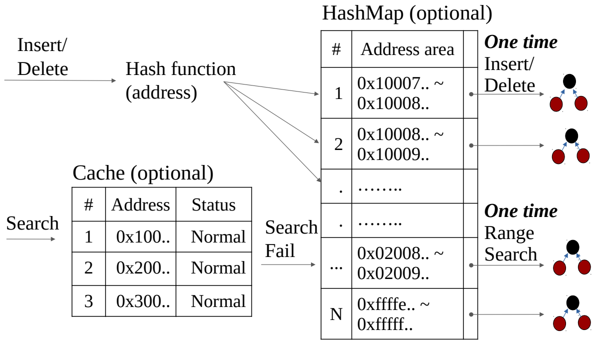
ASan shadow memory		High	Low
FuZZan	Customized RB-tree	Low	High
	Min-shadow memory	Medium	Low

Table 2: Comparison of metadata structures.

3.1.1 Customized RB-Tree

To optimize ASan's metadata structure for test cases where a fuzz testing application only executes for a very short time with few metadata accesses, we introduce a customized RB-tree, shown in Figure 2. Nodes in the RB-tree store the redzone for each object. Although each metadata access operation (insert, delete, and search) in the RB-tree is slower than its counterpart in the shadow memory metadata structure, our RB-tree has the following benefits: (i) low total memory overhead (leading to low startup/teardown overhead); (ii) removal of poisoning/unpoisoning page faults (as each RB-tree node compactly stores the redzone addresses and these nodes are grouped together in memory); and (iii) a faster range search than shadow memory for operations such as `memcpy`. For example, in order to check `memcpy`, ASan must validate each byte individually using shadow memory. However, in our approach, we can verify such operations through only two range queries for `memcpy`'s source and destination memory address range.

In our RB-tree design, when an object is allocated (e.g., through `malloc`), the range of the object's high address redzone is stored in a node of the RB-tree. During a query, if the address range of the target is lower than the start address of the node, we search the left subtree (and vice versa). If the address is not found in the tree, it is a safe memory access. During redzone removal, the requested address range may only be a subset of an existing node's range (and not the full range of a target node in the RB-tree). In this case, the RB-tree



#	Address area
1	0x10007.. ~ 0x10008..
2	0x10008.. ~ 0x10009..
.	……..
.	……..
...	0x02008.. ~ 0x02009..
N	0xffffe.. ~ 0xfffff..

#	Address	Status
1	0x100..	Normal
2	0x200..	Normal
3	0x300..	Normal

Figure 2: Design of FuZZan's customized RB-tree.

deletes the existing RB-tree node, creates new RB-tree nodes which have non-overlapping address ranges (e.g., the left and right side of an overlapped area), and inserts these nodes into the RB-tree. Since we reuse ASan's memory allocator and memory layout (e.g., redzones between objects and a quarantine zone for freed objects), FuZZan provides the same detection capability as ASan.

3.1.2 Min-shadow memory

The idea behind Min-shadow memory (for executions with a mid-to-high number of metadata accesses) is to limit the accessible virtual address space, effectively shrinking the size of the required shadow memory. As the size of shadow memory is a key driver of overhead in the fuzzing environment, this enhances performance.

Figure 3 illustrates how min-shadow memory converts a 64-bit program running in a 48-bit address space to run in a 32-bit address space window (1GB for the stack, 1GB for the heap, and 2GB for the BSS, data, and text sections combined). Note that pointers remain 64 bits wide and the code remains unchanged: the mapped address space is simply restricted, allowing min-shadow memory to have a partial shadow memory map. To shrink a program's memory space, we move the heap (by modifying ASan's heap allocator) and remap the stack to a new address space. Min-shadow memory remaps parts of the address space but programs remain 64-bit programs. To accommodate larger heap sizes, we create additional min-shadow memory binaries with heap sizes of 4GB, 8GB, and 16GB.

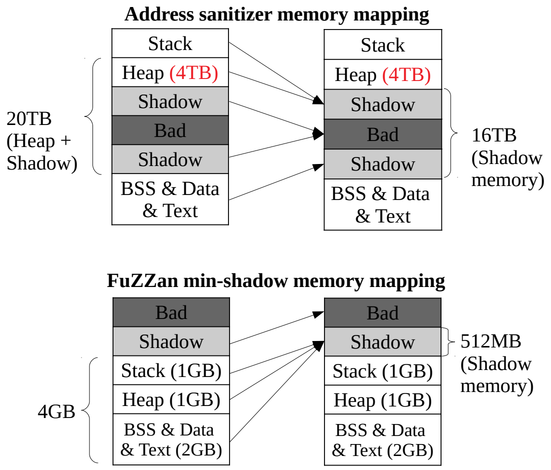


Figure 3: ASan and min-shadow memory modes' memory mapping on 64-bit platforms. ASan (top) reserves 20TB memory space for heap and shadow memory, conversely, min-shadow memory mode (bottom) reserves 4512MB memory space for heap and shadow memory. Each application's stack, heap, and other sections (BSS, data, and text) map to the corresponding shadow regions. Further, the shadow memory region is mapped inaccessible.

Our approach allows testing 64-bit code with 64-bit pointers without having to map shadow tables for the entire address space. We disagree with the recommendation of the ASan developers to compile programs as 32-bit executables, as changing the target architecture, pointer length, and data type sizes will hide bugs. Furthermore, min-shadow memory provides greater flexibility compared to using the `x32` ABI [53] mode (i.e., running the processor in 64-bit mode but using 32-bit pointers and arithmetic, limiting the program to a virtual address space of 4GB), as min-shadow memory can provide various heap size options.

3.2 Dynamic metadata structure switching

Dynamic metadata structure switching automatically selects the optimal metadata scheme based on observed behavior. At the beginning of a fuzzing campaign, dynamic metadata structure switching assesses the initial behavior and then periodically samples behavior, adjusting the metadata structure if necessary. Our intuition for dynamic metadata structure switching is that, during fuzzing, metadata access patterns and memory usage remain similar across runs and change in phases. While the fuzzer is mutating a specific input, the executions of the newly created inputs are *similar regarding their control flow and memory access patterns* compared to the source input. However, new coverage may lead to different execution behaviors. We therefore design a *dynamic metadata structure switching* technique that periodically and conditionally samples the execution and adjusts the underlying metadata structure according to the observed execution behavior.

Dynamic metadata structure switching compiles the program in four different ways in preparation for fuzzing: ASan, RB-tree, min-shadow memory, and sampling mode. The sampling mode repeatedly samples the runtime parameters and then selects the optimal metadata structure. The selection of the optimal metadata structure is governed by FuZZan's metadata structure switching policy.

3.2.1 Sampling mode

The sampling mode measures the behavior of the target program using the min-shadow memory-1GB metadata mode and, based on the behavior, reports the currently optimal metadata structure. The sampling mode profiles the following parameters: (i) the number of metadata accesses during insert, delete, and search; and (ii) memory consumption. Note that this information can be collected by simple counters: profiling is therefore light-weight.

Dynamic metadata structure switching starts in sampling mode and selects the optimal mode based on the observed behavior. Dynamic metadata structure switching then periodically (e.g., every 1,000 executions) and conditionally (e.g., when the fuzzer starts mutating a new test case) samples executions to select the optimal metadata structure based on the current behavior. To reduce the cost of periodic sampling, dynamic metadata structure switching implements a continuous back-off strategy that gradually increases the sampling interval as long as the metadata structure does not change (similar to TCP's slow-start [17]). Note that bugs may be triggered during sampling mode. As such, we maintain ASan's error detection capabilities while sampling to ensure that we do not miss any bugs.

3.2.2 Metadata structure switching policies

Our metadata structure switching policy is based on a mapping of metadata access frequency to the corresponding metadata structure. This heuristic is relatively simple in order to achieve a low sampling overhead. To determine the best cutoff points, we compile all 26 applications in Google's fuzzer test suite in two different ways: RB-tree and min-shadow memory. We then test these different configurations against 50,000 recorded inputs and determine the best metadata structure depending on the observed parameters, measuring execution time. Profiling reveals that the frequency of metadata access (insert, delete, and search) is the primary factor that influences metadata structure overhead, which confirms our original assumption. In this policy, depending on the metadata access frequency, we select different metadata structures (based on statistics from profiling): RB-tree if there are fewer than 1,000 accesses; and min-shadow memory if there are more than 1,000 accesses. Additionally, if the selected heap size goes beyond a threshold, we sequentially switch to other modes (min-shadow memory-4G, 8G, 16G, and ASan), thus increasing heap memory for continuous fuzzing.

4 Implementation

We implement FuZZan's two metadata structures and dynamic metadata structure switching mode on top of ASan in LLVM [28] (version 7.0.0). We support and interact with AFL [57] (version 2.52b). To address the other sources of overhead in ASan (shown in Table 1), we also implement two additional optimizations: (i) removal of unnecessary initialization; and (ii) removal of unnecessary logging. Our implementation consists of 3.5k LOC in total (mostly in LLVM, with minor extensions to AFL).

RB-tree. The RB-tree requires modifications to ASan's memory access instrumentation, as our RB-tree is not based on a shadow memory metadata structure. Thus, we modify all memory access checks, including interceptors, to use the appropriate RB-tree operations instead of the equivalent shadow memory operations. As an optimization, and for compatibility with min-shadow memory mode, the RB-tree mode also reserves 1GB for the heap memory allocator. A compact heap reduces memory management overhead. The RB-tree mode is used when fuzz tests only execute for a very short time with few metadata accesses (i.e., they allocate relatively a small amount of memory).

Min-shadow memory. Unlike the RB-tree, we are able to repurpose ASan's existing memory access checks, as the min-shadow memory metadata structure is based on a shadow memory scheme. To shrink a 64-bit program's address space, we modify ASan's internal heap setup and remap the stack using Kroes et al.'s linker/loader tricks [22]. More specifically, based on this script, we hook `__libc_start_main` using "`LD_PRELOAD`" and then `remap` the stack to a new address, update `rbp` and `rsp`, and then call the original `__libc_start_main`. This allows us to reduce ASan's shadow map requirements from 16TB of mapped (but not necessarily allocated) virtual memory to 512MB (1 bit of shadow for each byte in our 4GB address space window). We also create an additional 192MB shadow memory for ASan's secondary allocator and dynamic libraries (which are remapped above the stack). Finally, we implement four different min-shadow memory modes with increasing heap sizes (1GB, 4GB, 8GB, and 16GB) to handle the different memory requirements of a variety of programs.

Heap size triggers. As previously stated, min-shadow memory is configured for different heap sizes. We therefore use out of memory (OOM) errors to trigger callbacks that notify FuZZan to increase the heap size.

AFL modifications. The target program is compiled once per FuZZan mode. By default, AFL uses a random number generator (RNG) to assign an ID to each basic block within the target program. Unfortunately, this would result in the same input producing different coverage maps across the set of compiled targets, breaking AFL's code coverage analysis. We therefore modify AFL to use the same RNG seed across the set of compiled targets. This ensures that the same input produces the same coverage map across all compiled variants.

Removing unnecessary initialization. ASan makes a number of global constructor calls on program startup, performing several `do_wp_page` calls for copy-on-write. These constructor calls are unnecessarily repeated each time AFL executes a new test input, leading to redundant operations. Unfortunately, the AFL fork server is unaware of ASan's initialization routines. Therefore, to remove unnecessary (re-)initialization across fuzzing runs, we modify ASan's LLVM pass so that global variable initialization occurs *before* AFL's fork server starts. This is achieved by adjusting the priority of global constructors which contain ASan's initialization function.

Removing unnecessary logging. ASan provides logging functionality for error reporting (e.g., saving allocation sizes and thread IDs during object allocation). Unfortunately, this logging functionality introduces additional page faults and performance overhead. However, this logging is unnecessary because fuzzing inherently enables replay by storing test inputs that trigger new behavior. Complete logging information can be recovered by replaying a given input with a fully-instrumented program. We therefore identify and disable ASan's logging functionality (e.g., `StackDepot`) for fuzzing runs, allowing it to be reenabled for reportable runs.

5 Evaluation

We provide a security and performance evaluation of FuZZan. First, we verify that FuZZan and ASan have the same error-detection capabilities. Second, we evaluate the efficiency of FuZZan's new metadata structures and dynamic metadata structure switching mode using deterministic input from a record/replay infrastructure to ensure fair comparisons. Next, to consider the random nature of fuzzing and to show FuZZan's real-world impact, we evaluate FuZZan's efficiency without deterministic input. Here we evaluate the number of code paths found by FuZZan in a 24 hour time period, demonstrating the impact of FuZZan's increased performance. We also measure FuZZan's bug finding speed by using known bugs in Google's fuzzer test suite to verify that FuZZan maximizes fuzzing execution speed while providing the exact same bug detection capabilities as ASan. Finally, we port FuZZan to another sanitizer (MSan) [48] and another AFL-based fuzzer (MOpt-AFL) [31] to verify its flexibility.

Evaluation setup. All of our experiments are performed on a desktop running Ubuntu 18.04.3 LTS with a 32-core AMD Ryzen Threadripper 2990WX, 64GB of RAM, 1TB SSD, and Simultaneous MultiThreading (SMT) disabled (to guarantee a single fuzzing instance is assigned to each physical core). Across all experiments, we apply FuZZan to AFL's fork server mode, which is a widely-used and highly optimized out-of-process fuzzing mode. We evaluate FuZZan on all applications in the Google fuzzer test suite [11] and other widely used real-world software.

Evaluation strategy. Evaluating fuzzing effectiveness is challenging. In a recent study of how to evaluate fuzzing by Klees et. al. [21], the authors find that the inherent randomness of the fuzzer's input generation can lead to seemingly large but spurious differences in fuzzing effectiveness. However, we are at an advantage as we do not need to compare different fuzzers nor do we change the input generation. We therefore record the fuzzer-generated inputs during a regular run of AFL, and then replay these recorded inputs to compare our different ASan optimizations to the same baseline, effectively controlling for randomness in input generation by using the same input for all experiments. For our experiments we record the first 500,000 executions for replay, yielding a large enough test corpus for reasonable performance comparisons. We also undertake a real-world fuzzing campaign (i.e., without inhibiting fuzzing randomness by record/replay) to measure FuZZan's real-world impact on code path exploration. Finally, Klees et. al. demonstrate the importance of the initial seed(s) when evaluating fuzz testing, as performance can vary substantially depending on what seed is used. We therefore compare two scenarios: (i) starting with the empty seed; and (ii) starting with a set of valid seeds (we use Google's provided seeds for the input record/replay experiment and randomly selected seeds of the right file type for our real-world fuzz testing).

CWD (ID)	**Good tests**	**Bad tests**
	(Pass/Total)	**(Pass/Total)**
Stack-based Buffer Overflow (121)	2,432 / 2,432	2,314 / 2,432
Heap-based Buffer Overflow (122)	1,594 / 1,594	1,328 / 1,594
Buffer Under-write (124)	682 / 682	641 / 682
Buffer Over-read (126)	524 / 524	359 / 524
Buffer Under-read (127)	682 / 682	641 / 682
Total	5,914 / 5,914	5,283 / 5,914

Table 3: Three different metadata structure modes' detection capability based on the Juliet Test Suite for memory corruption CWEs. FuZZan and ASan have identical results. Good tests have no memory corruption to check for false positives. Bad tests are intentionally buggy to check for false negatives.

5.1 Detection capability

We verify that FuZZan and ASan detect the same set of bugs in three different ways. First, we use the NIST Juliet test suite [35], which is a collection of test cases containing common vulnerabilities based on Common Weakness Enumeration (CWE). We use the full Juliet test suite for memory corruption CWEs to verify FuZZan's capability to detect the same classes of bugs as ASan, without introducing false positives or negatives. Second, to verify that FuZZan and ASan also have the same detection capability under fuzz testing, we use the Google fuzzer test suite and our recorded input corpus. Finally, we leverage the complete set of ASan's public unit tests as a further sanity check.

For the Juliet test suite (Table 3), we select CWEs related to memory corruption bugs and obtain the same detection results from the three different modes (ASan's shadow memory, RB-tree, and min-shadow memory). To validate FuZZan against ASan on the Google fuzzer test suite, we compare AFL crash reports across the full set of target programs in the Google fuzzer test suite with our recorded inputs (to identify both false positives and false negatives). Note that we force ASan to crash (the default setting under fuzz testing) when a memory error happens as fuzzers depend on program crashes to detect bugs. As expected, FuZZan's different modes all obtain the same crash results as ASan. However, we encounter minor differences between FuZZan and ASan when sanity-checking on the ASan unit tests. These differences are due to internal changes we made when developing FuZZan, such as min-shadow memory's changed memory layout (failed test cases include features such as fixed memory addresses).

Modes	Empty seed			Provided seed		
	time (s)	vs. Native (%)	vs. ASan (%)	time (s)	vs. Native (%)	vs. ASan (%)
Native	199	-	-	274	-	-
ASan	809	306	-	1,105	303	-
RB-tree	1,541	673	90	3,308	1,106	199
Min-1G	443	122	-45	632	131	-43
Min-4G	465	133	-43	666	143	-40
Min-8G	467	134	-42	685	150	-38
Min-16G	477	139	-41	710	159	-36

Table 4: Comparison between four min-shadow memory modes, RB-tree, Native, and ASan execution overhead during input record and replay fuzz testing with empty and provided seed sets. The time (s) indicates the average of all 26 applications' execution time during testing. Positive percentage (e.g., 20%) denotes overhead while negative percentage indicates a speedup.

5.2 Efficiency of new metadata structures

We perform input record/replay fuzz testing to evaluate the effectiveness of FuZZan's new metadata structures. Doing so isolates the effects of our metadata structures by removing most of the randomness/variation from a typical fuzzing run.

Over the full Google fuzzer test suite, the RB-tree, without any other optimization, shows shorter execution times than ASan if the target application has less than 1,000 metadata accesses; conversely, the RB-tree is slower than ASan when the target application has more than 1,000 metadata accesses. On average, as shown in Table 4, several applications in the Google fuzzer test suite have more than 1,000 metadata accesses, and so RB-tree is overall slower than ASan on average.

Despite being slower on average, the RB-tree can be faster on individual applications and inputs. For instance, FuZZan in RB-tree mode demonstrates a 19% performance improvement (up to 45% faster) for 15 applications (the remaining 11 applications show higher overhead compared to ASan) when benchmarked using the inputs generated from an empty seed. On the subset of applications for which seeds are provided, RB-tree shows less performance improvement (17% and up to 39% faster) for 14 applications (the remaining 12 applications show higher overhead than ASan) when benchmarked using inputs generated from those seeds as provided seeds help to create valid input, lengthening execution times and thus metadata accesses. Note that RB-tree shows the best fuzzing performance when the target application (e.g., `c-ares`) has less 1,000 metadata access. Additionally, even for applications where RB-tree is slower across all inputs, it is still *faster* on inputs with few metadata accesses. The variable performance of RB-tree, which is highly dependent on the number of metadata accesses, highlights the need for dynamic metadata structure switching to automatically select the optimal metadata structure.

Modes	Empty seed			Provided seed		
	time (s)	vs. Native (%)	vs. ASan (%)	time (s)	vs. Native (%)	vs. ASan (%)
Logging-Opt.	613	208	-24	891	225	-19

Logging+Init	552	177	-32	826	201	-25
Min-Shadow	443	122	-45	632	131	-43
Min-Shadow-Opt.	385	93	-52	574	109	-48
Dynamic	387	94	-52	578	111	-48

Table 5: Comparison between FuZZan's three different optimization modes, native min-shadow memory (1G) mode, and min-shadow memory (1G) mode with FuZZan's two optimizations, and dynamic metadata structure switching (Dynamic) mode execution overhead during all 26 applications' input record and replay fuzz testing.

Modes	ASan's init time ms (%)	ASan's logging time ms (%)	Memory manage time ms (%)	Page fault #
Native	0.00 (0.00%)	0.00 (0.00%)	0.05 (11.49%)	2,569
ASan	0.17 (10.58%)	0.30 (18.86%)	0.63 (40.16%)	11,967
Min	0.10 (9.51%)	0.01 (1.33%)	0.24 (24.77%)	7,386
Min-Opt.	0.00 (0.00%)	0.00 (0.00%)	0.24 (24.71%)	6,139

Table 6: Comparison between native, ASan, min-shadow memory (1G), two optimizations with min-shadow memory executions with a breakdown of time spent in memory management, and time spent for ASan's initialization and logging. Results are aggregated over 500,000 executions of the full Google fuzzer test suite. Times are shown in milliseconds, and % denotes the ratio between single execution time and each section execution's time.

Min-shadow memory mode, without additional optimization, outperforms ASan on all 26 programs (for both empty and provided seeds), as shown in Table 4. More specifically, the average improvement is 45% when starting with an empty seed and 43% when starting with the provided seeds. While different min-shadow memory heap configurations show gradual increases in memory overhead (from 1GB to 16GB, in line with the heap size), all of them outperform ASan (at worst, min-shadow memory is still 36% faster than ASan with a provided seed).

Additionally, both metadata configurations can utilize our two engineering optimizations; i.e., removing logging and modifying ASan's initialization (as described in § 4). Table 5 shows that the average improvement of removing unnecessary logging is 24% when starting with an empty seed and 19% when starting with the provided seeds. Similarly, modifying the initialization sequence improves performance by 15% when starting with an empty seed and by 11% when starting with the provided seeds. Combining the two engineering optimizations with min-shadow memory demonstrates synergistic effects: the combined performance is 52% (7% better than native min-shadow memory) faster for empty seeds, and 48% (5% better than native min-shadow memory) faster for provided seeds.

Overall, FuZZan's metadata structures show better performance than ASan's shadow memory for all 26 Google fuzzer test suite applications. As shown in Table 6, the main reasons for FuZZan's improvement are: (i) the smaller memory space reduces memory management overhead as page table management is more lightweight and incurs fewer page faults, (ii) our two engineering optimizations further reduce overhead and number of page faults by removing unnecessary operations, and (iii) the min-shadow memory mode has the same $O(1)$ time complexity for accessing target shadow memory as accessing the original ASan metadata. However, we also observe that the RB-tree is faster than min-shadow memory for some configurations and programs (e.g., `c-ares-CVE`). This motivates the need for dynamic metadata structure switching, which observes program behavior and dynamically selects the best metadata structure based on this behavior.

5.3 Efficiency of dynamic metadata structure

As described in § 3.2, the dynamic metadata structure switching mode leverages runtime feedback to select the optimal metadata structure, dynamically tuning fuzzing performance according to runtime feedback. The intuition behind the dynamic metadata structure switching mode is that (i) no single metadata structure is best across all applications, (ii) the best metadata structure is not known a priori, so the analyst cannot pre-select the optimal metadata structure, and (iii) fuzzing goes through phases, e.g., alternating between longer running tests (e.g., exploring new coverage) and shorter running tests (e.g., invalid input mutations searching for new code paths). A consequence of the phases of fuzzing is that the same metadata structure is not optimal for every input to a given application. To verify the effectiveness of dynamic metadata structure switching, which is implemented based on these intuitions, we apply dynamic metadata structure switching mode to fuzz testing for seven widely used applications for fuzzing and all 26 applications' in Google's fuzzer test suite.

Our evaluation of dynamic metadata structure switching validates our intuitions, as shown in Figure 4. Observe that different applications are dominated by different metadata structures, e.g., `c-ares` for RB-tree and `pngfix` for min-shadow memory. This is because dynamic metadata structure switching automatically selects the optimal metadata structure (which is unknown a priori). Because dynamic metadata structure switching is automatic, it prevents users from making errors such as selecting RB-tree for applications with a large number of metadata accesses, and removes the need for any user-driven profiling to make metadata decisions. Further, dynamic metadata structure switching scales alongside with the required memory of applications as it increases when the fuzzer finds deeper test cases, as evidenced by `size`, `pngfix`, or `nm` switching to different min-shadow memory modes (4GB, 8GB, and 16GB heap sizes), without user intervention. Without dynamic metadata structure switching, inefficient min-shadow memory modes would be used at the beginning of fuzzing campaigns, or users would have to pause and restart fuzzing campaigns to change metadata modes.

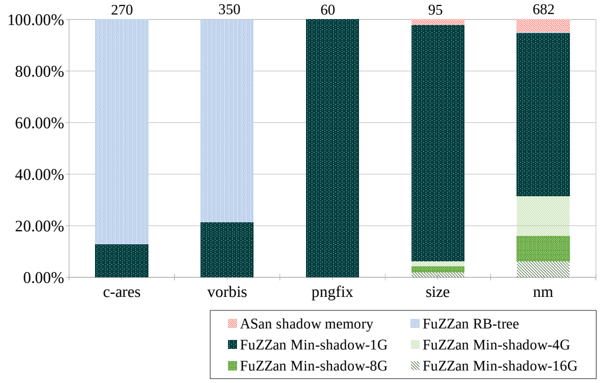

Figure 4: Evaluating the frequency of metadata structure switching and each metadata structure selection over the first 500,000 tests each for c-ares and vorbis in Google's fuzzer test suite and pngfix, size, and nm. The number on each bar indicates the total metadata switches.

As an extreme example highlighting the need for automatic metadata switching, the `nm` benchmark changes metadata structures 682 times, underscoring the infeasibility of having a human analyst determine the single best metadata structure.

As a result of these factors, FuZZan's dynamic metadata structure switching mode improves performance over ASan by 52% when starting with empty seeds and 48% when starting with non-empty seeds. Further, ASan has 306% and FuZZan has 94% (212% less) overhead with empty seeds and ASan has 303% and FuZZan has 111% (192% less) overhead with non-empty seeds compared to native execution. Note that dynamic metadata structure switching has identical fuzzing performance to using min-shadow memory with 1GB heap alone, and improves performance over RB-tree up to 870%. Consequently, automating metadata selection is not adding noticeable overhead, while substantially improving user experience. We recommend using dynamic metadata structure switching mode for the following four reasons: (i) if the target application exceeds FuZZan's heap memory limit (1GB), dynamic metadata structure switching automatically increases the heap size for the few executions that require it (a fixed heap size results in *false positive crashes* due to heap memory exhaustion), (ii) preventing users from selecting an incorrect metadata structure, (iii) using only one metadata structure (e.g., min-shadow memory) may miss the opportunity to further improve throughput, as, in some cases, RB-tree (or some future metadata structure) may be faster than min-shadow memory; (iv) manually selecting a metadata structure requires extra effort (e.g., measuring each metadata structure's efficiency for the target application), which dynamic metadata structure switching mode avoids by automatically selecting the optimal metadata structure.

Programs	Native		ASan		FuZZan	
	exec \#	path \#	exec \#	path \#	exec \# (%)	path \# (%)
cxxfilt	86M	2,769	33M	2,442	51M (55%)	2,651 (9%)
file	29M	1,126	7M	763	9M (29%)	845 (11%)

Table 7: Evaluating FuZZan's total execution number and unique discovered path for 24 hours fuzz testing with provided seeds. The (M) denotes 1,000,000 (one million) and ratio (%) is the ratio between ASan and FuZZan.

Programs	ASan	FuZZan		Type (source)
	TTE (s)	TTE (s)	rate (%)	
c-ares	45	25	46	BO (ares_create_query.c:196)
json	29	11	61	AF (fuzzer-parse_json.cpp:50)
libxml2	7,314	4,194	43	BO (CVE-2015-8317)
openssl-1.0.1f	443	336	24	BO (t1_lib.c:2586)
pcre2	7,056	4,020	43	BO (pcre2_match.c:5968)
Total	14,887	8,586	42	-

Table 8: Evaluating FuZZan's bug finding speed. The TTE denotes the mean time-to-exposure. The AF is assertion error and the BO denotes buffer overflow.

5.4 Real-world fuzz testing

Our experiments validating FuZZan use a record/replay approach to avoid any impact of randomness, allowing meaningful comparisons to a baseline. However, real-world fuzzing is highly stochastic, and so we also evaluate FuZZan in the context of several real-world end-to-end fuzzing campaigns without deterministic input record/replay. For this experiment, we select the following widely used programs: `cxxfilt`, `nm`, `objdump`, `size` (all from binutil-2.31), `file` (version 5.35), `pngfix` (from libpng 1.6.38) and `tcpdump` (version 4.10.0). Klees et al. [21] select and test `cxxfilt`, `nm`, and `objdump` in their fuzzing evaluation study. The remaining four programs (`size`, `file`, `pngfix`, and `tcpdump`) are widely tested by recent fuzzing works [1, 3, 6, 26, 36, 46]. For each binary, we run a fuzzing campaign. Each campaign is conducted for 24 hours and repeated five times. We measure the number of total executions and discovered unique paths when fuzzing with seeds from the seed corpus of each program with the right type file and three different configurations: native, ASan, and FuZZan's dynamic metadata structure switching mode, and report the mean over the five campaigns.

As a result, FuZZan improves throughput over ASan by 61% (up to 88%). Interestingly, FuZZan discovers 13% more unique paths given the same 24 hours time due to improved throughput. Our evaluation also shows that improved throughput increases the possibility of finding more bugs in the same amount of time, as we discuss next.

Modes	time (s)	vs. Native (%)	vs. MSan (%)	vs. MSan nolock (%)
Native	146	-	-	-
MSan	14,074	9,575	-	-
MSan-nolock	386	165	-97	-
Min-16G	335	130	-98	-13

Table 9: Comparison between Native, MSan, MSan-nolock, and min-shadow memory execution overhead during input record and replay fuzz testing with provided seed sets. MSan-nolock disables lock/unlock for MSan's logging depots. Time (s) indicates the average of execution time. Positive percentages denote overhead, negative percentages denote speedup.

5.5 Bug finding effectiveness

FuZZan increases throughput while maintaining ASan's bug detection capability, potentially enabling it to find more bugs. To demonstrate this, we evaluate FuZZan's bug finding speed and compare it to a fuzzing campaign with ASan. In this evaluation, we target five applications in Google's fuzzer test suite. These applications are chosen because we found bugs in them (using ASan and dynamic metadata structure switching mode) within a 24 hour fuzzing campaign. We use the seeds provided by the test suite and repeated each campaign five times. Note that we do not replay recorded inputs during these campaigns, instead letting the fuzzer generate random inputs. Table 8 shows the mean time (over five campaigns) to find each bug. Notably, FuZZan finds all bugs up to 61% (mean 42%) faster than ASan, and is faster in all cases. This experiment emphasizes our belief that throughput is paramount when fuzzing with sanitizers.

5.6 FuZZan Flexibility

Appling FuZZan to Memory Sanitizer. Like ASan, numerous sanitizers use shadow memory for their metadata structure [47]. For example, other popular sanitizers, such as Memory Sanitizer (MSan) [48] and Thread Sanitizer (TSan) [42], also rely on shadow memory for metadata. FuZZan optimizes sanitizer usage of shadow memory *without* modifying the stored shadow information or how the sanitizer uses that information. Consequently, porting our shadow metadata improvements in FuZZan from ASan to other sanitizers is a simple engineering exercise. To demonstrate this, we port FuZZan to MSan. In so doing, we shrink MSan's memory space to implement min-shadow memory 16G for MSan (1GB for the stack, 16GB for the heap, and 2GB for the BSS, data, and text sections combined). We only implement one metadata mode for our MSan proof-of-concept to validate our claim that applies FuZZan to other shadow memory based sanitizers is an engineering exercise.

Table 9 summarizes MSan's performance overhead on different modes for all 26 evaluated applications. Initially, min-shadow memory shows high overhead—around 96 times native. Analyzing this, we found that MSan's `fork()` interceptor locks all logging depots before `fork()` and similarly unlocks them afterwards to avoid deadlocks. However, as explained in § 4, locking/unlocking logging depots is unnecessary for fuzzing because these logging depots exist for bug reporting and fuzzing inherently enables replay by storing test inputs when the fuzzer finds bugs. We thus disable these lock/unlock functions to create the MSan-nolock mode, which has reasonable overhead (2.6 times that of native).

FuZZan's MSan min-shadow memory 16G mode shows 13% performance improvement compared to MSan-nolock mode, demonstrating FuZZan's efficacy when applied to MSan. We expect that additional optimization and the application of the dynamic switch mode will lead to even higher performance improvement. We leave this engineering as future work.

Applying FuZZan to MOpt-AFL. FuZZan is not coupled to a particular fuzzer or fuzzer version. Most modern fuzzers [2, 3, 31, 31] extend AFL, so our approach applies broadly. To demonstrate this, we apply FuZZan to MOpt-AFL [31], which is an efficient mutation scheduling scheme to achieve better fuzzing efficiency. We modify MOpt-AFL to add FuZZan's profiling feedback and dynamic metadata switching functions. To measure FuZZan's impact on MOpt-AFL, we select seven real-world applications (the same set as Table 7) and fuzz them for 24 hours each, repeating the experiment five times to control for randomness in the results. On average, ASan-MOpt-AFL mode discovers 85% more unique paths given the same 24 hours time due to MOpt-AFL's effectiveness compared to ASan. Notably, FuZZan-MOpt-AFL mode discovers 112% more unique paths (27% higher than ASan-MOpt-AFL) due to the improved throughput.

6 Discussion

In this section, we summarize some potential areas for future work, a possible security extension enabled by FuZZan, and lessons learned in designing FuZZan.

Removing conflicts between sanitizers. ASan's shadow memory scheme conflicts with other sanitizers that are also based on shadow memory, e.g., MSan and TSan. Each sanitizer interprets the shadow memory in a mutually exclusive manner, prohibiting the use of multiple concurrent sanitizers. For example, ASan uses shadow memory as a metadata store, while MSan prohibits access to the same memory range. FuZZan's new metadata structures can be adapted to avoid this conflict, and enable true composition of sanitizers, since we use lightweight, independent metadata structures. Each sanitizer can map its own instance of our metadata structure, and all sanitizers may coexist in a single process. However, some engineering effort is required to port sanitizers to our new metadata structures. An alternate approach would be to have one metadata structure that stores information for all sanitizers. Whether having a unified metadata structure or a metadata structure per sanitizer is more efficient is an interesting research question.

Possible security extension. Unfortunately, ASan's virtual memory requirements directly conflict with fuzzers' abilities to detect certain out-of-memory (OOM) bugs. For example, fuzzers typically limit memory usage to detect OOM errors when parsing malformed input. However, ASan's large virtual memory requirement masks OOM bugs, leaving them undetected because of the difficulty of setting precise memory limits. Consequently, using a compact metadata structure with ASan not only improves performance, but also can enable an extension of ASan's policy to cover OOM bugs.

Lessons Learned. Our initial metadata design leveraged a two-layered shadow memory metadata structure that split metadata lookups into two parts: a lookup into a top-level metadata structure, followed by a lookup into a second-level metadata structure a la page tables. While this design vastly reduced memory consumption and management overhead, the additional runtime cost per metadata access of the additional indirection resulted in the two-layer structure being slower than ASan in all cases.

For dynamic metadata structure switching, we evaluated two additional policies: (i) utilizing more detailed metadata access information such as each object type's (e.g, stack) metadata access (e.g., insert) count and each operation's microbenchmark results, and (ii) running each metadata mode, measuring their execution time, and selecting the fastest metadata mode. In our evaluation, the additional sampling complexity of these policies outweighed any gains from more precisely selecting a metadata structure.

7 Related Work

7.1 Reducing Fuzzing Overhead

Several approaches reduce the overhead of fuzzing. One approach is to reduce the execution time of each iteration. AFL supports a deferred fork server which requires a manual call to the fork server. The analyst is encouraged to use the deferred fork server, and manually initiate the fork server as late as possible to reduce, not only overhead from linking and libc initializations, but also overhead from the initialization of the target program. Deferred mode, however, cannot reduce the teardown overhead of heavy metadata structures. AFL's persistent mode and libFuzzer eliminate the overhead from creating a new process. However, these approaches require manual effort, and users must know the target programs. Xu et al. [55] implement several new OS primitives to improve the efficiency of fuzzing on multicore platforms. Especially, by supporting a new system call, `snapshot` instead of `fork`, they reduce the overhead of creating a process. Moreover, they reduce the overhead from file system contention through a dual file system service.

However, this approach requires kernel modifications for the new primitives, and does not reduce the overhead of sanitizers.

Another approach is to improve fuzzing itself so that it can find more crashes within the same amount of executions. AFLFast [3] adopts a Markov chain model to select a seed. If inputs mutated from a seed explore more new paths, the seed has higher probability to be selected. With given target source locations, AFLGo [2] selects a seed that has higher probabilities to reach the source locations. Several approaches adopt hybrid fuzzing, taint analysis, and machine learning to help fuzzers explore more paths. SAVIOR [8] uses hybrid fuzzing, combining it with concolic execution to explore code blocks guarded by complex branch conditions. RedQueen [1] uses taint analysis and symbolic execution for the same purpose. VUzzer [40] also uses dynamic taint analysis and mutates bytes which are related to target branch conditions to efficiently explore paths. TIFF [18] infers the type of the input bytes through dynamic taint analysis and uses the type information to mutate the input. Matryoshka [7] uses both data flow and control flow information to explore nested branches. In addition to hybrid fuzzing with traditional techniques such as symbolic and concolic executions, NEUZZ [46] adapts neural network and sets the number of covered paths as an objective function to maximize covered paths. Angora [6] adapts both taint analysis and a gradient descent algorithm to improve the number of covered paths. These approaches do not reduce the execution time of each iteration. They are therefore orthogonal to our work. Thus, we can use these approaches to further increase fuzzing performance.

7.2 Optimizing Sanitizers

Since C/C++ programming languages are memory and type unsafe languages, several sanitizers [47] target memory safety violations [5, 23, 41, 48, 49] and type safety violations [14, 19, 24, 29]. Despite their broad use, sanitizers have several limitations such as high overhead, limited detection abilities, and incompatibility with other sanitizers.

To reduce sanitizer overhead, ASAP [52] and PartiSan [25] disable check instrumentation on the hot path according to their policies. The intuition of both approaches is that most of the sanitizer's overhead comes from checks on a few hot code paths that are frequently executed (e.g., instrumentation in a loop). ASAP removes check instrumentation on the hot path based on pre-calculated profiling results at compile time. In PartiSan [25], Lettner et al., propose runtime partitioning to more effectively remove check instrumentation based on runtime information during execution. However, both approaches miss a main source of overhead when reducing the cost of ASan during fuzzing campaigns: the overhead is due to memory management and not due to the low overhead safety checks. As ASAP and PartiSan target the cost of checks, they are complementary to FuZZan. To fuzz quickly, there is an option to generate a corpus from a normal binary, and then feed the corpus to an ASan binary. FuZZan can also adopt this option for fast fuzzing.

Pina et al., [38] use multi-version execution to concurrently run sanitizer-protected processes together with native processes, synchronizing all versions at the system-call level. To synchronize all versions, they use a system-call buffer and a Domain-Specific Language [37] to resolve conflicts between different program versions. Xu et al., [54] propose Bunshin to reduce the overhead of sanitizers and conflicts based on the N-version system through their check distribution, sanitizer distribution, and cost distribution policies. Since these approaches are based on N-version systems, they increase hardware requirements such as several dedicated cores and at least N times of memory. Also, these approaches do not address the fundamental problem of ASan memory overhead.

8 Conclusion

Combining a fuzzer with sanitizers is a popular and effective approach to maximize bug finding efficacy. However, several design choices of current sanitizers hinder fuzzing effectiveness, increasing the runtime cost and reducing the benefit of combining fuzzing and sanitization.

We show that the root cause of this overhead is the heavy metadata structure used by sanitizers, and propose FuZZan to optimize sanitizer metadata structures for fuzzing. We implement and apply these ideas to ASan. We design new metadata structures to replace ASan's rigid shadow memory, reducing the memory management overhead while maintaining the same error detection capabilities. Our dynamic metadata structure adaptively selects the most efficient metadata structure for the current fuzzing campaign without manual configuration.

Our evaluation shows that FuZZan improves performance over ASan 52% when starting with empty seeds (48% with Google's seed corpus). Based on improved throughput, FuZZan discovers 13% more unique paths given the same 24 hours and finds bugs 42% faster. The open-source version of FuZZan is available at https://github.com/HexHive/FuZZan.

Abstract

Configuration has become ever so complex and error-prone in today's server software. To mitigate this problem, software vendors provide user manuals to guide system admins on configuring their systems. Usually, manuals describe not only the meaning of configuration parameters but also *good practice recommendations* on how to configure certain parameters. Unfortunately, manuals usually also have a large number of pages, which are time-consuming for humans to read and understand. Therefore, system admins often do not refer to manuals but rely on their own guesswork or unreliable sources when setting up systems, which can lead to configuration errors and system failures.

To understand the characteristics of configuration recommendations in user manuals, this paper first collected and studied 261 recommendations from the manuals of six large open-source systems. Our study shows that 60% of the studied recommendations describe specific and checkable specifications instead of merely general guidance. Moreover, almost all (97%) of such specifications have not been checked in the systems' source code, and 61% of them are not equivalent to the default settings. This implies that additional checking is needed to ensure the recommendations are correctly applied.

Based on our characteristic study, we build a tool called PracExtractor, which employs Natural Language Processing (NLP) techniques to automatically extract configuration recommendations from software manuals, converts them into specifications, and then uses the generated specifications to detect violations in system admins' configuration settings. We evaluate PracExtractor with twelve widely-deployed software systems, including one large commercial system from a public company. In total, PracExtractor automatically extracts 338 recommendations and generates 173 specifications with reasonable accuracy. With these generated specifications, PracExtractor detects 1423 good practice violations from open-source docker images. To this day, we have reported 325 violations and have got 47 of them confirmed as real configuration issues by admins from different organizations.

1 Introduction

1.1 Motivation

Misconfiguration (error in configuration settings) has become one of the major causes of failures in large-scale cloud and Internet systems, as reported by many system vendors [29,45,64] and service providers [20,26,32,34,37,51]. While various fault tolerance and recovery mechanisms are effective in handling hardware and software failures, they are less effective in handling configuration errors [27,32,37]. In 2017, a configuration error at Level 3, an Internet backbone company, caused a nationwide network outage [22]. On March 13th, 2019, the recent outage in Facebook was also caused by a server configuration error, affecting millions of users [52]. In addition to reliability, configuration errors can also lead to security issues [59]. OWASP reports misconfiguration as one of the top 10 most critical web security risks [38]. In 2017, a configuration error of Amazon S3 storage exposed personal information of 200 million U.S. voters [53].

One of the primary reasons for configuration errors is the ever-increasing configuration complexity, especially with system software [60]. Configuration complexity is partially reflected by the large and almost always increasing number of configuration parameters, as well as their configuration constraints and inter-dependency [31, 35, 44, 47, 63], which inevitably increase system admins' error rates [40, 46]. For example, MySQL 8.0 has more than 460 configuration parameters. Similarly, Apache httpd 2.4 has more than 550 parameters. Such a high level of complexity makes system configuration an error-prone task.

While research efforts have been attempted on reducing configuration complexity [55, 60], it is still a long journey to fully tame the complexity issue. Today, to assist system admins, software vendors typically release user manuals together with their software. A manual describes in detail the name, usages and sometimes constraints of each configuration parameter. It can be in print as a PDF file or accessed electronically as HTML/XML files, providing good guidance

Software	Pages	Software	Pages
COMP-A[1]	8283	Httpd	1009
MySQL	5494	HBase	787
PostgreSQL	3724	Freebsd	726
CentOS	2297	Ubuntu server	413
Hadoop	2331	Zookeeper	181

Table 1: Number of pages in ten popular software's manuals.

and reference for system admins to configure and manage server software.

Unfortunately, system manuals are quite large, containing hundreds or even thousands of pages. Table 1 lists the numbers of pages in the manuals of ten software, including one commercial software, COMP-A [1]. from a large public company. As the table shows, manuals of MySQL, PostgreSQL, CentOS and Hadoop have 2331-5494 pages. COMP-A has 8283 pages in its technical documentation.

With such a daunting number of manual pages, system admins find manuals hard and time-consuming to refer to and understand. As such, system admins often do not refer to them when configuring systems. Instead, they either rely on their own judgment/guesswork or ask for help from other admins [36]. Previous studies have shown that system admins solved only a small proportion of usage problems (4% to 25%) by referring to manuals [21, 33, 36].

However, manuals still contain useful information and ignoring manuals can lead to configuration errors that cause server downtime and data center outages. Figure 1 gives six real-world configuration errors of commercial and open-source software, in which system admins clearly do not follow good practice recommendations in manuals. The misconfigured parameters in these examples were set to incorrect values, leading to problems of systems' availability, performance and security. Since these incorrect values are totally legal values (i.e. violating no constraints in source code), they cannot be detected by software's own checking logic, as well as tools that focus on checking for illegal values [63]. However, in all these cases, the corresponding manuals actually have clearly given recommendations on how to set these parameters. Had these recommendations been followed by system admins, these misconfigurations would have been avoided.

Unfortunately, good practices recommended in manuals or other documents are not fully utilized by system admins to avoid configuration errors mainly due to three reasons:

- Recommended practices are spread out in various parts of manuals and cannot be easily found by system admins due to manuals' bulkiness and poor navigation [36].
- Many good practice recommendations are not always the same as default settings (more details in §2). A recent study shows that admins tend to go with default settings for more than 80% of configuration parameters, and many configuration errors were caused exactly because admins do not change the default setting [60]. As later shown in our evaluation (cf. Table 12), we also found many (997) cases that system admins just went with bad defaults. Had system admins read the recommendations in the manuals, they could have avoided some of these mistakes.
- As shown in all the examples in Figure 1, good practices recommended in manuals are often *soft* constraints, which usually are not checked inside software. Thereby, the violations of them cannot be detected by previous tools that were built by either inferring configuration specification from the software's source code [63] or just directly reusing the source code to check configuration [61].

1.2 Our Contributions

This paper studies the research questions on whether it is useful to automatically extract good practice recommendations from manuals and use them to detect system admins' configuration issues, and if so, how to do it. We first collected and studied 261 recommendations from six large open-source software manuals. Our study shows that 60% of the studied recommendations described specific, checkable specifications instead of just general guidance. In addition, almost all (97%) of the checkable specifications are not checked in source codes, and 61% of them are different from the default settings (reasons and details are discussed in §2).

Based on our characteristic study, we build a tool called PracExtractor, which employs Natural Language Processing (NLP) techniques to automatically extract good practice recommendations from manuals, converts them into specifications, and then uses the generated specifications to detect violations in system admins' configurations.

We evaluated PracExtractor with manuals of *twelve* widely-deployed software systems, including one from a *commercial* company with tens of thousands of customers. Overall, PracExtractor automatically extracts 338 recommendations, with a precision of 86% and a recall of 83%. PracExtractor converts 173 recommendations into specifications with reasonable accuracy. For the six "new" manuals not included in our characteristic study, PracExtractor can achieve a precision of 83% for recommendations and 88% for specifications.

To evaluate the capability of detecting real-world misconfigurations, we run PracExtractor against real-world configurations from top-downloaded container images on DockerHub [24]. PracExtractor detects 1423 violations in 853 images. We reported 325 violations to the image maintainers and got 47 confirmed as real configuration issues, including six issues in images with over 1M downloads and 28 in images with over 1K downloads.

Interestingly, in addition to detecting system admins' configuration problems, PracExtractor also detects a few incorrect

[1] We are required to keep the company and the product anonymous.

Comp-A
Parameter: *export-policy*
Incorrect setting by admins: *none*
Outcome: NFS mount permission deny
Fix: Specify a rule for export-policy
Recommendation in manual:
"Always *create a rule* with a policy to control access to a volume."

(a)

Comp-A
Parameter: *security-style*
Incorrect setting by admins: *mix*
Outcome: NFS volumes are not mounted
Fix: change *security-style* to *unix*
Recommendation in manual:
"Choose either NTFS- or UNIX-style security unless there is a specific reason to use mix."

(b)

Comp-A
Parameter: *rsize*
Incorrect setting by admins: *32k*
Outcome: Performance slowdown
Fix: change *rsize* to *64k*
Recommendation in manual:
"Comp-A highly recommends using *64k* rsize/wsize for better performance with NFS v4."

(c)

Httpd
Parameter: *EnableSendfile*
Incorrect setting by admins: *on*
Outcome: web pages become unavailable
Fix: change the value to *off*
Recommendation in manual:
"Within some filesystems, it is better to *disable* this feature to avoid operational problems."

(d)

HBase
Parameter: *hbase.regionserver.thrift.framed*
Incorrect setting by admins: *false*
Outcome: vulnerable to DoS attack
Fix: change the value to *true*
Recommendation in manual:
"Setting this to false will select the default transport, vulnerable to DoS..."

(e)

Cassandra
Parameter: *enable_transient_replication*
Incorrect setting by admins: *true*
Outcome: potential service failure
Fix: change the value to *false*
Recommendation in manual:
"Transient replication is experimental and is not recommended for production use."

(f)

Figure 1: Six real-world configuration errors that were made by system admins without following recommendations from manuals. (a)(b)(c) are from COMP-A's customer ticket database, (d)(e)(f) are new misconfigurations our work discovered from public Docker images and have been confirmed by multiple image maintainers [3–10].

default settings, three of which have already been confirmed by MySQL and Cassandra developers as real bugs. Incorrect default settings can easily cause configuration errors since system admins are most likely to go with the default [60].

2 Characteristic Study

Before we build a tool to extract good practice recommendations from manuals, we first collected and studied 261 real-world recommendations from manuals of six widely-deployed systems listed in Table 2. Our study answers two questions: (1) *Is it useful to extract those recommendations from manuals?* If they are all general advice such as "recommend to set it to a large value", extracting them is not very helpful since they cannot be used as specifications for automatically checking system admins' settings. In contrast, if the recommendations are clear specifications such as "recommend to set this to greater than 2000", extracting them out from manuals can help build checkers to detect violations to them. Additionally, have developers already put in their code to check if system admins follow these recommended practices? If so, there is no need to extract them from manuals. Finally, how often are these recommendations the default settings for the corresponding configuration parameters? If they are not default, why? *(2) How difficult is it to extract good practice recommendations from manuals?* In particular, are manuals structured enough for information extraction?

Observation 1: *157 (60%) of the studied good practice recommendations are specific instead of just general advice.* We manually studied all recommendations and categorized them based on their contents. If a recommendation is about something that is hard to be checked automatically, it is classified as a "general advice" (e.g. Table 3 last row). Otherwise, it is classified as a "clear specification", which is further categorized into value, usage, correlation, and property by what is recommended, as explained in the caption of Table 2. An example is given for each category in Table 3.

Table 2 shows the number of recommendations of each category. In total, 157 (60%) of the 261 recommendations describe clear specifications that if extracted can be used for automatically checking system admins' configuration settings. The remaining 104 recommendations are general advice that is hard to check automatically.

Observation 2: *152 (97%) of the specific good practices recommended in manuals are not checked in source code.* For each recommendation, we manually examine the source code of each software to see if the recommended practices are checked in source code to warn/inform system admins upon violations. Table 4 shows that only five out of the 157 specific recommendations in manuals are checked in source code.

Listing 1 shows an example where a recommended practice is checked in HBase code. In this case, if the practice is violated by system admins, they will be warned to reexamine the setting of this parameter more carefully.

The goal of our work is exactly to generate more checkings like the HBase case shown in Listing 1, i.e. automatically extract good practice specifications from manuals and build a checker to warn system admins when their settings do not follow the recommended practices.

Violations to good practices may not always be configuration errors. However, as previous work [60, 62] has shown,

Software	#Rec	Specific					General
		value	usage	correl	property	**total**	
MySQL	78	27	6	2	5	40	38
Httpd	92	25	16	8	3	52	40
PostgreSQL	49	21	1	3	3	28	21
HDFS	18	13	0	3	0	16	2
HBase	12	10	1	0	0	11	1
Spark	12	9	0	0	1	10	2
Total	261	105	24	16	12	157	104

Table 2: Characteristics of the 261 studied good practice recommendations from six widely used software. "Specific": describe a clear specification; "value": recommend to (not) set to one or multiple values (e.g. Table 3 row 2); "usage": recommend to (not) use an option, typically for command-line options without a value (e.g. Table 3 row 3). "correlation": recommend to set to a value smaller, larger or equal to another parameter (e.g. Table 3 row 4). "property": recommend to set to a value with some property, such as in the absolute path format(e.g. Table 3 row 5).

Category	Example Practice Description in Manuals
Value	It is generally not desirable to set this to a value *greater than 2000*.
Usage	This option may be useful for diagnostic purposes, to see the exact text of statements as received by the server, but for security reasons is *not recommended for production use*.
Correlation	Setting this *lower than the dfs.namenode.replication.min* is not recommend and/or dangerous for production setups.
Property	It is best to specify the datadir value as *an absolute path*.
General	We recommend that this setting be kept to *a high value* for maximum server performance.

Table 3: Real examples of recommendations of different types.

Software	# (%) of prac checked in code
MySQL	1 (2.5%)
Httpd	1 (1.9%)
PostgreSQL	1 (3.6%)
HDFS	1 (6.3%)
HBase	1 (9.1%)
Spark	0 (0.0%)

Table 4: Number of good practices checked in source code.

```
if(balancedPreferencePercent
< 0.5) {
  LOG.warn("The value of " +
  DFS_DATANODE_BALANCED_SPACE
  _PREFERENCE_FRACTION_KEY +
  " is less than 0.5 so
  volumes with less available
  disk space will receive
  more block allocations");

}
```

Listing 1: Example of a good practice check in HBase's source code.

Software	Same -val	Multi -val	Rela -val	Cond -rec	No default	Others
MySQL	14	10	1	10	4	1
Httpd	16	6	3	9	16	2
PostgreSQL	10	8	2	6	0	2
HDFS	9	1	3	3	0	0
HBase	6	3	0	1	0	1
Spark	6	2	0	1	1	0
Total	61 (39%)	30 (19%)	9 (6%)	30 (19%)	21(13%)	6 (4%)

Table 5: The number of recommendations that are the same as the default and different categories of recommendations that are not the same as the default (multiple-value, relative-value, condition-recommendation, no-default, and others).

many system admins simply rely on guesswork or unreliable sources (e.g. online forums) to configure complex server software. If our checker can give a warning like Listing 1 when the settings do not follow practices, system admins can at least have a chance to *reexamine* the settings more carefully.

Observation 3: *96 (61%) of the specific good practice recommendations are not equivalent to default settings.* It is conceivable that some recommended practices might be the default settings (after all, the vendor recommends them). If this is the case, there is no need to extract recommended practices from manuals. System admins simply just go with default if they do not know how to set it better.

However, as shown in Table 5, only 61 (39%) good practices are equivalent to the default settings. For the majority (61%) cases, recommendations are not the same as default due to several reasons, including (a) 30 recommend multiple different values, e.g. a range or a set of values. In real settings, they may need to be modified to accommodate different situations, so it is worthwhile for sysadmins to double-check if the settings follow recommendations.; (b) 30 recommend some settings based on some conditions, e.g. "Enable A along with B"; (c) 21 recommendations are on command line options that have no default values; (d) 9 recommend relative values, such as "25% system RAM size"; (e) 6 cases have no clear reason why the default is different. They may be potential bugs and we have one of them confirmed as a bug by developers.

Observation 4: *The six studied manuals are organized in a similar structure.* As shown in Table 6, the six manuals are either in HTML or XML format and parameters in them are described in a similar structure:

- Each parameter is described in one separate section.
- Parameter names are often used as the section headings.
- There is some meta-info of the parameter described in the format of `<key>:<value>`, such as "Type:string".
- Most information related to each parameter is described in one or several paragraphs of free texts.

The per-parameter section structure makes it possible to relate each parameter name and its description by parsing the section structure. In addition, data types and default values can be used to identify parameter values in plain text descriptions which is necessary for generating specifications.

3 Design and Implementation

We design and implement PracExtractor to automatically extract recommendations from manuals, convert them into specifications and then uses them to detect violations. PracExtrac-

Software	Manual format	Parameter section?	Data type?	Default value?
MySQL	html	Yes	Table	Table
Httpd	xml	Yes	No	Table
PostgreSQL	html	Yes	KV	Text
HDFS	xml	Yes	No	Table
HBase	html	Yes	No	KV
Spark	html	Yes	No	Table

Table 6: Format and structure of manuals regarding how they describe configuration parameters. "Parameter section"— a separate section describes each individual parameter, "Data type"/"Default value" — the format they are described in, including table and KV (`<key>:<value>`).

tor faces two main challenges: (1) As manuals are written in plain texts and have a large amount of texts unrelated to recommendations, how to effectively filter noises and extract only recommendations? (2) Even after we extract recommendations, how to convert them into formal specifications that can be used to automatically check for violations?

To address the first challenge, PracExtractor breaks manual texts into sentences and extracts recommendation sentences with two filtering steps: keyword-based filtering (coarse grained) and syntactic-pattern-based filtering (fine grained). PracExtractor mines the keywords and syntactic patterns from the studied 261 recommendations.

To address the second challenge, PracExtractor first identifies semantic entities (e.g. parameter name and values) in a recommendation sentence and then convert it into a formal specification by matching them with semantic patterns.

3.1 Preprocessing and Parsing

PracExtractor first preprocesses and parses software manuals into parameter name, meta-info and free-text descriptions. The meta-info, including type and default value, is necessary for recognizing setting entities later (cf. §3.3). One special parameter type is enum, for which manuals usually also indicate all valid values along with a parameter. PracExtractor extracts the valid values for each parameter and uses them to identify enum values from a sentence in §3.3.

PracExtractor parses manuals based on the observed manual structure. Table 6 shows that manuals are usually written in HTML/XML formats with separate sections for different parameters. PracExtractor parses HTML and XML files, identifies each separate parameter section, and extracts parameter name, meta-info and free-text description from each. PracExtractor then breaks free-text descriptions into sentences.

Different manuals may still have slightly different formats for parameter sections. To handle that, PracExtractor takes an input of a small code snippet (format spec). A format spec is easy to write: according to our evaluation of twelve large manuals, they are typically fewer than 30 lines of Python code, and each of them can be written in 0.5-2 hours. (cf. Table 14).

Word	Covered sentences
recommend	74
well	26
good	26
appropriate	21
want	17

Bigram	Covered sentences
be recommended	34
should only	20
may want	13
good idea	7
with caution	7

Table 7: 10 sample keywords (words and bigrams) collected by PracExtractor from 261 studied recommendations and how many recommendations each covers.

3.2 Recommendation Sentences Extraction

Most sentences in manuals do not contain recommendations. For the twelve evaluated software manuals, 696–25510 sentences are extracted from parameter sections, but only 0.4%–2.7% of them contain recommendations. To extract these small percentage of recommendations, PracExtractor performs two steps filtering:

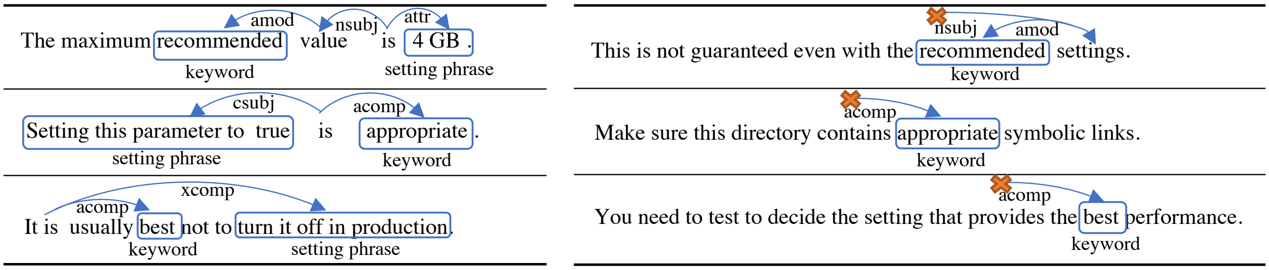
Keyword-based Filtering Following the intuition that recommendations are usually described with certain keywords (e.g. "recommend", "suggest"), PracExtractor extracts candidate recommendations with keyword filtering. To find out which words/phrases should be used as the keywords, PracExtractor first breaks the studied 261 recommendation sentences into individual words and bigrams (two consecutive words) and uses them as the candidate keywords T. PracExtractor then uses inverse document frequency (IDF) to rank the candidate keywords. IDF reflects how frequently a term t (word/bigram in our case) occurs in a set of sentences set S, as:

$$IDF(t,S) = \log\frac{|S|}{|\{s \in S : t \in s\}|}.$$

PracExtractor calculates $IDF(t,R)$ for the studied recommendations R and $IDF(t,S)$ for all the manual sentences S. PracExtractor ranks T based on $IDF(t,R)$ and $IDF(t,S)$ and get the smallest 100 and 300 terms separately as T_R and T_S. PracExtractor uses $T_R - T_S$ as the final keywords. The intuition behinds this is to find the words that are important in recommendations but not normal sentences. In Table 7, the sample keywords show that PracExtractor has effectively found keywords related to recommendations.

Syntactic-Pattern-based Filtering Using keyword filtering alone is not enough. After keyword-based filtering, only 7.3% of the remaining sentences are recommendations. Many sentences with the recommendation-related keywords are not true recommendations. Figure 2 (a) and (b) gives examples that the same keywords can be contained both in recommendation and non-recommendation sentences.

The key difference between these recommendations and non-recommendations in Figure 2 is their syntactic patterns.



The maximum recommended value is 4 GB .

Setting this parameter to true is appropriate.

It is usually best not to turn it off in production.

This is not guaranteed even with the recommended settings.

Make sure this directory contains appropriate symbolic links.

You need to test to decide the setting that provides the best performance.

(a) Recommendation sentences

(b) Non-recommendation sentences

Figure 2: Comparison of syntactic patterns of recommendation and non-recommendation sentences that contain likely-recommendation keywords. The patterns are labeled as undirected dependency paths from a keyword to a setting phrase, where a dependency path consists of a sequence of syntactic relations annotated with Universal Dependencies [23]: **amod** – link from a noun to an adjective modifier; **nsubj** – relation between a verb/noun and a prepositional phrase; **attr** – relation between a verb/adjective and a complement, etc.

Besides a keyword, the recommendations also contain a *setting phrase*, a noun/verb phrase describing what setting is recommended. Between such setting phrases and keywords, there are certain syntactic relations (patterns), which do not exist in non-recommendation sentences. PracExtractor leverage the syntactic-patterns to do fine-grained filtering.

PracExtractor first adopts the universal dependency (UD) tree [23] to represent a sentence's syntactic structure. A UD tree $T = (V, E)$ consists of vertices V and edges E, where $v \in V$ is labeled with a word's part of speech (POS) and $e \in E$ represents the syntactic dependency between two words (cf. Figure 2). Let $T' = (V, E')$ be an undirected correspondence of T, the syntactic pattern between a keyword and a setting phrase can be represented with an undirected path $p = (v_0, e'_{v_0,v_1}, v_1, \ldots, v_n)$, where v_0 is the keyword, v_n is the setting phrase, and $e'_{v_{i-1},v_i} \in E'$ for $i \in [1, n]$.

With the UD representation, PracExtractor mines the unique patterns for recommendations from the studied 261 recommendations S_{rec} and a set of non-recommendation samples $S_{\text{not\_rec}}$ that contains the keywords. For each sentence s, PracExtractor builds $T'_s = (V_s, E'_s)$ and extracts all paths

$$\begin{aligned}\rho_s = \{(v_0,\ e'_{v_0,v_1},\ v_1,\ \ldots,\ v_n) : \\ v_0 \in \textsc{Keywords} \wedge \forall i \in [1,n]\ e'_{v_{i-1},v_i} \in E'_s \\ \wedge \forall i \in [0,n]\ v_i \in V_s \wedge v_n \in \textsc{SettingPhrases}\},\end{aligned}$$

that starts from each keyword and ending at each setting phrase. The keywords are from the last step and the setting phrases are labeled by human inspectors. PracExtractor extracts all such paths from all recommendations and non-recommendation samples, denoted as P_{rec} and $P_{\text{not\_rec}}$. PracExtractor then extracts patterns P_{pattern} with Algorithm 1.

With the identified syntactic patterns P_{pattern}, PracExtractor classifies a new sentence s' into a recommendation or non-recommendation. PracExtractor traverse P_{pattern} and check if any pattern matched with s'. If at least one pattern matched then s' is classified as a recommendation otherwise non-recommendation. Such a matched pattern also labels the setting phrase in s' at the pattern's end (cf. Figure 2). The setting phrase will be used in specification generation (cf.§3.3).

Algorithm 1: Syntactic-pattern extraction algorithm

```
Input: $P_{\text{rec}} = \bigcup_{s \in S_{\text{rec}}} \rho_s$, $P_{\text{not\_rec}} = \bigcup_{s \in S_{\text{not\_rec}}} \rho_s$
Output: a pattern set $P_{\text{pattern}}$
$P'_{\text{rec}} \leftarrow []$, $P_{\text{pattern}} \leftarrow \emptyset$;
for $\rho_i \in P_{\text{rec}}$ do
    // Collect all the prefixes of $\rho_i$
    for $\rho_{i,j} \in \texttt{prefix}(\rho_i)$ do
        $P'_{\text{rec}}.\texttt{append}(\rho_{i,j})$;
// Traverse elements in $P'_{\text{rec}}$ in the order of frequency
// to extract the most general patterns
for $\rho_i \in \texttt{mostFrequentElement}(P'_{\text{rec}})$ do
    if $\texttt{prefix}(\rho_i) \cap P_{\text{pattern}} \neq \emptyset$ then
        continue;
    if $\rho_i \notin P_{\text{not\_rec}}$ then
        $P_{\text{pattern}} = P_{\text{pattern}} \cup \{\rho_i\}$;
return $P_{\text{pattern}}$
```

3.3 Specification Generation

In §3.2, PracExtractor identifies recommendation sentences and the setting phrases within it. PracExtractor then converts the setting phrases into checkable, formal specifications. Table 8 gives three example recommendations and the corresponding specifications. In general, PracExtractor can generate four types of specifications, including value, correlation, usage and property, as shown in Table 9.

A naïve way to generate specifications is to match setting phrases with predefined regular expressions and convert them accordingly. This can transform simple phrases with numbers (e.g. "less than 8"), but cannot convert more complex phrases (e.g. phrases with `enum` or parameter names). For instance, a phrase could be "set to chain", where "chain" is an `enum` value in Httpd. Such software-specific words can hardly be predefined in regular expressions and so cannot be matched.

Sentence	Specification
It is recommended to enable this option.	p == true
A value between 8 to 16 is suggested.	p ∈ [8, 16]
We suggest to set it less than ThreadsPerChild.	p < ThreadsPerChild

Table 8: Examples of specifications generated by PracExtractor. Setting phrases are marked with rectangles.

Category	Specification	Description Patterns Example
value/ correlation	p == v p < v | p > v p ∈ [v, v′] p ∈ {v, v′}	v$_{\text{<value>}}$ less$_{\text{syn}}$ | more$_{\text{syn}}$ than v$_{\text{<value>}}$ between$_{\text{syn}}$ v$_{\text{<value>}}$ to v′$_{\text{<value>}}$ v$_{\text{<value>}}$ or v′$_{\text{<value>}}$
correlation	with (p, p′) prefer (p, p′)	along$_{\text{syn}}$ with p′$_{\text{<para>}}$ prefer$_{\text{syn}}$ p′$_{\text{<para>}}$
usage	use (p)	used$_{\text{syn}}$ | useful$_{\text{syn}}$
property	format (p, f)	f$_{\text{<format>}}$

Table 9: Category of specifications PracExtractor generates and example of patterns for each specification. "<value>" is defined as "<bool>\|<num><unit>?\|<enum>\|<parameter>" from Table 10. "less$_{\text{syn}}$" means the synonyms of "less".

PracExtractor addresses this issue in three steps. First, given a recommendation sentence, PracExtractor identifies which parameter the sentence is associated with. Then, PracExtractor uses the parameter's meta-info (e.g. type and default value) extracted before (cf. §3.1) to identify setting entities, such as values and formats. Third, PracExtractor matches the identified setting entities with predefined semantic patterns to generate specifications.

Identify Parameter Names PracExtractor first identifies which parameter a sentence is associated with. For a recommendation sentence s in a paragraph p related to parameter X, there are four possible cases: 1) Only X is mentioned in s. PracExtractor determines this sentence is for X; 2) Another parameter Y is mentioned in s. PracExtractor checks if Y is a subject or object to a verb like "set" or "specify" and determines the sentence is for Y if it is the case; 3) No parameter is mentioned in s. PracExtractor further searches previous sentences in paragraph p; 4) No parameter is mentioned in p, PracExtractor determines the sentence is for X.

Identify Settings Entities Give the identified setting phrase and associated parameter of a sentence, PracExtractor then recognizes setting entities (e.g. values and formats) from the setting phrase based on the associated parameter's type. Table 10 shows the seven types of setting entities that PracExtractor can identify. For different types of setting entities, PracExtractor identifies them with different syntax:

Type	Setting Syntax
<bool>	"enable" | "on" | "true" | "disable" | "false" | "off"
<num>	[-+]?\d+(\.\d+)?
<unit>	"byte" | "MB" | "ms" | "%" | "% of RAM" | …
<enum>	∀w ∈ VALID_VALUES
<parameter>	∀w ∈ ALL_PARAMETERS
<format>	"email address" | "absolute path" | "domain name" | …
<string>	∀w ∉ (<bool> ∪ <num> ∪ <unit> ∪ <enum> ∪ <parameter> ∪ <format>)

Table 10: Types of setting entities PracExtractor identifies from recommendation sentences. `VALID_VALUES` and `ALL_PARAMETERS` are from the type-info and parameter list that PracExtractor identifies in the parsing step (cf. §3.1).

- For basic types, including `<bool>` and `<num>`, PracExtractor identifies them with regular expressions. For `<num>`, PracExtractor also identifies common `<unit>` (e.g. "GB", "byte") along with it.
- For `<enum>`, PracExtractor takes advantage of parameters' type-info to identify it. The type-info of an `<enum>` parameter does not only indicate it is `<enum>` but also indicates the valid values that can be set to the parameter. PracExtractor has parsed these in the parsing step (cf. 3.1) and now searches a setting phrase for the valid values.
- `<parameter>` is for the case that the setting phrase describes current parameter with respect to another parameter, such as "set A to be larger than B". PracExtractor identifies this by searching for valid parameter names in the setting phrase. Note PracExtractor has extracted all parameter names in the parsing step (cf. 3.1).
- For `<format>`, PracExtractor identifies common formats (e.g. "email address", "absolute path") of parameters based on word matching. PracExtractor allows users to provide new words to extend the identifiable formats.
- All other words/phrases are identified as `<string>`. PracExtractor further handles two kinds of strings that have special meaning. First, some of them use "this value" or "this" to refer to a value mentioned in previous sentences. PracExtractor recognizes such references and identifies the actual value from previous sentences. Second, some may use "default" to refer to parameters' default value. In this case, PracExtractor uses the corresponding default value extracted from the parsing step (cf. §3.1) as the recommended setting.

Generate Specification PracExtractor generates checkable formal specifications by matching the setting phrases with predefined semantic patterns. Table 9 lists the types of specifications that can be generated by PracExtractor, each with an example pattern. Before blindly matching a setting phrase with patterns, PracExtractor first considers the associated parameter's data type. For example, if the data type is `<bool>` or `<enum>`, there is no need to match semantic patterns like "less than `<value>`", "between `<value>` and `<value>`", or anything that is for `<num>`. Second, synonyms are also considered for these patterns. For instance "less$_{syn}$ than" can also match with "lower than" and "smaller than", etc.

Detect Negation PracExtractor also detects negation in a recommendation sentence and negates a specification when necessary. Two different types of negations are handled by PracExtractor. First, PracExtractor finds direct negation words, such as "not" (or abbreviation "n't") "none" and "never", in sentences. In addition, PracExtractor also detects indirect negation words and phrases, such as "avoid", "with caution", "rarely", and "seldom", etc. to identify the negation.

3.4 Violation Detection from Configurations

PracExtractor parses a configuration file and turns the settings into key-value pairs of (`parameter name`, `value`). Although the formats of configuration files for different software can vary depending on the software implementation, most of them have similar formats. The configuration files of the twelve popular systems in our evaluation, including MySQL, Httpd, HBase, HDFS, Spark, Squid and even the commercial system, all follow two common and simple formats: key-value pairs with separator like '=' or ':' or XML format.

Then PracExtractor checks the parsed parameter values against extracted specifications and generates warning messages if it detects violations. PracExtractor uses the *original sentences* from manuals as the warning messages. An example warning could be "Setting dfs.safemode.replication.min lower than dfs.replication.min is not recommended and is dangerous for production setups". This warning can remind sysadmins to double-check the configurations to avoid potential mistakes, just like the one shown in Figure 1 and 3.

Most of the violations detected by PracExtractor cannot be detected by previous works. Previous works [44, 61, 63] mainly use configuration checking/usage logic in source code to detect misconfigurations. However, most recommendations (97% as in Table 4) are not checked in source code, so violations to them cannot be detected by these works.

4 Experimental Evaluation

As shown in Table 11, we evaluate PracExtractor on twelve large software systems including eleven popular open-source server systems and one commercial systems (COMP-A) from a public company that serves many enterprise customers. These systems' manuals have 543 to 8283 pages. These manuals include not only the six manuals in our characteristic study, but also six new manuals that are not studied before. We evaluate both the precision and recall of PracExtractor by comparing its results with recommendations identified by human inspectors. In our evaluation, two human inspectors manually and independently examined each manual to identify recommendations.

For violation detection, we evaluate PracExtractor with real-world settings from top-ranked container images on DockerHub (200 images for each open-source systems). We run PracExtractor against configuration files in these docker images to detect violations to the specifications extracted from manuals. The evaluated images include both Linux-based and Windows-based one. However, as PracExtractor currently does not support platform-specific checking, our evaluation does not include checking platform-related specifications. In total, only 4 specifications are platform-related.

Recommendation and Specification Extracted As shown in Table 11, PracExtractor extracts a total of 338 good practice recommendations (including specific and general advice) from manuals and automatically converts 173 of them into formal specifications that can be used to check system admins' configuration settings. Among all software, Httpd has the most number (81) of recommendations extracted as well as the most number (31) of specifications generated.

Results with the six "new" manuals excluded from our study PracExtractor works reasonably well with the six "new" software manuals that are not included in our characteristic study. PracExtractor extracts 117 recommendations and 59 specifications from these manuals. For example, it extracts 35 recommendations and 22 specifications for the commercial software, COMP-A. The precision and recall are only slightly lower than the one for the six studied manuals, but are still reasonably good (with a 0.83 precision and 0.80 recall for recommendations, and 0.88 precision and 0.66 recall for specifications).

Violations Detected PracExtractor detects in total 1423 practice violations from 853 unique images. We manually validated all the violations. We reported 325 (that are maintained on GitHub) of them to their maintainers and have got 47 confirmed as real configuration issues, including six in images with >1M downloads and 28 in images with >1K downloads.

Table 12 shows a breakdown of all detected violations. 426 are "wrong change", namely a parameter is explicitly changed to a non-recommended value by system admins. 997 violations are "wrong default", namely a parameter has a non-recommended default value but is not changed. This also matches with the finding from a previous real-world misconfiguration study [60] that many configurations are left as default. In this case, system admins are afraid of changing default settings, even though the default is not recommended or is simply a placeholder value, which needs system admins to explicitly change to fit their own system environments.

Software	Category	Update Time of Manuals	# Recommendations				# Specifications			
			total	extracted	precision	recall	total	generated	precision	recall
MySQL	database	Aug. 2019	78	61	0.90	0.78	40	30	0.88	0.75
Httpd	web server	Aug. 2019	92	81	0.83	0.88	52	31	0.79	0.60
PostgreSQL	database	Aug. 2019	49	38	0.95	0.78	28	20	0.87	0.71
HDFS	distributed storage	Aug. 2019	18	17	1.00	0.94	16	14	0.93	0.88

new			147	117	0.83	0.80	90	59	0.88	0.66
overall			408	338	0.86	0.83	247	173	0.87	0.70

Table 11: Numbers of recommendations extracted and specifications generated by PracExtractor and corresponding accuracy (precision=$\frac{\text{TruePositive}}{\text{TruePositive+FalsePositive}}$ and recall=$\frac{\text{TruePositive}}{\text{TruePositive+FalseNegative}}$). Recommendations consist of both general advice and specific ones that can be converted into specifications. "studied" refers to the software included in our characteristic study (first 6 rows) , while "new" refers to other software not included in our study (last 6 rows) .

Software	Wrong change	Wrong default	Software	Wrong change	Wrong default
MySQL	20	200	Nginx	0	0
Httpd	338	200	Flink	0	0
PostgreSQL	8	0	Squid	20	0
HDFS	21	0	Mapred	0	0
HBase	0	199	Cassandra	9	398
Spark	10	0			
Total	Wrong change	426	Wrong default	997	

Table 12: Detected good practice violations in container images from Dockerhub. We reported 325 violations to the image owners, and 47 of them have been confirmed as real configuration errors. Three wrong defaults are also confirmed by MySQL and Cassandra.

Figure 3 gives three examples of real-world violations that are detected by PracExtractor from popular container images on DockerHub. They have been confirmed by the image owners as real configuration errors or by the software developers as real bugs. Here are the root causes:

(a) HDFS manual recommends to leave the parameter as `true` to avoid registration of excluded hostnames. However, it is ignored and violated in 21 images, which can cause security issues. We reported them and so far two of them have been confirmed [11, 12].

(b) Cassandra manual does not recommend to enable the experimental feature as it may cause potential failure. However, the default setting enables it, which is a bug, and 199 images just keep the default. The bug has been confirmed and fixed by Cassandra in its new version [1].

(c) The default setting for this parameter in MySQL is much larger than the recommended value in the manual, and the default value (set by MySQL developers) is actually incorrect. We report it to MySQL official Bugzilla and it has been confirmed as a bug [16].

Indeed, not all the 1423 violations are configuration errors or bugs. However, as discussed before in the real-world example from HBase (cf. §2 Listing 1) that explicitly performs such checks in its source code, when such violations are warned to system admins, they at least get a chance to *reexamine and reconsider* the settings more carefully.

Maintainers' Feedback on Violations We reported 325 to the image maintainers and so far have got 47 violations confirmed that they need to be changed. We list three example confirmations in Table 13 (row 1, 2, 3). We took a further look into the impact of these confirmed violations: 11 cause security vulnerabilities, 31 cause unreliable services, 2 cause performance issues and 3 cause database inconsistency.

We also got 46 other feedbacks that the maintainers hesitated to fix the violations. They either think it is the upstream vendors' responsibility to handle the issues (Table 13 row 4, 5) or are aware of the limitations but make the settings for particular environments (Table 13 row 6).

Lines of Customized Code for Each Manual Table 14 shows the lines of Python code (LOC) of the format spec for each manual. It needs only 6-73 LOC for the software manuals with hundreds and thousands of pages. Also, the LOC is not proportional to the number of pages in manuals, and it is only one-time effort to each software. On average, it needs little effort (0.5-2 hours) to customize PracExtrac-

HDFS

Parameter: *dfs.namenode.datanode.registration.ip-hostname-check*
Default: *true*
Recommendation: *true*
Misconfiguration: *false*
Violated docker images:
Babbleshack/hadoop, jamesmcclain/hadoop

Recommendation in manual:
"It is recommended that *this setting be left on* to prevent accidental registration of datanodes listed in the excludes file…"

(a)

Cassandra

Parameter: *enable_materialized_views*
Default: *true*
Recommendation: *false*
Misconfiguration: keep wrong default
Violated docker images:
199 images

Recommendation in manual:
"Materialized views are considered experimental and are not recommended for production use."

(b)

MySQL

Parameter: *max_binlog_cache_size*
Default: *2^64*
Recommendation: *4GB*
Misconfiguration: keep wrong default
Violated docker images:
200 images

Recommendation in manual:
"The maximum *recommended value is 4GB* …MySQL currently cannot work with binary log positions greater than 4GB."

(c)

Figure 3: Example of new violations detected by PracExtractor in popular images from DockerHub. The violations have been confirmed by image maintainers [11, 12] and software vendors (Cassandra and MySQL). Cassandra has fixed (b) in its new version [1].

Image	Feedback on Violation Reports from Image Maintainers
eviles/ httpd	"Ok, I've fixed two images: eviles/httpd, eviles/httpd-tomcat.' [3]
newnius/ hbase	"Thanks for pointing out this. I have added that to the default configuration files and rebuilt the images." [5]
oscerd/ cassandra	"Yes we can do that. I can update the configuration for 3.10 and 3.11." [9]
vitessio/ mysql	"As a general strategy, I plan to use MySQL's default values unless there is a strong use-case to override." [13]
madflojo/ cassandra	"Since we are using the upstream cassandra/latest, I'd prefer that this issue go to them." [14]
publicisw/ httpd	"We are aware of these limitations...This is only used on new linux kernels, which should support this feature..." [15]

Table 13: Example of positive and less-positive (in gray background) feedback. Due to page limit, we list three for each.

tor for a new software manual, including even for the large commercial software manual with 8283 pages.

Accuracy — False Negatives and False Positives Table 11 shows PracExtractor's accuracy in terms of recall and precision. For recommendation extraction, PracExtractor has a reasonable high recall, 0.83. In other words, overall, PracExtractor misses only 17% of the recommendations. For specification extraction, PracExtractor's recall is slightly lower (0.70) (i.e. miss 30% of the specification). This is mainly because some descriptive texts and string values are hard to be automatically recognized and converted into specification (cf. Table 15). This can be further improved by analyzing the semantics of parameter names so that string values can be better matched with parameter meanings.

PracExtractor has low false positives, too. Its overall precision is 0.86 for recommendation and 0.87 for specification. That is, only 14% of the recommendations and 13% of the specifications extracted by PracExtractor are false positives. The false positives are introduced mainly due to texts are incorrectly identified as parameter values (cf. Table 15).

Software	Manual pages	LOC
MySQL	5494	73
Httpd	1009	10
PostgreSQL	3724	24
HDFS	1031	12
HBase	787	14
Spark	599	6

Software	Manual pages	LOC
COMP-A	8283	18
Nginx	543	24
Flink	6152	6
Squid	1391	10
Mapred	1318	12
Cassandra	913	11

Table 14: Lines of code (LOC) of format specs for the twelve evaluated manuals.

Impacts of False Positives The false positives will not cause serious impacts as they can be recognized easily. Table 16 shows three cases of false recommendations that PracExtractor extracted from the evaluated manuals. They *are* descriptions related to the parameters but just are not recommendations. For example, "there may be circumstances where it is desirable for a configuration section's authorization to be combined with that of its predecessor" is a false positive, which describes a parameter usage but gives no recommendation. Since PracExtractor includes such an *original* sentence from manuals in a warning message, sysadmins who read it can easily realize that it is not a recommendation and will not be misguided.

Evaluation with Existing Misconfiguration Dataset We also evaluate PracExtractor with existing configuration issues. As there is no existing dataset for good practice violations, we use a dataset [2] for general configuration issues used in previous works [60, 61]. This dataset contains configuration issues from various online forums and mailing lists. We use the issues categorized as "error" to evaluate PracExtractor. Out of the 63 evaluated configuration errors, PracExtractor can detect 7 (10%) of them. We validated that these detected errors cannot be detected by previous works [35, 61] as they violate no constraint in source code while previous works use code constraints to detect errors. For the undetected errors, we found that manuals do not provide recommendations for

Software	False Negatives		
	R1	R2	R3
Httpd	10	11	0
COMP-A	8	3	4
Mapred	1	2	3

Software	False Positives	
	R4	R5
Httpd	4	4
Nginx	4	0
Squid	2	0

Table 15: Root causes for PracExtractor's False Negative and False Positive. R1 — descriptive recommendations that are not identified, such as "it is recommended to not configure a ticket key file". It is hard to automatically infer that this refers to not using `SSLSessionTicketKeyFile`. R2 — unknown string values that are not identified. For example, in "it's recommended the username 'anonymous' is in allowed userIDs", it is hard to recognize the common word "anonymous" as a value. R3 — sentences that are not covered by our syntactic patterns. R4 — texts that are incorrectly identified as parameter values. R5 — non-recommendation sentences that are mismatched with syntactic patterns of recommendations.

the error-related parameters. With a grain of salt, this shows that current manuals have not provided enough recommendations for avoiding many real-world misconfigurations. Further enriching manuals with good practices may improve PracExtractor's detecting capability and also benefit system admins who refer to manuals to resolve configuration issues.

5 Discussion

Generality. PracExtractor is reasonably general for manuals from different software. As our evaluation on six new manuals shows, PracExtractor can identify most (80%) recommendations from these manuals with a precision of 83%.

Human Effort. PracExtractor can easily be extended with new format specs to accommodate future manuals. In our evaluation, the specs for the six new software manuals are all less than 30 lines (cf. Table 14) and were written by a first-year graduate student, each in 0.5-2 hours.

Accuracy of Manuals. Another concern is whether manuals themselves deliver accurate information for PracExtractor to extract. After all, manuals can be outdated and can have mistakes made by the writers. In our work, we considered these factors. First, we validated the last update time of our evaluated manuals. As shown in Table 11, all twelve manuals are updated recently this year. Second, we compared the specifications extracted from manuals against source code and reported all differences to developers to check. If either is wrong/obsolete, it may introduce problems. Interestingly, in three cases, developers from MySQL and Cassandra confirmed that the source code is wrong (cf. Figure 3).

6 Related Work

Misconfiguration detection and troubleshooting. Many works have been done on detecting [25, 28, 30, 61, 66, 68] and troubleshooting [17–19, 42, 43, 54, 56, 57, 65, 69] configuration errors. Almost all of these works detect configuration errors by either checking against (a) patterns mined from tons of configuration files, or (b) constraints inferred from source code. Our work is complementary to these approaches. We extract recommendations from vendor-provided manuals as specifications, use them to detect violations, and warn system admins to reexamine the violations. Each of the approaches has its own strengths and weaknesses. Below, we compare our approach with each previous one respectively.

Parameter	False Positive Recommendations
adaptive_hash _index	It may be desirable to dynamically enable or disable adaptive hash indexing to improve query performance.
AuthMerging	There may be circumstances where it is desirable for a configuration section's authorization to be combined with that of its predecessor.
LimitRequest Line	When name-based virtual hosting is used, the value for this directive is taken from the default (first-listed) virtual host best matching the current IP address and port combination.

Table 16: Example of false positive recommendations PracExtractor extracted. They can be easily recognized by system admins and will not misguide them to make wrong changes.

Xu [61,63], Rabkin [44], and Nadi [35] propose approaches to extract configuration constraints from source code using static analysis. While it can infer simple constraints such as parameter types, range and some simple dependencies, it is less effective in checking against more complex constraints, especially *configuration settings that are legitimate but may not be good or optimal*. In our work, we focus on good practices recommended by vendors. If a system admin configures a parameter with a valid setting but does not achieve the intended goal (e.g performance, reliability or security goal), previous works that focus on detecting *invalid* configurations will not report any problem. In comparison, our PracExtractor can still warn him/her about the setting if it does not follow the good practices PracExtractor extracts from manuals.

Encore [68], PeerPressure [54] and Santolucito et al's work [47, 48] propose to extract configuration constraints and good practices from existing settings. These approaches assume that a large number of *independent* configuration samples are available for learning and the correct configurations are the common ones. This assumption can be true for some systems where configuration settings can be collected from users/customers back to vendors. However, for many enterprise software such as database or storage systems that are mainly deployed in enterprises (e.g. financial companies and government), each system's configuration settings are confidential information and cannot be shared back with vendors. As such, these approaches are less applicable. In comparison, PracExtractor is applicable to such scenarios because it automatically extracts good practice recommendations that *are already written in vendor-provided manuals*, and the checkers generated by PracExtractor can be shipped to enterprise customers to check their configuration settings.

In addition to the above two approaches, another closely related work is ConfSeer [41], which takes a user's configuration of one or multiple parameters to search against the vendor's Knowledge Base (KB) articles and identifies those highly relevant ones so that users can read those KB articles to self-diagnose and self-correct misconfiguration (with no need to call customer support). While this work also uses NLP techniques, their goal is to narrow down the match so that users do not need to read hundreds of KB articles. For a given configuration parameter setting from a user, ConfSeer returns *a ranked list of KB articles for the user to explore, in a way similar to a search engine like Google that tries to return the most relevant web pages to a user's query*. In other words, ConfSeer is an improved Google search engine for configuration-related KB articles. In comparison, our goal is to extract configuration recommendations from manuals and convert them into *formal and checkable* specifications. Our checker can be shipped to the customer sites to *automatically* detect violations and warn system admins to reexamine their settings to proactively avoid problems instead of waiting for postmortem troubleshooting.

Inferring specification from text. Some past works also aim to infer specifications from program-related texts, including from program comments [49, 50], API documents [39, 67, 70, 71], and man pages [58]. Our work differs from previous works both on purposes and techniques. First, instead of helping developers find bugs in source code as in [49, 50, 70], our work aims to help system admins detect misconfigurations in their system settings. Secondly, comments and API documents have relatively uniform structures, which makes it easy to extract information like function names and variable types. In comparison, manuals are much less structured. The only structure is that each parameter has its own section/chapter. Inside a section, it is mostly free text. Thirdly, PracExtractor extracts much more complex constraints than previous work on man pages [58]. DASE [58] uses regular expression to extract valid options from man pages. In comparison, PracExtractor can extract option value, correlation and property from software manuals.

7 Conclusions and Future Work

This paper focused on the usefulness and feasibility of extracting good practice recommendations from software manuals to detect configuration problems. Specifically, we first conducted a characteristic study on 261 recommendations from six large open source software manuals. Based on the observations learned, we designed and implemented a tool, called PracExtractor, that can extract 338 recommendations and generate 173 specifications with reasonable accuracy from twelve large software manuals, including one for a large commercial software system. Additionally, with the generated specifications, PracExtractor have detected 1423 violations from 853 container images on DockerHub. We reported 325 of them and so far have got 47 confirmed as real configuration issues by the image maintainers from different organizations.

Interestingly, in addition to detecting system admins' configuration problems, PracExtractor can also help detect incorrect default settings for configuration parameters. When a default setting differs from a recommendation in the manual, it may indicate that the default setting is wrong. Incorrect default settings can easily cause configuration errors because system admins are most likely to go with default [60]. In our experiments, we did discover a few such software bugs, and three of them have already been confirmed respectively by MySQL and Cassandra.

PracExtractor is far from perfect. First, there is still much space to further improve its accuracy based on our analysis of false positives and false negatives (cf. Table 15). Further semantic analysis of parameter descriptions can improve the identification accuracy of parameter type, name and value. Second, PracExtractor currently cannot extract specifications with descriptive conditions, such as "set A with a large workload". This may possibly be handled by further incorporating domain knowledge of common descriptions and sub-clause analysis techniques.

Several other directions are also valuable to explore in the future. First, from our experience, we found that a uniform structure (e.g. per-parameter section) and consistent word usage (e.g. recommend) benefit extracting recommendations a lot. Therefore, it would be interesting to explore how manuals may be restructured so more information can be automatically extracted. Second, PracExtractor may be potentially used to detect documentation drift — manuals are not updated along with source code. By combining PracExtractor with source code analysis tools, it is possible to compare the configurations described in manuals and used in source code. Third, while PracExtractor focuses on analyzing user manuals, the approach may be applicable to extract good practices from other text-based documents such as knowledge-base (KB) articles, which are used by support engineers to troubleshoot customer issues.

Acknowledgments

We greatly appreciate the anonymous reviewers and our shepherd, Scott D. Stoller, for their insightful comments and feedback. We thank the Opera group, the Systems and Networking group at UCSD as well as Anita Jinda, Sam Lin and Jianmo Ni for useful discussions and paper proofreading. We thank Tianyin Xu for sharing a configuration issue dataset with us. This work is supported in part by NSF grants (CNS-1814388, CNS-1526966) and the Qualcomm Chair Endowment.

Abstract

Post-mortem diagnosis of kernel failures is crucial for operating system vendors because kernel failures impact the reliability and security of the whole system. However, debugging kernel failures in deployed systems remains a challenge because developers have to speculate the conditions leading to the failure based on limited information such as memory dumps. In this paper, we present Kernel REPT, the first practical reverse debugging solution for kernel failures that is highly efficient, imposes small memory footprint and requires no extra software layer. To meet this goal, Kernel REPT employs efficient hardware tracing to record the kernel's control flow on each processor, recognizes the control flow of each software thread based on the context switch history, and recovers its data flow by emulating machine instructions and hardware events such as interrupts and exceptions. We design, implement, and deploy Kernel REPT on Microsoft Windows. We show that developers can use Kernel REPT to do interactive reverse debugging and find the root cause of real-world kernel failures. Kernel REPT also enables automatic root-cause analysis for certain kernel failures that were hard to debug even manually. Furthermore, Kernel REPT can proactively identify kernel bugs by checking the reconstructed execution history against a set of predetermined invariants.

1 Introduction

Post-mortem diagnosis of software failures in deployed systems is becoming increasingly important for today's software development process. Many software vendors such as Microsoft and Apple have insider programs to test their latest software before it is released to the general public. Software developers rely more and more on debugging failures reported from early adopters to fix critical issues before every software release. In particular, the operating system is of the utmost importance because it is the foundation of the software stack and its bugs can have catastrophic impact on the reliability and security of the whole system.

Debugging kernel failures in deployed systems has been a challenge. The fundamental reason is that developers have to speculate on the conditions leading up to the failure based on the limited information available for post-mortem diagnosis such as crashing stacks or memory dumps. The complexity of the kernel makes developers' speculation ineffective in many cases. For example, the Windows kernel checks a set of invariants upon returning to the user mode, and terminates the system if any invariant is violated. Such a failure leaves developers an empty call stack, which makes it almost impossible to debug.

This motivates us to build a *practical* solution that enables developers to go back in time and examine the root cause of kernel failures in deployed systems. Reverse debugging is not a new idea [5, 10], and researchers and practitioners have developed record and replay solutions that can precisely log the execution of the whole system [16, 21, 22, 28]. However, existing whole-system record and replay solutions require the target operating system to run on top of emulation or virtualization, use an excessive amount of memory and storage space to support the record and replay, and introduce significant performance slowdown. On contrary, a practical reverse debugging solution for deployed systems must be able to provide a high-fidelity execution history for post-mortem diagnosis while meeting the requirements of low performance overhead, small memory footprint, no additional setup of software emulation or virtualization, minimal change to the operating system, and zero compromise on the backward compatibility with existing applications.

In this paper, we present Kernel REPT, the first practical solution for reverse debugging of kernel failures in deployed systems. It is an extension of REPT [19], a reverse debugging solution for user-mode applications. Kernel REPT leverages online hardware tracing to log the control flow of kernel executions and performs an offline binary analysis to recover the data flow. By configuring the hardware to trace the target kernel inside the kernel itself, Kernel REPT avoids the extra layer of software emulation or virtualization, has the minimal change to the target operating system, and is fully compatible with existing applications. Furthermore, hardware tracing is shown to be efficient [27].

Kernel REPT traces the kernel execution on each CPU core instead of on each software thread as done in REPT. This helps Kernel REPT achieve a small memory footprint because the number of CPU cores is much less than the number of software threads in a system. In this tracing configuration, one trace buffer may contain traces of multiple threads and the trace of one thread may span multiple trace buffers. To allow reverse debugging over the execution of a thread, Kernel REPT requires the context switch history to assemble the trace of the thread. However, Kernel REPT cannot infer the context switch history based on the control flow or the memory dump. Instead, Kernel REPT logs the context switch events during runtime and uses them to reconstruct the execution of a given thread during offline analysis. This way Kernel REPT can provide reverse debugging over the execution of a thread on top of the core-based tracing.

REPT performs forward and backward instruction emulation to recover the program's data flow, however, it is insufficient to just emulate the semantics of machine instructions in Kernel REPT. This is because a processor modifies the kernel state when a hardware event such as interrupts or exceptions occurs. To correctly recover the kernel state, Kernel REPT needs to emulate the semantics of these hardware events properly. However, these hardware events are not explicitly logged in the control flow trace, and different events may make different changes to the kernel state. Kernel REPT solves this problem by leveraging the kernel configuration of hardware event handlers. For instance, Kernel REPT can tell a page fault just happened when the page fault handler is executed as shown in the control flow trace.

We implement Kernel REPT and deploy it on a billion devices running Microsoft Windows. Our experiments show that Kernel REPT is efficient as it incurs less than 10% slowdown for microbenchmarks and 2% slowdown for applications like Nginx and Chrome. Windows kernel developers use Kernel REPT to debug real-world kernel failures and find the root cause of some kernel bugs that have existed for a decade and caused innumerable failures.

The usage of Kernel REPT is not limited to interactive reverse debugging. To this end, we develop an automatic root-cause analysis for a common class of kernel failures where the kernel fails when it detects that certain resources are not properly released before returning to the user mode. This class of failures is hard to debug even manually without Kernel REPT because the kernel stack is empty when a failure happens. Based on the execution history reconstructed by Kernel REPT, our analysis can *automatically* identify the buggy function for 136 out of 188 real-world kernel failures of this class. This automatic root-cause analysis is deployed as part of Microsoft's error reporting service [24].

The reconstructed kernel execution history can enable not only automatic root-cause analysis but also proactive bug detection. A common kernel bug pattern is that the *exception* handling code fails to properly release resources acquired during the execution wrapped in the *try* block. We build a hybrid analysis to proactively look for this bug pattern by dynamically analyzing the execution in a *try* block and statically analyzing the code in the *exception* handling block. By analyzing thousands of real-world kernel execution histories, our hybrid analysis finds 17 new bugs in the Windows kernel, and all of them are confirmed and fixed.

2 Overview

The goal of Kernel REPT is to reconstruct the execution history of kernel failures in deployed systems for effective post-mortem diagnosis without incurring noticeable runtime overhead. As an extension of REPT [19], it utilizes hardware tracing to log the kernel's control flow to a circular buffer at runtime, and recovers its data flow by running binary analysis on the recorded control flow and the memory dump of a failure. In the rest of this section, we first provide a background of REPT. Then we discuss the challenges faced by Kernel REPT.

2.1 REPT

REPT shows a promising way to do reverse debugging for user-mode failures in deployed systems. REPT logs a program's control flow into a *per-thread* circular buffer with low runtime overhead via hardware tracing (e.g., Intel Processor Trace [18]), and then recovers its data flow offline by combining the control flow with the memory dump taken at the failure point. To do so, REPT runs an iterative binary analysis that performs forward and backward instruction emulation on the recorded instruction sequence to infer the program state before every instruction based on the final state stored in the memory dump. REPT checks for conflicts during the execution history reconstruction and performs error corrections based on heuristics. REPT also supports multi-threaded programs by merging the instruction sequences of different threads into a partially ordered single instruction sequence based on the fine-grained timestamps logged by the hardware tracing, and limiting the use of concurrent shared memory writes in the binary analysis if their exact order cannot be determined. The reconstructed execution history is not perfect, but it is shown that REPT achieves high accuracy and enables effective reverse debugging of real-world application failures.

To illustrate how REPT works, we show an example borrowed from the REPT paper [19, Figure 2] in Figure 1. This example has 5 instructions in the control-flow trace ($I_1..I_5$). The program state S_i represents the state *after* the execution of instruction I_i. Therefore, the final program state S_5 stored in the memory dump has `rax`=3, `rbx`=0, and `[g]`=3. REPT performs backward and forward analysis iteratively

			Iteration 1	Iteration 2	Iteration 3
		S_0	↑ {rax=?, rbx=?, [g]=3} →		↑ {rax=?, rbx=?, [g]=2}
I_1	`lea rbx, [g]`	S_1	↑ {rax=?, rbx=?, [g]=3}	↓ {rax=?, rbx=g, [g]=3}	↑ {rax=?, rbx=g, [g]=2}
I_2	`mov rax, 1`	S_2	↑ {rax=?, rbx=?, [g]=3}	↓ {rax=1, rbx=g, [g]=3}	↑ {rax=1, rbx=g, **[g]=2**}
I_3	`add rax, [rbx]`	S_3	↑ {rax=3, rbx=?, **[g]=3**}	↓ {**rax=3**, rbx=g, [g]=3}	↑ {rax=3, rbx=g, **[g]=?**}
I_4	`mov [rbx], rax`	S_4	↑ {rax=3, rbx=?, [g]=3}	↓ {rax=3, rbx=g, [g]=3}	↑ {rax=3, rbx=g, [g]=3}
I_5	`xor rbx, rbx`	S_5	↑ {rax=3, rbx=0, [g]=3}	↓ {rax=3, rbx=0, [g]=3} →	

Figure 1: "This example shows how REPT's iterative analysis recovers register and memory values when there exist irreversible instructions with memory accesses. We use "?" to represent "unknown", and use "g" to represent the memory address of a global variable. Some values are in bold-face because they represent key updates in the analysis. We skip the fourth iteration which will recover [g]'s value to be 2 due to the space constraint." [19, Figure 2]

to recover data values. In the first iteration, REPT does not update the global variable `[g]` in S_3 because `rbx`'s value is unknown. In the second iteration, there is a conflict for `rax`'s value in S_3. Its original value is 3, but the forward analysis would infer value 4 for it (`rax + [g] =` 1 + 3 = 4). REPT keeps the original value of 3 because it is from the final program state stored in the memory dump. In the third iteration, REPT recovers `[g]`'s value to be 2 based on `rax`'s value before and after the `add` instruction I_3.

For the purpose of this paper, we abstract REPT as a mechanism that takes as the input a final machine state and its preceding instruction sequence, and outputs the recovered machine state before every instruction with high accuracy. Kernel REPT leverages this data recovery mechanism to enable reverse debugging of kernel failures.

2.2 Challenges

A straw-man solution to support reverse debugging of kernel failures is to modify REPT to trace the kernel execution of each software thread and run the same binary analysis on a kernel memory dump. However, this simple solution does not work for two reasons.

First, it incurs unacceptable memory overhead. The kernel is shared by all threads on a system and allocating a trace buffer for each of them can consume an unpredictable amount of memory, especially when a system can have thousands or even tens of thousands of threads.

Second, the kernel has to handle hardware events of which user-mode applications are unaware. For instance, interrupts and exceptions can change the kernel's stack layout without executing any explicit instruction. The details of these hardware events such as the exception vector are not logged by the hardware tracing. However, such information is important for the data flow recovery because different types of hardware events have different architectural effects that must be emulated.

3 Kernel REPT

In this section, we present the design of Kernel REPT. We first describe how Kernel REPT avoids excessive memory consumption via per-core tracing while still allowing reverse debugging over the execution of a thread. Then we present how Kernel REPT handles hardware events when performing the offline binary analysis to recover the data flow.

3.1 Per-Core Tracing

To minimize the memory footprint, Kernel REPT chooses to do *per-core tracing* instead of per-thread tracing for the kernel. That is, Kernel REPT allocates a circular trace buffer for each logical core and logs the kernel-mode execution on a core to its corresponding buffer. Kernel REPT does not log the control flow of user-mode executions because the actual machine code executed in the user mode is not directly related to the root cause of kernel failures. Per-core tracing ensures that Kernel REPT's memory usage is linear in the number of logical cores on a system, and the number of logical cores is fixed and small compared to the number of software threads. This allows Kernel REPT to configure a large trace buffer for each core when necessary without the risk of exhausting the memory.

Per-core tracing does come with its own problems. It is more intuitive for developers to follow the execution on a software thread as opposed to a hardware core. On a multiprocessor system, per-core tracing may mix traces of different threads into one trace buffer and spread the trace of a single thread into multiple trace buffers. This requires Kernel REPT to obtain the context switch history to identify the trace of a single thread.

Ideally, Kernel REPT should recover the context switch history from a per-core trace by leveraging the binary analysis. However, the binary analysis cannot effectively reverse the context switch routine because the scheduling history is neither preserved in the memory dump nor can be inferred from the recorded instruction sequence. We show the pseudo code of a typical context switch routine in Figure 2. The context switch routine saves the register context of the previous

```
; pseudo code for context switch
; rdi points to the old thread
; rsi points to the new thread
push rax                  ; save GPRs
push rbx
...
mov KernelStack[rdi], rsp ; switch stack
mov rsp, KernelStack[rsi]
...                       ; restore GPRs
pop rbx
pop rax
ret
```

Figure 2: Pseudo code for context switch. Basically, the context switch routine saves the register context to the previous thread's stack and the stack pointer to the previous thread's internal data structure, and then restores the context of the new thread by doing the opposite operations.

Type	Origin	Details
Interrupt	User/Kernel	Vector number
Exception	User/Kernel	Vector number
Syscall	User	N/A

Table 1: Information about hardware events needed for software emulation.

thread on its stack, swaps the stack pointer, and then restores the register context of the newly scheduled thread to resume its execution. In this process, the context switch routine does not save the information about the previous thread before resuming the execution of the new thread, and hence the binary analysis is unable to recover the scheduling history. This also makes the binary analysis ineffective when applied directly to the per-core trace because the register values before a context switch cannot be recovered. Therefore, Kernel REPT chooses to log the context switch history in software.

3.2 Handling Hardware Events

The operating system manages hardware resources and has to handle hardware events. Therefore, the architectural effects of these hardware events, which are transparent to user-mode execution, are part of the kernel-mode execution and must be emulated when running the binary analysis for kernel data recovery.

Different hardware events have different architectural effects, and Kernel REPT has to understand the semantics of each hardware event for emulation. We list the information about the hardware events required for software emulation in Table 1. Specifically, Kernel REPT has to not only tell the type of a hardware event, but also infer whether this event occurred in the user or kernel mode and what it was about.

To do so, Kernel REPT first infers the occurrence of a hardware event based on the hardware trace. Given that Kernel REPT only traces the kernel-mode execution, hardware tracing will be paused when the execution returns to the user mode, and resumed when the execution enters the kernel mode. Therefore, the signal of tracing being resumed already indicates the occurrence of a hardware event—a system call or an interrupt/exception happening in the user mode. The hardware trace logs the occurrence of an asynchronous event during the kernel execution. Kernel REPT uses such information to detect the occurrence of an interrupt or exception in the kernel mode.

Next, Kernel REPT needs to infer additional information about a hardware event such as its type and the vector number for an interrupt. The Windows kernel configures the handlers for these hardware events at the boot time and never reconfigures the settings throughout the rest of its lifetime. Kernel REPT assumes this invariant holds for the vast majority of kernel failures under non-adversarial scenarios, and determines the event type as well as the vector number for interrupts/exceptions by comparing the control flow to the kernel configuration stored in the memory dump.

Finally, Kernel REPT emulates the architectural effect of these events according to the hardware specification. Kernel REPT performs the emulation during the binary analysis as if it were emulating a special instruction. However, not all data values are available to Kernel REPT when emulating a hardware event. For example, when emulating an exception from the user mode, Kernel REPT does not know the user-mode instruction that triggers the exception, so it cannot fill up all fields of the trap frame. Similarly, Kernel REPT does not log the parameters of system calls, so it does not necessarily have the register context of a system call event if it cannot be recovered from the memory dump. In these cases, Kernel REPT simply marks the register and memory values as unknown to avoid propagating stale values during the binary analysis.

4 Automatic Analyses

In this section, we present two automatic analyses enabled by Kernel REPT. The first analysis is an automatic root-cause analysis that can identify the buggy function for a specific class of kernel failures. The second analysis is a hybrid analysis that can *proactively* detect bugs that may lead to this class of kernel failures.

4.1 Root-Cause Analysis

A common kernel bug is that calls to *do* operations (e.g., resource acquisition) are *not* matched by calls to *undo* operations (e.g., resource release). For example, if the kernel disables interrupts before entering a critical region but fails to re-enable interrupts after leaving the critical region, the system will crash eventually. Despite the simple nature of this failure type, it is difficult to debug kernel failures caused by these bugs simply based on a memory dump. The key challenge is that the buggy function that missed the *undo* operation may have returned a long time ago. Without an execution history, it is hard to infer which function could be the buggy one. Particularly, the Windows kernel checks if there is a missing *undo* operation (e.g., resource not released) before it returns to the user mode. A failed check leaves developers an empty call stack, which makes it almost impossible to debug. What makes the matter worse is that some operations allow recursion by maintaining a counter for all pending *do* operations (e.g., recursive lock). This requires the developers to match the *do* and *undo* operations in a potentially long history before they can identify the unmatched *do* operation, which further complicates the diagnosis process.

The root-cause analysis identifies the buggy function that misses the *undo* operation by searching along the execution history to find the *first* function where a specified value changes between the function entry and return. For example, to detect when the kernel fails to re-enable the interrupts upon exiting a critical section, the analysis checks for the interrupt enablement at each function entry and return, and reports the first one that has a mismatched value. However, there are exceptions to the above analysis because some functions are designed to just perform the *do* or *undo* operation. For example, if enabling/disabling interrupts is implemented in a library function, then the function is expected to modify the value between its entry and return. The library functions that are designed to perform only a *do* or *undo* operation are relatively stable across kernel versions, so we maintain a whitelist for such functions. The root-cause analysis ignores them when searching for the buggy function.

4.2 Proactive Bug Detection

A common bug pattern that causes *undo* operations being missed is related to the try/catch-like primitives designed to handle hardware exceptions gracefully. For example, the Windows kernel uses Structured Exception Handling (SEH) [9] to handle page faults when accessing a user-mode page. An *undo* operation may be missed when an exception occurs if the try scope contains a *do* operation and the catch scope does not have the corresponding *undo* operation. We show an example of this bug pattern in Figure 3. foo calls read_user_obj in a try block to handle page faults in case the user-mode page is not mapped with proper permissions (line 12). read_user_obj temporarily disables Supervisor-Mode Access Prevention (SMAP) in order to access user-mode pages (line 4). If a page fault occurs when read_user_obj dereferences user_ptr, the page fault handler will redirect the execution back to the catch block in foo (line 15), skipping the subsequent call to enable_smap (line 5). The correct implementation is to apply the scope of the try block to the dereference of user_ptr instead of the entire read_user_obj function.

```
1  obj_t read_user_obj(int *user_ptr) {
2      obj_t obj;
3      disable_smap();
4      obj.a = *user_ptr;
5      enable_smap();
6      return obj;
7  }
8
9  int foo() {
10     obj_t obj;
11     try {
12         obj = read_user_obj(user_ptr);
13     }
14     catch {
15         return -1;
16     }
17     return 0;
18 }
```

Figure 3: Example code that misuses try/catch leading to a missing *undo* operation.

Leveraging the execution history reconstructed by Kernel REPT, we design an automatic *hybrid* analysis to proactively detect bugs of this pattern. Our hybrid analysis has two steps. First, it uses a dynamic analysis to check if there is any *do* operation in a try scope based on the execution history. Second, it uses a static analysis to check if the matching catch scope does *not* have the corresponding *undo* operation. The analysis identifies try and catch scopes based on the unwind information in the binaries [14].

The assumption behind this analysis is that a hardware exception may happen at any time within the try scope, and missing the *undo* operation in the catch scope means that the kernel would fail to restore the state if an exception happens after the *do* operation. Even though this assumption may not be true for all cases, a violation implies an overuse of the try scope that should be addressed by developers.

The hybrid analysis is accurate and effective because it leverages execution traces from a huge number of deployed systems. First, a try scope may include a significant amount of execution involving multiple levels of function calls. Statically analyzing such a try scope is challenging, and our dynamic analysis avoids this challenge. Second, the executions of all kernel threads (i.e., not limited to the failure thread) in a failure report are used in the hybrid analysis. This allows the analysis to avoid the common constraint on completeness for dynamic analysis. Third, the code logic in the catch scope is usually straightforward, so simple static analysis is sufficient for checking if an expected *undo* operation exists.

5 Implementation

In this section, we describe the implementation and deployment of Kernel REPT on Microsoft Windows.

5.1 Kernel Tracing

Kernel REPT logs both the context switch history and the control flow of the Windows kernel. To log the context switch history, Kernel REPT leverages Event Tracing for Windows (ETW) [4]. ETW logs the timestamp, identifiers of both the old thread and the new thread for each context switch event. These ETW events will be included in the memory dump of a kernel failure.

To record the kernel's control flow, Kernel REPT enables Intel Processor Trace (PT) [18] on each processor core for the kernel-mode execution at system start. We adapt the driver from REPT to enable Intel PT for the Windows kernel. Our driver change has roughly 2K lines of C code. We mark the virtual memory of trace buffers as read-only to prevent the Windows kernel from accidentally corrupting them. This can be done because Intel PT outputs the trace directly to the physical memory and is not subject to the page permission we set on the virtual memory. Similar to the user-mode tracing in REPT, the kernel-mode trace is stored in the memory dump when a kernel failure is reported.

Kernel REPT currently disables multithreaded analysis for kernel failures due to a caveat of Intel PT. The timestamp logging of Intel PT cannot be configured for a specific privilege level. Without such a privilege-level filtering, the timestamps generated during the user-mode execution will overwrite the kernel's control-flow trace in the circular buffer. One possible solution is to dynamically enable and disable timestamps in software when the processor switches between the user and kernel mode. We leave its exploration to future work.

5.2 Trace Parsing

Intel PT encodes the control flow in a highly compact format. It requires the code binary to parse the trace to reconstruct the control flow. Meanwhile, an operating system can swap out kernel code pages to reclaim its underlying physical memory. This can fail the trace parsing because even capturing the entire physical memory upon a kernel failure can be insufficient due to the unavailability of swapped-out code pages. One possible solution to this problem is to lock all the kernel code pages into the physical memory, but this will increase the memory pressure to the overall system.

In Kernel REPT, we choose to reconstruct the code pages based on the image's metadata stored in the memory dump and its binary file. One disadvantage of this approach is that it does not work for third-party drivers where the binary files are unavailable. This is not a big issue in practice because the code that was executed close to the failure point is usually available in the physical memory (thanks to the memory manager's policy).

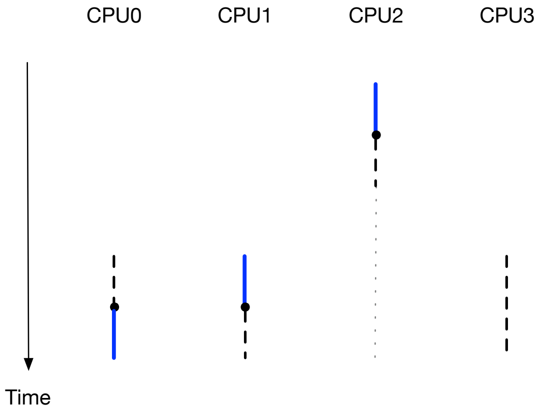

Figure 4: An example scenario where traces of a thread are not contiguous. Solid lines represent the execution trace of the interesting thread. Dashed lines represent the execution trace of other threads. Dots (•) connecting them represent context switches. Dotted lines mean the processor was in sleep mode and no execution trace was generated.

5.3 Binary Analysis

We implement Kernel REPT's binary analysis in 15K lines of C++ code on top of REPT. It includes the emulation of hardware events, the thread trace reconstruction based on the context switch history, and the two automated analyses. Most of the implementation is straightforward, but there are two technical details worth mentioning here.

First, a thread's trace may be *noncontiguous* with respect to the thread's execution. We show an example in Figure 4. In this example, core 2 was in sleep mode for a long period of time, and no execution trace was generated. The trace of the target thread in its circular buffer can be obsolete and disconnected from the rest of the thread's trace on other cores. This can happen when the trace of the target thread on core 1 was overwritten by another thread, and the overwritten trace was more recent than the trace in core 2's trace buffer. Kernel REPT checks for such cases based on the timestamps of context switch events, and discards those disconnected traces.

Second, certain kernel instructions can be missing from the control-flow trace when the system is running inside a virtual machine. In a virtualized environment, guest instructions that can modify the system state (e.g., `wrmsr`) are trapped and emulated by the hypervisor. Kernel REPT only traces the kernel-mode execution, so its binary analysis will be under the illusion that these instructions are skipped according to the Intel PT trace. This can result in an inconsistent state in the data flow recovery. Kernel REPT solves this issue by detecting VMEXIT and adding the skipped instruction back to the instruction sequence if it is deemed as emulated by the hypervisor. Specifically, for each asynchronous event logged in the trace, Kernel REPT checks if there is one and only one possible instruction between the current instruction and the next instruction in the instruction sequence. If so, Kernel REPT determines that the instruction is emulated by the hypervisor, and adds it back to the instruction sequence before running the binary analysis. This check is straightforward to implement because the hypervisor-emulated instruction is typically a non-branch instruction.

5.4 Deployment

We have deployed Kernel REPT in the ecosystem of Microsoft Windows. The deployment of Kernel REPT spans three parts: Windows, Windows Error Reporting (WER) [24], and Windows Debugger [12].

On Windows, we released the kernel driver that configures Intel PT tracing and the ETW context switch logger for the kernel, and a user-mode daemon that communicates with WER to decide when to start/stop the driver. These components were released as part of Windows 10 version 1803.

On the WER service, we added support for requesting Intel PT traces for a given kernel failure. When the WER service receives such a request, it selects devices that have reported the same kernel failures in the past and are capable of Intel PT to enable tracing for future failure reporting. The WER service also runs the automatic root-cause analysis on kernel failures of the specific error code [2].

On Windows Debugger, we implemented Kernel REPT's interactive reverse debugging by extending REPT's debugger extension. This extension allows an developer to set breakpoints, go back and forth on the reconstructed execution history, switch to different threads, and inspect the local and global variables.

6 Evaluation

In this section, we evaluate the performance and effectiveness of Kernel REPT. For performance, we run both microbenchmarks and real-world applications with Kernel REPT enabled to measure the runtime overhead. For effectiveness, we evaluate Kernel REPT's data recovery and report how it helps developers debug real-world kernel bugs.

6.1 Performance

We evaluate the performance impact of Intel PT tracing and context switch logging on kernel-mode execution by running UnixBench 5.1.3 [11], ApacheBench [1] on Nginx 1.17.5 [7], and JetStream 2 benchmarks [6] on Chrome 79 [3]. We choose UnixBench because it measures the micro-level performance impact on a kernel's key functions such as system calls and context switches. We choose Nginx and Chrome because they represent popular programs for server and client scenarios, respectively. We run the experiments on a Windows 10 (version 1903) machine equipped with an Intel i7-6700K processor (8 logical cores) and 16GB RAM. We allocate two separate circular buffers for each logical core: a 1MB buffer for Intel PT tracing and a 128KB buffer for context switch logging. We choose this default setting empirically for experiments, but our real-world deployment allows developers to adjust the configuration as needed.

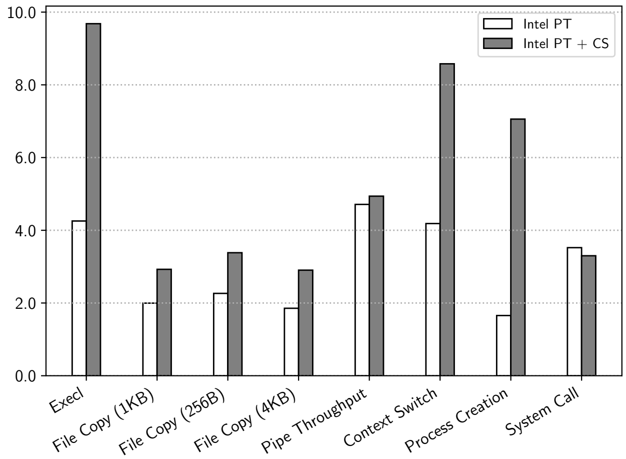

Figure 5: Performance overhead of running UnixBench with Intel PT tracing and context switch logging.

6.1.1 UnixBench

We run UnixBench on the Windows Subsystem for Linux 1 (WSL 1) [13]. WSL 1 implements Linux system calls from the Windows kernel to run unmodified Linux ELF binaries such as UnixBench. We show the performance results of UnixBench in Figure 5. For Intel PT tracing only, the average performance overhead is 3.06% with no single benchmark exceeding 5% overhead. With the context switch logging enabled in addition, the average performance overhead becomes 5.35% with the highest performance overhead of 9.68%. In particular, three benchmarks, Execl, Context Switch and Process Creation, have more frequent context switches than other benchmarks. Therefore, they have higher overhead when context switch logging is turned on.

6.1.2 Nginx

We evaluate the performance overhead of different tracing setups on Nginx using ApacheBench. We run Nginx on the test machine with 8 logical cores and 16GB RAM. We use the default configuration provided by Nginx but modify worker_processes to 8 to use all the logical cores. We

	# Instructions	Data Recovery
IRQL Fault (Kernel)	3,310,906	65.13%
Code Overwrite	1,151,315	73.18%
Stack Trash	315,046	65.75%
IRQL Fault (User)	9,176,219	61.56%
Stack Overflow	10,421,430	60.97%
Hardcoded Breakpoint	9,129,048	61.65%
Double Free	5,232,343	43.03%

Table 2: Kernel REPT's data recovery rate on kernel failures caused by notmyfault [8].

run ApacheBench on a separate client machine with 16 logical cores. We use the client to make 100,000 HTTP requests over 16 concurrent connections and then measure the throughput (requests/second). We run each session 10 times and report the average throughput. The reduction of the average throughout when the Intel PT tracing is enabled (with or without the context switch logging) is about 2%.

6.1.3 Chrome

We run JetStream 2 benchmarks on the Chrome browser to evaluate the performance impact on web browsing, one of the most common client-side scenarios. There is no visible performance slowdown when both the Intel PT tracing and the context switch logging are enabled. We believe this is because the benchmarks have most of their computation in the user mode.

6.2 Effectiveness

We evaluate the effectiveness of Kernel REPT from four perspectives: (1) how well it can recover data; (2) how its interactive reverse debugging can help developers debug kernel bugs; (3) how accurate the automatic root-cause analysis is; (4) how well the proactive bug detection works.

6.2.1 Data Recovery

We evaluate Kernel REPT's data recovery based on the same metric as REPT [19]. Specifically, we measure the data recovery rate as the percentage of *register uses* (i.e., a register used as the source operand or in the address of a memory operand) for which the register value is recovered by Kernel REPT. Register use is a good metric because it avoids double counting (e.g., we only count it once when rax and rbx are both known in an instruction mov rax,rbx) and memory values are often loaded into registers first before being used in an operation.

In our experiment, we trigger Windows kernel failures by using a public utility program called notmyfault [8], which injects a kernel driver to cause various types of failures such as stack overflow and double free. We pick notmyfault because its injected failures are reproducible. Our experiment does not include the Buffer Overflow fault in notmyfault because it cannot trigger a kernel failure on the latest Windows. For each failure, we count the number instructions and measure the data recovery rate for the crashing thread. Our experimental results are shown in Table 2.

```
bool get_desc(..., desc_t **p) {
    int size;
    bool success;
    *p = malloc(sizeof(desc_t));
    driver = find_driver();
    success = (driver->op)(*p, &size);
    return success;
}

void foo() {
    desc_t *p;
    bool success;
    if (...) {
        success = get_desc(..., &p));
    } else {
        success = get_desc(..., &p));
    }
    if (success) {
        bar(p->owner->sid); // CRASH!
    }
}
```

Figure 6: A real-world example that showcases how Kernel REPT helps developers find bugs.

Kernel REPT's data recovery rate is over 60% for all but one failure even when some execution contains over 10 million instructions. The Double Free case involves a series of memory allocation/free operations. As reported in REPT, memory allocation operations are hard to reverse because their metadata may be completely overwritten by subsequent free and reallocation operations. We believe this is the main reason for the Double Free case to have a lower data recovery rate than others.

Comparing with REPT's data recovery on user-mode programs [19, Figure 4], we can see that Kernel REPT achieves a similar data recovery rate for kernel failures. Note that some recovered data may be incorrect, but we cannot directly measure it due to the lack of a ground truth. However, we expect it to be in the same low percentage as REPT.

6.2.2 Interactive Reverse Debugging

We use a real-world case to demonstrate how Kernel REPT can help developers debug kernel bugs through interactive reverse debugging. This bug was introduced to the Windows kernel more than a decade ago. It was not fixed until Kernel REPT became available due to the lack of information in memory dumps. We show a simplified version of the code around the bug in Figure 6. In the code snippet, `foo` calls `get_desc` to receive a pointer to a descriptor object. Depending on certain conditions (line 13), the call can happen at two places with potentially different parameters (line 14 and 16). `get_desc` allocates the memory for the descriptor object (line 4) and finds the driver that provides the corresponding callback (line 5). Then, `get_desc` invokes the driver's callback function to initialize the object, which returns whether the initialization succeeds and the number of bytes being initialized (line 6). Finally, the crash happens when `foo` dereferences a pointer field (`owner`) inside the descriptor object (line 19).

To debug this kernel failure, a developer first has to determine where `get_desc` is called (line 14 or 16). Without Kernel REPT, a developer would need to use some auxiliary information to figure it out. However, with the recorded control flow, it is straightforward to find it. The next step is to determine the target function of the callback (line 6). This can be challenging without the recorded control flow because `get_desc` has already returned and the relevant information may no longer be available. In fact, the actual code involves multiple levels of indirect function calls, making the problem even harder. With Kernel REPT, the developer can easily reach the correct target function based on the recorded control flow. Finally, the developer has to understand how the descriptor is mis-initialized by the callback function. In this particular case, it turns out that the callback function does not attempt to initialize the descriptor object at all. It just returns success with the number of initialized bytes being zero. Unfortunately, `foo` does not check the number of bytes being initialized, leading to the subsequent crash caused by dereferencing an uninitialized pointer value. To fix this bug, the developer changes the callback function to return an error code indicating that the operation is not supported.

6.2.3 Root-Cause Analysis

We run the automatic root-cause analysis described in §4.1 on 377 real-world kernel failures of a specific error code [2] reported to Microsoft over two weeks. This error code is used by the kernel when it detects a specific resource is not properly released upon returning to the user mode. The analysis identifies potential buggy functions in 33 kernel components including the core OS kernel, the GUI subsystem, the file system, and some third-party drivers. To evaluate the accuracy of the root-cause analysis, we manually check each identified buggy function either based on the source code or the confirmation from developers. Since the source code of third-party drivers is unavailable and it is difficult to reach their developers, we exclude the 189 kernel failures whose buggy functions are in a third-party driver.

We show the accuracy of the root-cause analysis for the remaining 188 kernel failures in Table 3. The root-cause analysis correctly identifies the buggy function for 148 failures. 136 of these failures are caused by unsafe `try/catch` operations and 12 of them are caused by other miscellaneous issues (e.g., the code fails to properly clean up the state on an error handling path). The root-cause analysis fails to identify the true buggy function for 40 kernel failures. We manually analyze them via interactive reverse debugging and find that we can find the true buggy function for 23 failures. The rest 17 failures cannot be resolved due to the limited trace size or data recovery.

True Blame		False Blame	
Try/Catch	Misc.	Manual	Unresolved
136	12	23	17

Table 3: The accuracy of the automatic root-cause analysis on 188 real-world kernel failures for which Kernel REPT blames a function in the first-party components.

While analyzing the memory dumps of the 23 failures manually, we find that one common reason for the automatic root-cause analysis to miss the true buggy function is that the *do* and *undo* operation pair is tied to an object's lifetime instead of a function's lifetime. For example, one way to manage the acquisition and release of a lock is to implement the acquire operation in a constructor function and the release operation in the corresponding destructor function. In this case, a function can indirectly acquire the lock by creating such an object, and then passes it to another function that releases this lock by destructing the object. If the kernel fails to destruct the object due to programming errors, it not only causes memory leaks but also leads to the missing *undo* issue. The root cause of such programming errors can vary case by case, and blaming the function that creates the object and seemingly misses the destruction does not always lead to the correct outcome. However, even in these cases, the root-cause analysis can provide useful information to help developers find the root cause.

6.2.4 Proactive Bug Detection

We run the proactive bug detection described in §4.2 over 2000 execution histories reconstructed from memory dumps of real-world kernel failures. We do not limit the failure type, and use the execution histories of *all* threads in a memory dump. We use memory dumps of kernel failures instead of normal executions because they are currently the major source of recorded real-world kernel executions.

We have found a total of 17 previously unknown kernel bugs, and all are confirmed and fixed. For one of the bugs, we observed an actual kernel failure caused by it a few days after we reported it to the developer. This shows the potential of using Kernel REPT to uncover bugs even before they are triggered in practice.

7 Discussion

Kernel REPT extends REPT's support for reverse debugging of user-mode failures to kernel-mode failures. Therefore, it shares two limitations with REPT. First, the reconstructed execution history is incomplete because the circular trace buffer only captures a fixed amount of control-flow information before the kernel failure. Second, the reconstructed execution history is imperfect because many instructions are not reversible. Despite the two limitations, Kernel REPT's reverse debugging capability allows successful diagnosis of many real-world kernel failures that were impossible to debug before.

The automatic root-cause analysis described in §4.1 requires a whitelist of functions that perform only a *do* or *undo* operation by design. It requires manual effort to construct and update the whitelist. The root-cause analysis may have false blames due to the incompleteness of the whitelist. In practice, we rely on developers' feedback to keep the whitelist up to date.

One interesting observation we have is that REPT-style reverse debugging is more effective for kernel-mode failures than for user-mode failures. We believe the key reason is that the Windows kernel operates in a more *defensive* manner: it performs various checks of invariants in kernel state at different times of the execution, such as checking missing undo operations before returning to the user mode (see §4.1 for details). These checks shorten the execution between the program defect and the program failure. This is crucial for the effectiveness of REPT-style reverse debugging since its reconstructed execution history is incomplete and imperfect.

8 Related Work

In this section, we discuss the previous work related to Kernel REPT in three categories: record and replay, failure analysis and failure reproduction. We omit the discussion of REPT [19] as we have covered it comprehensively in §2.1.

8.1 Record and Replay

Record and replay tools have been applied to debugging for both user-mode applications [15, 25, 30, 33] and operating systems [16, 21–23, 28, 31, 32, 34, 35]. Software-based record and replay tools [16, 21–23, 28, 35] for operating systems require running the whole system in a virtualized environment to log all non-deterministic inputs to the target system. These tools are rarely deployed in production environments because of their significant runtime overhead and compatibility issue. The latter is caused by the requirement for a special setup such as installing a custom virtual machine.

Hardware-based record and replay tools [31, 32, 34] modify the underlying hardware to record the execution of a target system. For example, Flight Data Recorder (FDR) [34] instruments the processor's cache coherency protocol to enable record and replay of a multiprocessor system. The required hardware modification makes these systems expensive to build and adopt in practice.

Compared to the above record and replay tools, Kernel REPT enables effective reverse debugging for operating systems running on commodity hardware with low performance and space overhead at runtime, making it practical for deployment on real-world systems.

8.2 Failure Analysis

RETracer [20] is a triaging system for both user-mode and kernel-mode failures. It starts with a corrupted pointer, performs backward taint analysis on memory dumps, and assigns the blame to a function that contributes to the access violation. RETracer uses the crashing stack as an approximate execution trace when performing backward taint analysis, so it cannot effectively analyze kernel failures with an empty call stack.

Postmortem Symbolic Evaluation (PSE) [29] performs static backward slicing on memory dumps to identify where a bad pointer is originated. PSE is also limited by the information available in the dump, and can have false positives due to unresolved memory aliases.

SherLog [36] analyzes the log messages generated during a failed execution to infer control and data values before the failure point. While this approach may be useful to diagnose logical bugs in a program, log messages cannot be used to diagnose low-level software bugs such as memory safety errors. In addition, its effectiveness depends on the developer's expertise in determining the key information to log, which varies case by case.

Kernel REPT is complementary to the above production failure analysis techniques. For instance, we integrated REPT-style reverse debugging into RETracer so that the latter can run its backward taint analysis on the reconstructed execution history to derive a more precise blame for production failures.

8.3 Failure Reproduction

Execution Synthesis (ESD) [37] explores possible program paths to search for inputs that can lead to the same failure. ESD relies solely on memory dumps, and its symbolic execution [17] may not be able to solve complicated constraints when exploring a long execution history of complex program state. This makes it difficult to work for complex programs such as the operating system kernel.

BugRedux [26] reproduces a production failure by instrumenting the program to collect execution data at different levels and employing symbolic execution to compute an input leading to a similar execution. Program instrumentation incurs overhead even for normal executions, and symbolic execution is known to have path explosion problems.

Kernel REPT allows developers to examine the execution history of a kernel failure without the need to reproduce it.

9 Conclusion

We have presented the design and implementation of Kernel REPT, the first practical solution for reverse debugging of kernel failures in deployed systems. Kernel REPT records the kernel's control flow and context switch events on each processor, and recovers its data flow on each software thread via binary analysis. Its analysis emulates both machine instructions and hardware events such as interrupts and exceptions. In addition to the support for interactive reverse debugging, we have developed two automatic analyses on top of Kernel REPT: a root-cause analysis that can identify the buggy function for a class of kernel failures, and a hybrid analysis that can proactively detect bugs due to a misuse of the `try/catch` primitive. We show that Kernel REPT is efficient for real-world deployment and effective for debugging real-world kernel failures.

Acknowledgments

We thank our shepherd, David Devecsery, and other reviewers for their insightful feedback during this unprecedented time. We are also very grateful for all the help from our colleagues at Microsoft during the development and deployment of Kernel REPT. In particular, we thank Alan Auerbach, Joe Ballantyne, Harini Bandi, Abolade Gbadegesin, Stephen Hufnagel, Mehmet Iyigun, Pedro Justo, Scott Lee, Graham McIntyre, Timothy Misiak, Viorel Mititean, Jordi Mola and Pin Wu for their tremendous help in making this project a fully deployed end-to-end system.

Abstract

As specialized hardware accelerators such as GPUs become increasingly popular, developers are looking for ways to target these platforms with high-level APIs. One promising approach is *kernel libraries* such as PyTorch or cuML, which provide interfaces that mirror CPU-only counterparts such as NumPy or Scikit-Learn. Unfortunately, these libraries are hard to develop and to adopt incrementally: they only support a subset of their CPU equivalents, only work with datasets that fit in device memory, and require developers to reason about data placement and transfers manually. To address these shortcomings, we present a new approach called *offload annotations (OAs)* that enables heterogeneous GPU computing in existing workloads with few or no code modifications. An annotator annotates the types and functions in a CPU library with equivalent kernel library functions and provides an *offloading API* to specify how the inputs and outputs of the function can be partitioned into chunks that fit in device memory and transferred between devices. A runtime then maps existing CPU functions to equivalent GPU kernels and schedules execution, data transfers and paging. In data science workloads using CPU libraries such as NumPy and Pandas, OAs enable speedups of up to 1200× and a median speedup of 6.3× by transparently offloading functions to a GPU using existing kernel libraries. In many cases, OAs match the performance of handwritten heterogeneous implementations. Finally, OAs can automatically page data in these workloads to scale to datasets larger than GPU memory, which would need to be done manually with most current GPU libraries.

1 Introduction

The public cloud has commoditized specialized hardware such as GPUs, giving developers a new way to speed up their applications using these new accelerators. One increasingly popular way of doing this is to use accelerator-compatible *kernel libraries* with APIs that mirror those of popular CPU libraries. For example, in just the last two years, the Python ecosystem has seen a rapid explosion of popular GPU libraries such as PyTorch [24], cuML [8] and cuDF [7], and the RAPIDS [9] suite for data science; these libraries mirror the APIs of popular packages such as NumPy, Scikit-Learn, and Pandas. In keeping a familiar interface, accelerator libraries promise a seamless path to supporting new hardware for both new and existing applications.

Unfortunately, in reality, accelerator libraries for GPUs are not so simple to adopt into new or existing code. First, many of these libraries only implement a subset of functionality present in their CPU counterparts, e.g., because some functions are inefficient on parallel architectures such as GPUs [14, 15, 28]. This means that most applications must use *both* CPU and accelerator libraries, thus violating the promise of seamless integration with new hardware platforms. In addition, small API differences mean that even supported functions often warrant application changes. Finally, since most accelerator libraries operate over data that fits entirely in device memory, workloads in domains such as data science cannot seamlessly reap the benefits of new hardware because their working sets far outsize device memory. Developers must manually page and transfer data between the accelerator and CPU, or forego accelerators altogether.

In this paper, we propose *offload annotations (OAs)*, a new approach for incrementally integrating existing CPU libraries with emerging accelerator libraries. With this approach, an *annotator* (e.g., an application or library developer) adds annotations to CPU functions that specify a corresponding accelerator function from an accelerator library. An underlying runtime uses the annotations to automatically schedule functions either onto the CPU or the accelerator. In our system, we show that annotations enable end users to use both established CPU libraries and emerging GPU libraries without having to change their code or learn a new API. We also show that our runtime can allow end users to invoke GPU functions transparently even when data does not fit in accelerator memory. However, designing and leveraging annotations to offload computation to accelerators poses a unique set of challenges.

First, applications that mix CPU and accelerator code must be cognizant of *data placement*. For example, accelerator libraries such as PyTorch [24] can only process data resident in device memory, and GPU-resident data has an entirely different format than CPU-resident data. Our annotations explicitly keep track of the device on which a particular data value resides, and include a new API to let annotators specify how to transfer data between devices. In addition, some library functions that *allocate* new data, such as `numpy.eye()` (which creates an identity matrix), have equivalent functions in an accelerated library, so OAs let users explicitly identify such functions. The runtime uses this additional information specified in OAs to ensure that data is in the correct format on each device, helping to optimize the computation.

A second challenge in offloading functions to accelerators is *memory management*. Accelerators generally have far smaller attached memories than CPUs: this means that large CPU-resident datasets cannot naively be copied to the accelerator in entirety. To address this challenge, OAs leverage the splitting mechanism of *split annotations* [23], originally used for cross function cache pipelining on the CPU, in the new use case of *paging* memory. Our runtime partitions inputs into chunks that fit in device memory, and automatically schedules data transfer and function invocation on partitioned values. Values are partitioned and merged using a user-defined *splitting API*. By identifying splittable functions using OAs, developers can run existing CPU workloads across different platforms transparently, even if the working set does not fit in device memory. Some accelerated functions available in libraries *cannot* be split into smaller computations, however, but OAs can still offload the computation up to a certain size.

Finally, a third challenge unique to offloading functions is determining where to execute annotated functions. Since functions that execute on an accelerator must first transfer their inputs to device memory, they have an additional associated data transfer cost. This can negatively impact performance in cases where the function itself executes quickly. To address this challenge, our runtime includes a new scheduler that uses estimates of transfer cost and compute cost to determine when functions should be executed on the GPU vs. the CPU. We show that simple linear cost model estimators can yield 26× performance improvements compared to greedily executing all supported functions on a GPU.

The adoption of annotation-based approaches has already seen success in the past with systems such as TypeScript [12, 25]. In the TypeScript community, annotators crowdsource and share annotations for existing libraries. Unlike approaches that require building a complete end-to-end compiler, such as Weld [22] or Delite [31], the annotation-based approach also allows annotators to *incrementally* add support for individual accelerated functions. We hope to see a similar community develop around OAs to bridge existing CPU libraries with their accelerator library equivalents.

We implemented OAs by extending the Python runtime for split annotations, Mozart [23]. Our extended runtime, *Bach*, considers the challenges unique to offloading computation to capture device placement information and schedule computation in a heterogeneous setting. We evaluate OAs by integrating several CPU-only data processing libraries with their GPU library equivalents: PyTorch and cuPy for NumPy, cuDF for Pandas, and cuML for Scikit-learn. Our integration experience demonstrates the generality of OAs for popular data science libraries, and the minimal developer effort involved that requires little to no code modifications. On data science workloads ranging from options pricing to principal components analysis, OAs are able to achieve up to 1200× improvement with a median 6.3× over CPU-only code, with few or no application changes. OAs also enable many workloads to use GPUs when the dataset size exceeds the GPU memory, which would require manually paging code with the existing GPU computation libraries.

```
# Fit.
m1 = sklearn.StandardScaler()
m2 = sklearn.PCA() # or cuml.
m3 = sklearn.KNeighborsClassifier() # or cuml.
X_train = m1.fit_transform(X_train)
+ X_train = transfer(X_train, GPU)
X_train = m2.fit_transform(X_train)
+ Y_train = transfer(y_train, GPU)
m3.fit(X_train, Y_train)
+ for chunk in f:
  # Predict.
  X_test = m1.transform(X_test)
+ X_test = transfer(X_test, GPU)
  X_test = m2.transform(X_test)
  result = m3.predict(X_test)
+ result = transfer(result, CPU)
plottinglib.plot(result)
```

Listing 1: Example data science workload using `sklearn`. Lines preceeded with a **+** show modifications required for using a GPU with the `cuML` accelerator library.

In summary, we make the following contributions:

- We introduce offload annotations (OAs), an interface for heterogeneous computing with no library modifications that allows third-party annotators to incrementally add accelerated versions of library functions, and manages the offload and execution of these functions on devices. The OA interface extends split annotations with support for representing data in different formats on different devices and deciding when to offload a computation based on its estimated transfer size and computation cost.

- We describe Bach, a Python runtime that uses annotations to capture a lazy task graph of program operations and schedules execution and data transfer, including allocations, in order to improve application performance while staying within the accelerator's memory limits.

- We integrate OAs with four kernel libraries for GPU computation, and show that they can accelerate applications by a median of 6.3× over the CPU-only version of the library. We also compare the performance of OAs to hand-written heterogeneous code that manually combines these libraries with CPU libraries.

2 Motivating Example

To motivate the OA approach, consider the following simple scenario: A data scientist has a machine learning workload originally written for the CPU using `sklearn`. She reads the data from a file on disk, preprocesses the data, trains the model, and then tests it on a real dataset (Listing 1).

As her company sends her more and more data, the data science pipeline takes an order of magnitude longer to run. She learns about accelerators and accelerator libraries such as cuDF and cuML built to speed up data science workloads using GPUs. Since the pipeline was already running on cloud instances, the data scientist decides to move her code to another instance with accelerators attached.

The online documentation for these kernel libraries promises a seamless integration experience, offering almost exactly the same interface as their CPU library counterparts, but she soon discovers it is not as easy as it seems. Some of the functions have different names, requiring her to scour the documentation for functions with the corresponding functionality. Some functions do not have corresponding implementations at all, and can run only with the CPU library.

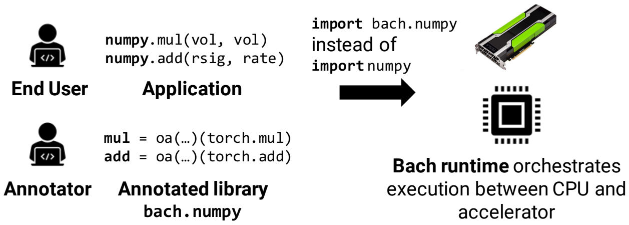
Next, the data scientist analyzes the program and manually inserts data transfer statements between the GPU and the host CPU so that data resides on the same device as the corresponding functions. Since the inputs to the program are usually read from another step in the pipeline, she assumes the inputs initially reside on the CPU. Since she initializes some of the intermediate objects herself, she allocates those directly on the GPU. Finally, since her plotting library requires the data to be on the CPU, she transfers the results back to the CPU at the end of the program.

With most CPU library functions replaced with the corresponding GPU library functions, she is ready to run the program, but it crashes due to insufficient GPU memory. Although her dataset was small enough to fit in CPU memory, the amount of memory attached to the GPU is significantly smaller. She writes additional code to page the data transfers to the GPU in the prediction phase, since the `predict` computation can be done independently on different data batches. The training function in the accelerator library *cannot* be run in independent batches, but fortunately, her training data is smaller than the data she predicts on, so that computation can run as one GPU function call.

Finally, after all the developer effort required to learn and integrate the GPU libraries, the code runs to completion, and the data scientist receives the same results on her dataset as when the pipeline ran only on the CPU. The performance of her new program has also improved. Nonetheless, the data scientist's code is now complex (Listing 1), with many new function calls and new control logic just to manage the GPU computation. Furthermore, all this new logic may need to change in the future as her workload changes or her dataset changes in size.

3 Design Overview

With *offload annotations* (or *OAs*, Figure 1), we reduce the developer effort for porting an existing workload to the GPU to just importing the annotated CPU library in place of the original CPU library. The annotator could be the kernel library developer, the end user writing applications, or any other third-party developer (similar to the open source contributors that provide type definition files for libraries in TypeScript [12]). Our system, Bach, uses the information in OAs to automatically offload functions to a GPU, page large datasets, transfer data across devices automatically, and manage allocations to minimize data transfer for better performance.



```
numpy.mul(vol, vol)
numpy.add(rsig, rate)
```

```
mul = oa(…)(torch.mul)
add = oa(…)(torch.add)
```

```
import bach.numpy
```
instead of
```
import numpy
```

End User
Application

bach.numpy
Bach runtime orchestrates execution between CPU and accelerator

Figure 1: Overview of writing and using OAs. An *annotator* writes annotations to bridge a CPU library with an accelerator library. An *end user* imports the new annotated library to automatically use new accelerators in her existing code.

Adding OAs to CPU libraries. First, an annotator identifies a corresponding accelerator library for her CPU library (e.g., `torch` for `numpy`). She then identifies a corresponding accelerator function for each CPU function she wishes to annotate (e.g,. `torch.multiply` for `numpy.mul`). The annotator then writes an OA for her CPU function: the OA specifies the corresponding GPU function that should be called in place of the CPU function, and split types for each function input and output (adapted from the split types used in split annotations [23]). Split types are an interface implemented by an annotator that provide information about a function input or output *at runtime* (e.g., the size of an array). The annotator can also write special OAs for allocation functions (e.g., `torch.zeros` for `numpy.zeros`), which enable data to be allocated directly on the device where they will first be used.

OAs extend the original split type interface to provide additional information about *data placement*. In particular, the annotator must implement a new *offloading API* for each split type. Most libraries only require implementing the offloading API once per *data type* in the library (e.g., for `ndarray` in NumPy). The offloading API specifies (1) where inputs to a function reside before execution (e.g., in GPU memory or CPU memory), and (2) how to *transfer* values from from one device to another. Since the offloading API extends the split annotation splitting API, it can also *optionally* describe how to split and merge data for data-parallel workloads. Splitting in OAs is used for paging data into an accelerator with limited memory (unlike in split annotations, where splitting enables cross-function cache pipelining on a CPU).

Once an annotator adds OAs and implements the offloading API for the data types in the CPU library, she can share the annotation file to allow other end users to reap their benefits.

Using annotated libraries. An *end user* integrates the annotated library into her code by changing the line that imports the CPU library to import the annotated library instead (the annotation file is just a Python module).

Generally, little to no code modification is required to use the annotated library in place of the original CPU library. The main difference is that Bach, our runtime, uses *lazy evaluation* to optimize data transfer across many functions. OAs can automatically evaluate lazy values in many cases (e.g., when calling `str()` in Python), but an end user may have to add `evaluate()`—a function automatically provided in annotated libraries—into her code to explicitly materialize lazy values.

Bach runtime scheduler. Bach builds on split annotations' Mozart runtime to automatically build and maintain a lazy task graph. Internally, when a lazy value is materialized, Bach uses OAs to automatically schedule data transfers and computation, deciding the device on which to run each operation (§5). Note that scheduling is completely packaged in our runtime, and does not require any additional annotator or end user code.

Although the Bach runtime defaults to greedily scheduling operations on the GPU, the annotator may still provide custom cost model estimators to the function annotations to assist the runtime with making scheduling decisions. However, these cost models are optional and are not usually required to benefit from OAs, as shown in our evaluation.

4 Offload Annotation Interface

The offload annotation (OA) interface provides a corresponding accelerator function for each function in a CPU library. The interface also provides a mechanism to discover runtime information about function arguments and outputs: namely, how to split inputs into chunks that will fit in device memory, the device on which an input is allocated before executing annotated functions, and how inputs can be transferred between devices. This information is relayed via *split types*, an abstraction from split annotations [23]. The OA interface also includes new *`alloc` annotations*, which specify functions that allocate new data (e.g., `numpy.zeros` to allocate an array of zeros). These annotations allow further optimizations when scheduling data transfer and are described further below.

Listing 2 shows an example of the extended offload split type API, and Listing 3 show examples of OAs, with `numpy` as the CPU library and `torch` as the accelerator library.

4.1 Primer: Split Types

Split types provide a mechanism that allow a runtime to discover runtime properties about a value (e.g., size of an array or dimensions of a matrix). In split annotations, split types are used to ensure that data is *split* in a consistent way across functions to enable safe pipelining of split values. For example, a split type will ensure that split arrays passed into a function together still have the same lengths at runtime.

```
class DataFrameSplit(OffloadSpliType):
  def split(start, end, value):
    # Splits a value to enable paging.
    return value[start:end]
  def merge(values):
    # Merges split values
    return pandas.concat(values)
  def size(value):
    # Returns number of elements in value
    return len(value)
  def device(value):
    # Specifies where this value is allocated.
    # Used by scheduler to decide where to run
    # functions.
    if isinstance(value, pandas.DataFrame):
      return Device.CPU
    else: # if a cuDF DataFrame.
      return Device.GPU
  def to(value, device):
    # Transfers [value] to specified [device].
    if device == Device.GPU:
      return cudf.from_pandas(value)
    else:
      return value.to_pandas()
```

Listing 2: Example implementation of the offload split type API for Pandas and cuDF DataFrames. The API adds two new functions—`device` and `to`—to the original split type API.

To use split types, an annotator implements an API that the runtime calls to interact with runtime values. In split annotations, split types provide a `split` function to partition values into chunks, and a `merge` value to merge split values together. The API also contains a `size` function for discovering the size of inputs (e.g., to determine split sizes). Listing 2 shows an example of these functions for DataFrames. We extend the split type API to allow our runtime to offload values onto other devices.

When splitting and merging data in a non-trivial way, end users must ensure the correctness of the application. Many data science applications operating on large collections of data, as in our workloads, are trivially parallelizable. Even when splitting and merging is impossible due to algorithmic correctness constraints or unavailable kernel library implementations, applications can still benefit from automatic offloading at smaller data sizes.

4.2 Offload Split Types

In addition to specifying how data should be split and merged, our extended *offload split types* additionally specify *(1)* the device on which a value is allocated, and *(2)* how to transfer a value between devices.

`Device` API. The `device` method specifies the device its input resides on. The method might check the instance type

```
# Offload split types for binary function inputs.
args = (NdArraySplit(), NdArraySplit())
# Offload split type of return value.
ret = NdArraySplit()

# OAs to provide offload split types for each
# argument and return value, as well as a corresonding
# accelerator function.
np.add = @oa(args, ret, func=torch.add)
np.subtract = @oa(args, ret, func=torch.sub)

# Allocation function.
np.empty = @oa_alloc(NdArraySplit(), func=torch.empty)
```

Listing 3: Offload annotations using `numpy` and `torch`.

of the input, or properties of the input. For example, NumPy arrays are on the CPU while CuPy arrays are on the GPU. Torch tensors can reside on either device, and have a property to describe where a particular value resides.

`To` API. The `to` method transfers the provided value to the target device. This usually involves converting a CPU library type (e.g., `numpy` array) to an accelerator library type (e.g., `torch` tensor) using a accelerator library function (e.g., `torch.to()`). The ability to transfer values is necessary to ensure that values reside on the device where the operation will run.

4.3 Using Offload Split Types in Annotations

OAs assign each input and output an offload split type. Additionally, the OA provides the name of the corresponding accelerator library function. If the accelerator function has a different function signature, an annotator can wrap the accelerator function in a lambda with an interface consistent with the CPU function.

Example. Listing 3 shows several examples where NumPy functions are annotated using PyTorch. The OAs assign the two arguments of `np.add` and `np.subtract` the offload split type `NdArraySplit`. This split type will define how to split, merge, and transfer `ndarray` and `torch.tensor` values. It will also tell Bach whether a particular value passed to these functions is already on the accelerator or CPU using the `device` API. The outputs of these functions also have the offload split type `NdArraySplit`.

4.4 Allocation Function Annotations

One unique challenge the runtime faces is avoiding unnecessary data transfers, which can lead to performance degradation. Consider when data is allocated on one device, and then immediately passed to a function that can be offloaded. In this case, it is more efficient to allocate the data directly on the device of the following function.

To support this, OAs provide a special kind of annotation, called an `alloc` annotation, which specify that the annotated function performs allocation. Like other annotated functions, annotators provide CPU allocation functions with an equivalent accelerator library functions (e.g., `torch.zeros` for `numpy.zeros`). Allocation functions differ from regular functions in one key aspect: their inputs do not need to be annotated with offload split types. Outputs are still annotated with a offload split type, similar to a regular function. CPU-only split annotations did not require allocation annotations since they did not need to avoid expensive data transfers.

Example. In Listing 3, the `np.empty` function allocates data: its OA specifies a corresponding PyTorch function, but does not provide offload split types for inputs. Its output has the same `NdArraySplit` offload split type.

5 Bach Runtime

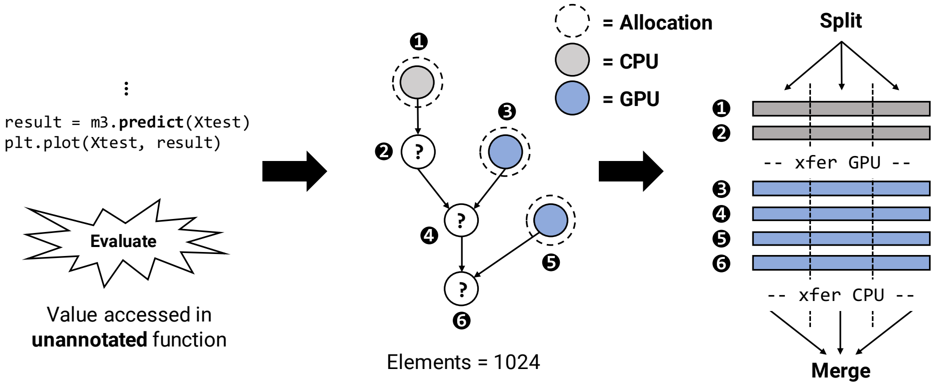
The Bach runtime uses the information in the OAs to schedule and execute functions across the CPU and accelerator. Figure 2 provides an overview of the Bach runtime.

Step 1: Construct Dataflow Graph. Bach's first goal is to extract a dataflow graph from the user program. To do this, Bach uses the same approach as Mozart: when annotators apply an annotation to a function, Bach wraps it to return a lazily evaluated placeholder object, using Python's metaprogramming facilities [23]. When placeholders objects are passed to other annotated functions, Bach stitches these functions into a task graph. This task graph captures dependencies between annotated functions: an edge between two operations exists if the output of one operation is used as an input into another.

Two scenarios trigger evaluation of the task graph. First, Bach detects accesses to the lazy placeholder objects by intercepting certain Python methods (e.g., `str` to convert an object into a string, or `__getitem__` to index into a collection). Internally, the placeholder object will trigger evaluation of the full task graph required to build it, and then forward these method invocations to the evaluated object. For example, this means that placeholder objects will be evaluated if the user passes them to `print()`. Alternatively, the user can also explicitly call an `evaluate()` function to trigger execution.

Step 2: Estimate Data Size and Allocate. In order to correctly partition the data for splitting, Bach must estimate the data size by using the `size()` API on the program inputs. Unlike in Mozart, Bach can lazily allocate values to optimally place data on the same device as the first function that uses that value. However, if all the program inputs are lazy allocations, there are no available values with which to estimate data size. Thus Bach must allocate lazy values before starting execution to estimate the data size.

Bach decides where to allocate each lazy value based on the device of the first function to use the value. OAs differ from split annotations in this regard because they need to decide which device to run each function on. A function can



```
⋮
result = m3.predict(Xtest)
plt.plot(Xtest, result)
```

Figure 2: Overview of the steps involved in Bach's runtime. Step 1 triggers evaluation of the dataflow graph with an access to a lazy value. Step 2 allocates the lazily allocated nodes and estimates the program data size. Step 3 dynamically schedules the instructions across devices, inserting data transfers and paging the inputs.

```
# Heuristic for estimating data transfer cost.
def transfer_estimator(ty, values, device):
    x = ty.size(values)
    return a * x + b

# Heuristic for estimating compute cost.
def compute_estimator(ty, values, device):
    x = ty.size(values[0])
    if device == CPU:
        return a_cpu * x + b_cpu
    else:
        return a_gpu * x + b_gpu
```

Listing 4: Linear estimators for estimating data transfer and compute cost.

run on the accelerator if it has an `oa` or `oa_gpu` annotation, and if its inputs either can be transferred to the device or already reside on the accelerator. All functions must be able to run on the CPU, which is the default device.

To decide where to run this first function, Bach estimates the data transfer costs and compute costs involved with running the function on either device and suggests the device with the lower cost. These cost estimates are calculated using heuristic functions optionally provided by the user. The heuristic functions are functions of the input values, their offload split types, and the target device, and we provide a simple linear cost model estimator (Listing 4). If cost models are not provided or all other inputs are also lazy allocations, Bach naively suggests the function run on the accelerator if possible. Otherwise Bach defaults to the CPU.

Step 3: Schedule and Execute. Once the data size is estimated, the operations in the task graph are converted into a list of instructions that can be executed serially for each split piece. To do this, the Bach runtime performs a topological sort of the task graph to obtain a list of instructions that satisfy data dependencies.

The device an instruction runs on is decided dynamically right before executing the instruction. The instruction first determines if it is eligible to run on the accelerator based on the requirements described in the previous section. If it is not eligible, it defaults to running on the CPU. Otherwise, the runtime performs the same cost model analysis as when deciding where to lazily allocate a value to determine which device to run the instruction on. Unlike before, all the inputs will be fully evaluated. After deciding which device to use, the instruction transfers inputs that are on a different device using the `to()` API in the offload split type for the input. Bach discovers where inputs are prior to executing functions by using the `device()` API. As before, if cost models are not provided, Bach defaults to using the accelerator if possible.

When executing functions, Bach uses the ability to partition data to enable *paging*: this allows for large, CPU-memory-resident datasets to be streamed through device memory, even when device memory is far smaller than the CPU memory. To achieve this, Bach splits the inputs into chunks based on the estimated data size and a default piece size. Inputs are split using the `split()` API provided in the input's offload split type. For each chunk, the program executes the generated list of instructions. The chunk is transferred to the device of the input argument if its current device does not match the device of the instruction. Each chunk is moved out of the device after the functions finish executing, to free space for the next chunk.

The final outputs are moved to the CPU by default after execution, but the end user can elect to keep the output on the accelerator by explicitly calling `evaluate()`. If paging is used to stream data through a device, the output is always allocated on the CPU (since it may not fit entirely in device memory).

6 Design Discussion

As described, OAs and the Bach runtime are designed specifically for offloading computation to a single GPU using Python kernel libraries. In this section, we discuss the possibilities of extending OAs for use with multiple GPUs or with other programming languages and accelerators.

Multiple GPUs. Similar to how split annotations split data-parallel workloads across CPU cores, we can extend OAs to automatically split computation across multiple GPUs. The implementation would need to modify the scheduler to recognize multiple GPU targets, and factor data transfer and concurrency into scheduling decisions. We do not expect these modifications to impact end user experience.

Non-Python programming languages. We chose to implement Bach in Python since Python is one of the most popular languages for data analysis, with a vast ecosystem of Python GPU libraries. We believe our implementation uses principles common to many programming languages and do not rely on any language-specific hacks. Specifically, "annotations" in Python are simply functions that wrap other functions, and the runtime logic is language-agnostic. Mozart [23] demonstrates that the annotation framework is viable in C++, so we imagine we could implement a similar runtime for C++ for GPU libraries like Thrust.

Non-GPU accelerators. Any accelerator with a kernel library that closely mirrors a CPU-only library and an API to offload data to that accelerator could potentially be suitable for OAs. We may also be able to adapt split data in streaming accelerators to overlap data transfer with computation like in CUDA streams. Data transfer costs are an issue common to many accelerators, and we could apply ideas about memory management and data placement from OAs even if the system cannot be used directly.

7 Library Integrations

We annotated three different CPU-only Python libraries for data science and machine learning: NumPy, Pandas, and Scikit-learn. The annotations used four different GPU kernel libraries: CuPy, PyTorch, cuDF, and cuML. The latter two kernel libraries are part of the RAPIDS [9] suite.

NumPy. NumPy is a library for high-level math operations on multi-dimensional arrays and matrices on the CPU. NumPy was the most popular library in terms of number of accelerator library equivalents. In their online documentation, these accelerator libraries directly claim to provide a NumPy-like API. CuPy is described as a NumPy-like API accelerated with CUDA, while PyTorch is described as a replacement for NumPy that leverages the power of GPUs. We integrate NumPy with CuPy and PyTorch in two separate OA-libraries, replacing NumPy `ndarrays` with CuPy `ndarrays` and PyTorch `tensors`.

CPU-only library	GPU kernel library	LOC	# Split Types	# Funcs
NumPy	CuPy	103	1	20
NumPy	PyTorch	90	1	10
Pandas	cuDF	241	7	27
Scikit-learn	cuML	81	2	12

Table 1: Integration effort for annotating various libraries. Lines of code include annotations, split type transfer functions, and splitting functions.

Pandas. Pandas is a data analytics library for operating on structured table-like or time series data. The cuDF accelerator library provides a Pandas-like API. We replace Pandas `DataFrame` and `Series` data types with the corresponding cuDF types.

Scikit-learn. Scikit-learn is a popular machine learning library. Machine learning is a natural fit for the GPU with its dense linear algebra operators. The cuML library's Python API attempts to closely match the Scikit-learn API.

7.1 Integration Experience

From our experience, library integrations required around 130 lines of code per library (Figure 1). The most lines of code come from implementing the offload split type API for transferring, splitting, and combining types. However, the split and combine API is optional if a user does not need to page large datasets. In the simplest and most common case, an OA requires only a single line of code per function to specify the offload split types of inputs and outputs, and the name of the kernel library function. These annotations resemble boilerplate code when libraries repeat a common pattern, like binary operations with a single output in NumPy. In more complex function annotations, the benefit of OAs is that it only needs to be done once in the annotated library as opposed to every instance in every workload.

7.1.1 Straightforward Drop-In Replacements

Every library has a straightforward way to transfer data to the appropriate device. Most accelerator library types automatically reside on the GPU, so using CuPy's `ndarray` or cuDF's `DataFrame` automatically transfers the data to the GPU. Scikit-learn can use either CuPy's `ndarray` or cuDF's `DataFrame` as the underlying representation. PyTorch tensors can reside on both CPUs and GPUs, so the transfer implementation from Numpy `ndarray` first converts the `ndarray` to a `torch.Tensor` (a zero-copy cast) and then calls a method on the tensor to transfer it to the GPU.

Just as many accelerator libraries claim to closely resemble the CPU libraries they attempt to replace, many accelerator library functions are indeed a drop-in replacement for the corresponding CPU library function. For example, numpy.add(), cupy.add(), and torch.add() are the same across all three libraries. Sometimes, the method names are trivially different but represent the same functionality, like numpy.arcsin() and torch.asin(). Scikit-learn's API utilizes a complex module structure that does not exist in cuML (e.g., sklearn.decomposition.PCA vs cuml.PCA), so annotators sometimes must mock module structure to make integration as seamless as possible.

7.1.2 Different Function Specifications

Even if two CPU and kernel library functions appear to be equivalent based on name, the annotator must be careful to ensure the function parameters and specifications are identical. For example, the array allocation functions numpy.ones() and torch.ones() both take a parameter dtype to specify the data type of the array. However, NumPy can accept strings like 'int8' as a parameter, while PyTorch only accepts library-defined types like torch.int8. In this case, the annotator must write a custom wrapper that converts function parameters.

We experienced another challenge involving different function specifications when integrating Pandas with cuDF. Both pandas.read_csv() and cudf.read_csv() read a CSV into a DataFrame object. In Pandas, the squeeze parameter causes the function to return a Series if the parsed data only contained one column. To achieve the same functionality in cuDF, which does not have this parameter, we wrote a custom function that converted the returned DataFrame into a Series if the squeeze parameter was included. Of the 48 parameters in v0.25.2 of pandas.read_csv()'s documentation, others are also bound to not exactly match the specifications in cuDF and require special implementation.

7.1.3 Missing Functions

When a function is missing from an accelerator library, any library annotator can annotate the library with a custom function. We implemented a custom GPU version of the Pandas mask() function, used for replacing values in a DataFrame based on a conditional DataFrame, by using the series.loc[cond] = val notation from the cuDF library instead. In our cuML annotations, we mimicked Scikit-learn's StandardScaler() model using CuPy operations for removing the mean and scaling to unit variance on the GPU. In general, cuML's preprocessing library is far behind Scikit-learn's, potentially because Scikit-learn's functionality is easy enough to achieve with other accelerator library functions.

In other cases, functions do not exist because the algorithm required to provide the functionality is either impossible or simply unsuitable for the GPU. In particular, many Pandas functions do not work in cuDF when string operations are involved, requiring the program to execute on the CPU. Though libraries like nvStrings and cuStrings are working to close the gap in text processing on the GPU, the state of strings on the GPU today still requires the developer to have a deeper understanding of its literal representation on the GPU.

Workload	Ops	CPU Library	Max Speedup
Black-Scholes	39	NumPy[1]	5.7×
Black-Scholes	39	NumPy[2]	6.9×
Haversine	19	NumPy[1]	0.81×
Haversine	19	NumPy[2]	1.7×
Crime Index	15	Pandas	4.6×
DBSCAN	7	NumPy[1]/Sklearn	1200×
PCA	8	Sklearn	6.8×
TSVD	2	Sklearn	11×

Table 2: The evaluated workloads, the number of annotated function operators, and the CPU Python libraries used by each workload. The median speedup across workloads is 6.3× with a maximum speedup of 1200× on DBSCAN. Annotated with CuPy[1]. Annotated with PyTorch[2].

7.1.4 Multi-Library Integration

Just as libraries in the Python data science ecosystem use each other in their implementations, annotated libraries must also be able to import and operate on other annotated libraries. In the CPU ecosystem, Scikit-learn's functions use the NumPy ndarray, while in the GPU ecosystem, cuML's functions use the CuPy ndarray. In our annotated Scikit-learn library, we analogously import the NdArraySplit type from our annotated NumPy library to define the argument and return types in the OAs. As OAs grow in popularity, we imagine an ecosystem of increasingly-interconnected annotated libraries that allow seamless execution across multiple devices in existing workloads.

8 Evaluation

We ran experiments on a 56-CPU server (2× Intel E5-2690 v4) with 512GB of memory, running Linux 4.4.0. The machine has a single NVIDIA Tesla P100 GPU with 16GB of memory and CUDA 10.2 installed. Each result is the median of five runs, with one warm-up run omitted to initialize the CUDA driver. Workload runtimes are measured end-to-end, including allocation and synchronization operations at the end. Our source code is available at https://github.com/stanford-futuredata/offload-annotations.

8.1 Workloads

We evaluated offload annotations on a variety of workloads adapted from common mathematical formulas, data science library tutorials, and popular online blog posts (Table 2).

Black-Scholes [1]. Determines the theoretical value for a large array of call or put options.

Haversine [3]. Determines the great-circle distance between points on a sphere.

Crime index [4]. Reads population and robbery data from a file on disk and calculates a numerical crime index score.

DBSCAN [5]. Standardizes a dataset with 256 features around 32 centers, and clusters the data with the DBSCAN algorithm, analyzing the predicted labels on the CPU.

PCA [6]. Standardizes training data and reduces the dimensionality with PCA, then classifies the points with K-Neighbors. Predicts the results, followed by plotting.

TSVD [10]. Applies the linear dimensionality reduction algorithm to a synthetic dataset with 512 features.

8.2 Results

Figure 3 showcases the performance of the data science and machine learning workloads on inputs of various sizes. We evaluate the workloads on a CPU-only implementation, a handwritten accelerator kernel implementation, and an annotated implementation with Bach.

We verified the numerical results of the workloads for correctness against each implementation. In the machine learning workloads, we selected parameters that produced reasonable results given the inputs (e.g., DBSCAN predicted 32 clusters and PCA classified points with greater than 90% accuracy). We maintained the same parameters for each implementation to ensure the parameters did not affect the runtime.

The results show that with less developer effort, Bach is able to match the performance of handwritten GPU implementations, scale to larger input data sizes that normally cause the GPU to run out of memory, and outperform CPU library implementations. We now discuss these results in more detail.

8.2.1 Results Summary

We make three main observations.

First, Bach matches the performance of handwritten GPU implementations in all workloads. Bach selects which CPU library functions to offload and how to transfer data, with minimal developer effort.

Second, Bach scales to larger input data sizes that normally cause the handwritten GPU implementations to run out of memory. In most workloads, Bach's performance continues to scale at the same rate as before the GPU implementation runs out of memory, giving the appearance of running the same program on a GPU with infinite memory. DBSCAN is the only workload that cannot be split since the clustering model must be fit on all data at once. However, this is not a significant limitation since DBSCAN also has the largest runtime, with Bach taking 7.5 hours to run at the largest piece size before running out of memory, and the CPU implementation taking considerably more for the same input size.

Third, Bach outperforms CPU implementations for almost all workloads. One exception is Haversine Torch, which has worse performance than the CPU implementation when paging large datasets due to the overhead from the additional data transfers. Another exception is PCA at data sizes below 2^{12}. We attribute this to overheads associated with initialization and launching GPU kernels with significant launch overhead. CPU implementations outperform Bach for other workloads as well, but only for small input sizes when runtimes are in milliseconds or less.

8.2.2 Runtime Distributions

Workloads that benefit from GPU acceleration are suitable for acceleration using OAs. At a high level, the decision to use the GPU is a tradeoff between expensive data transfers and faster compute. The impact of OAs, and more broadly the impact of the GPU, depends on the distribution of runtime between data transfer, computation, and memory allocation in each workload (Fig. 4).

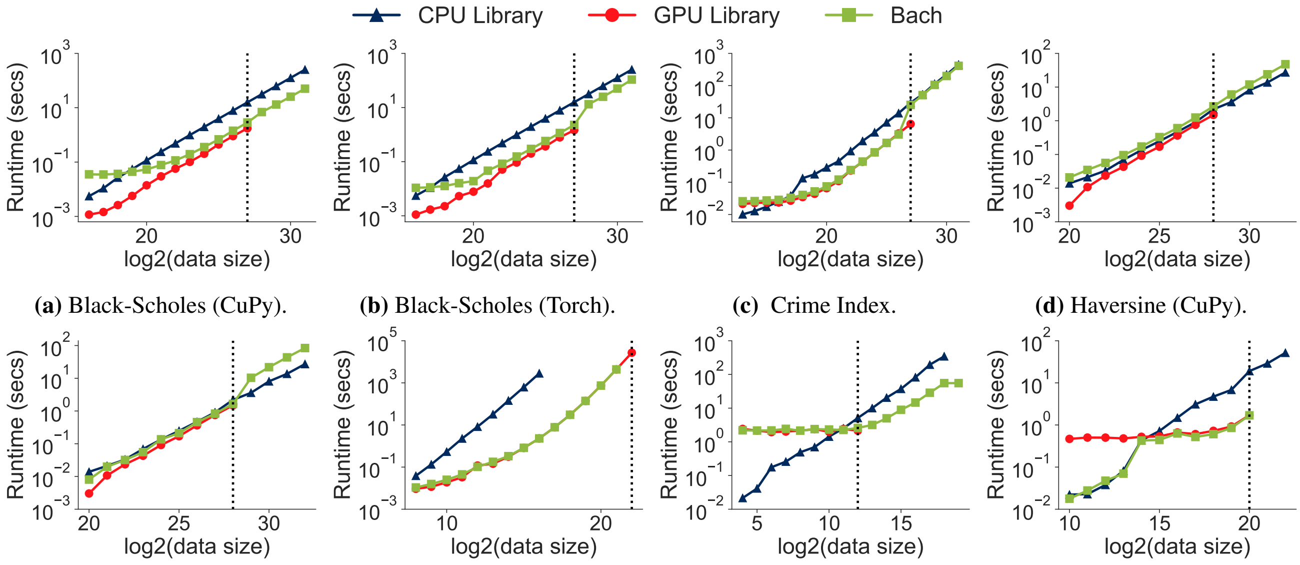
Allocation. Crime Index spends 93% of its total runtime of 29.74s on allocating data. In particular, the workload reads 1GB of data into memory before performing a series of fast numerical operations and calculating a single number, the crime index, as an output. Managing memory allocations are particularly important for expensive I/O operations like reading files from disk. Workloads with these kinds of operations particularly benefit from lazy allocation.

Though allocation can be fast on either device, the primary performance benefit of lazy allocation is eliminating the additional data transfer required to move the input to the appropriate device. At large data sizes that do not fit in GPU memory, the initial memory must instead be allocated on the CPU where it does fit and paged into GPU memory using data transfers. As shown by the dotted lines in Fig. 3, beyond a specific data size, Crime Index, Haversine Torch, and Black-Scholes Torch all have additional overhead when paging large data sets due to the extra initial data transfer.

When the Crime Index (Fig. 3c) dataset fits in GPU memory and the workload is able to use lazy allocation, an additional million rows of data increases the runtime by only 50 ms, compared to 190 ms when the dataset does not fit in GPU memory. The dataset size exceeds GPU memory beyond $2^{27} \approx 100$ million rows. We calculated these overheads as an average of the scaled Bach implementation runtimes for log data sizes 21-26 and 27-31, respectively. We do not consider data sizes below 2^{21} to discount the small absolute scheduler overheads that are independent of data size.

Data Transfers. Haversine CuPy and Black-Scholes CuPy spend 52% and 60% of their total runtimes of 2.85s and 2.60s on data transfers (Fig. 4). Both workloads apply a sequence of fast numerical operations on large arrays initialized on the CPU, which must be transferred to the GPU. The workloads output more large arrays which must be transferred back. However, Black-Scholes still beats the CPU library implementation with Bach at all sizes, meaning larger absolute performance gains at larger input sizes.

As the less computationally-intensive workload, Haversine is more significantly affected by additional data transfers when paging large datasets, no longer beating the CPU implementation at large dataset sizes. It should be noted that in



(a) Black-Scholes (CuPy).

(b) Black-Scholes (Torch).

(c) Crime Index.

(d) Haversine (CuPy).

(e) Haversine (Torch).

(f) DBSCAN.

(g) PCA.

(h) TSVD.

Figure 3: Runtime vs. input data size for the workloads in Table 2. Bach is able to match the performance of the corresponding GPU library for most applications. The framework in parentheses refers to the GPU library used by Bach in the workload. The dotted line represents the input data size at which the GPU runs into an out-of-memory exception; Bach is able to run workloads past this size by paging chunks in and out of GPU memory. (Log2 piece size = 27, 27, 21, 21, 26, 22, 12, 20 from (a-h))

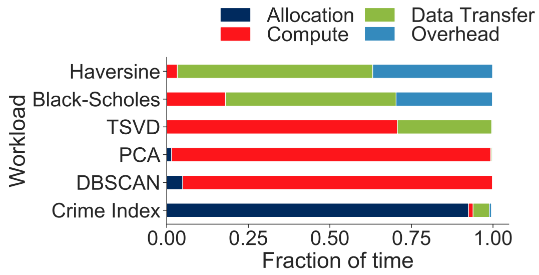


Figure 4: Proportion of total runtime split between memory allocation, data transfer, compute time, and runtime overhead in various workloads using Bach. Haversine and Black-Scholes mostly consist of data transfers; PCA, DBSCAN, and TSVD are compute-heavy; Crime Index spends the most time on allocation. (Log2 data size = 27, 28, 27, 19, 12, from top to bottom.)

absolute terms, the total time spent on data transfers for these workloads is relatively small. However, it is still important to optimize wherever possible, since the overheads can be exacerbated at scale or the applications using these pipelines might require real-time results.

Computation. DBSCAN and PCA, on the other end of the spectrum, are computationally-intensive workloads that are highly optimized for the GPU. In DBSCAN, data transfer took less than 1% of the total runtime of 130.81s, compared to the 94% spent on compute (Fig. 4). PCA spent 95% of the total runtime of 1.02s on compute. Machine learning models, with their parallelizable and computationally-intensive numerical operations, are particularly suited for the GPU.

8.2.3 Scheduling

The dynamic scheduling algorithm has minimal effect when all program inputs can be lazily allocated. In this case, all program inputs start out on the GPU if possible, even if the data size is small. Even though execution would have been been faster exclusively on the CPU, it is no longer worth transferring the inputs back to the CPU due to the overheads involved. This occurs in all workloads except the machine learning workloads: DBSCAN, PCA, and TSVD.

Among the machine learning workloads, we provided cost estimators to the TSVD workload to enable dynamic scheduling. DBSCAN already optimally executes the entire program on the GPU for all data sizes, and would not benefit from dynamic scheduling. We did not evaluate the dynamic scheduler on PCA, though it exhibits a similar runtime profile to TSVD.

In the TSVD workload, we used the linear estimators in Listing 4 as heuristics for transferring the input `ndarray` and computing the model's `fit()` function. In the transfer estimator, we use parameters `a = 1` and `b = 0` to indicate that data transfer is proportional to the size of the data regardless of device. In the compute estimator, we selected parameters based on the equilibrium point between and the CPU and kernel library lines in Figure 3h. We use `a_cpu = 2` and `b_cpu = 0` to indicate that on the CPU, computation is highly correlated to input size. For the GPU, we use `a_gpu = 0` and `b_gpu=14` to indicate that the computation is extremely cheap but incurs kernel launch overheads.

The result of using these linear estimators is a threshold scheduling algorithm that causes the total runtime of TSVD to be the minimum of the CPU library implementation and GPU library implementation (Fig. 3h). The scheduler switches from greedy GPU scheduling to CPU-only scheduling below the equilibrium data size 2^{14}. Below this data size, the GPU implementation remains constant at around 500 ms, while the CPU and Bach implementations become as low as 20 ms for data size 2^{10}. Thus Bach improves the TSVD runtime by up to 480 ms with the dynamic scheduler estimators, as it otherwise would have defaulted to using the kernel library.

It should be noted that in these workloads, the dynamic scheduler only generates an advantage at smaller data sizes where the overhead of GPU initialization is more pronounced. CPU libraries also tend to benefit from cache performance cliffs, which is why the CPU runtimes are not perfectly linear at smaller data sizes. In these cases however, the absolute runtime improvements from using the dynamic scheduler are small. In general, workloads do not require the annotator to implement any cost model at all to benefit from OAs especially at larger data sizes, where the execution is more likely to perform better on the GPU with the greedy scheduler.

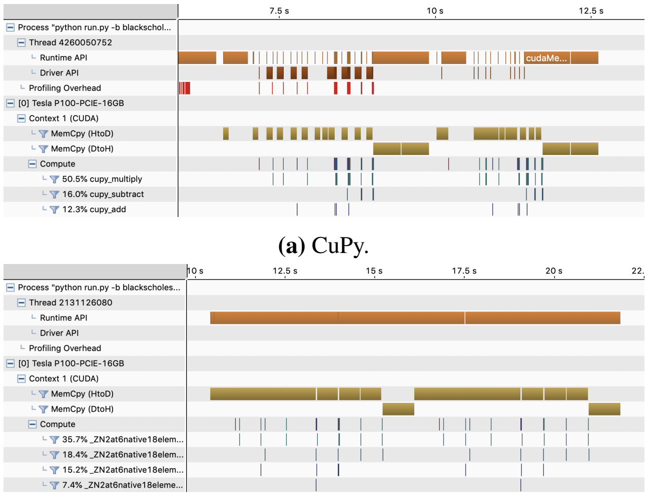
8.2.4 Discussion

Our experience integrating multiple kernel libraries with their CPU library equivalents gave us several interesting insights into the existing Python ecosystem for GPUs, including the lack of GPU kernels for several CPU functions and the differences in seemingly identical kernel library implementations.

Missing GPU implementations. Black-Scholes CuPy and PCA both contained functions without kernel library equivalents, the `numpy.erf()` error function and `sklearn.StandardScaler()`, respectively, despite these functions being trivial to run on the GPU. We addressed these performance issues in different ways.

In Black-Scholes, we wrote a custom GPU function to annotate `numpy.erf()` and eliminate additional data transfers that disrupted a numerical analysis pipeline that otherwise ran completely on a GPU. We copied the implementation from a file in CuPy's experimental folder for SciPy routines. This example demonstrates that regardless of whether the kernel library developer or third-party annotator contributes to an annotated library, annotations can make it easier to incrementally add support for GPUs into an existing workload.

Though we could have implemented a custom GPU function for `sklearn.StandardScaler()`, we did not do so because



(a) CuPy.

(b) PyTorch.

Figure 5: The NVIDIA Visual Profiler visualization of Black-Scholes annotated with CuPy and PyTorch, when paging large datasets into GPU memory. (Data size = 2^{28}; Piece size = 2^{27})

the compute time for this numerical preprocessing step was small in comparison to the prediction part of the workload, and the performance impact would not have been significant.

CuPy vs PyTorch. We were able to observe subtle differences between CuPy and PyTorch when integrating them with the NumPy data science library. When paging large datasets, annotated PyTorch incurred a higher overhead from the additional data transfers compared to annotated CuPy. Using the NVIDIA Visual Profiler, we observed that while PyTorch explicitly executed the memory transfers and kernels that we invoked, CuPy was significantly more complicated (Figure 5). In particular, CuPy made several calls to functions like `cudaHostAlloc()` and `cuModuleLoadData()`. These extra functions may have allowed CuPy to perform more efficient data transfers when paging large datasets, incurring less overhead.

9 Limitations

Without a more sophisticated scheduling algorithm, the end user may not get optimal performance using an OA-annotated library since all possible annotated functions will execute on the accelerator by default. Some functions, such as specific machine learning algorithms or analytics operations like joins, may be more efficient on the CPU in some cases. Although GPU scheduling is a complex problem, we found that greedy scheduling was effective in many applications. Though we cannot definitively state whether a holistic scheduler is better, we believe this problem is worth exploring and can utilize the information captured in the runtime's dataflow graph.

Another limitation is the need, in some cases, for the end user to provide cost models to their workload. It is difficult to know what constitutes a good cost model, much less an optimal one. With OAs, the end user can at least more easily evaluate different models and their downstream scheduling decisions with little code modification. In this case, the end user can simply change a few parameters and re-run the application, as opposed to re-inserting data transfer statements into the application code for each schedule. However, optimal scheduling remains a complex problem.

OAs are also unable to apply some types of low-level optimizations that require changes to the accelerator library functions. For example, the interface for CUDA streams, a method for overlapping data transfer and compute, is unavailable in cuDF and has a library-specific interface in PyTorch. Because OAs rely on diverse, existing libraries to provide optimized kernel implementations, indirectly calling into lower-level CUDA libraries like cuBLAS, cuDNN, and Thrust, they cannot coordinate calls to interfaces such as CUDA streams across these libraries. Nonetheless, users combining these accelerator libraries by hand would face the same limitation.

10 Related Work

OAs build on split annotations [23], which provide per-function annotations over existing CPU-based libraries to enable cross-function data pipelining and improved cache utilization. OAs extend split annotations by considering several new problems unique to accelerators, including data transfer and allocation across devices, memory limits of accelerators, and the problem of scheduling computations and transfers across CPUs and accelerators. These problems were not considered in the design of split annotations, so they require both an extended annotation interface (§4) and a different runtime and scheduler (§5).

Existing accelerator libraries such as PyTorch [24], cuDF [7], RAPIDS [9], and cuML [8] provide interfaces for targeting GPUs that intend to mirror CPU library APIs. However, they usually cannot handle data that does not fit in the accelerator memory, only support a subset of their CPU counterparts, and invariably involve application rewrites. OAs are a system designed to bridge these shortcomings, by leveraging new accelerator implementations of library functions but using annotations to automatically page and schedule work across the accelerator and CPU in complex applications that call multiple library functions.

Another popular approach for targeting heterogeneous platforms is compilation, where a compiler generates code (e.g., CUDA) underneath an existing library interface. Several solutions exist for data analytics [20–22, 27, 31, 34] and machine learning [11, 13, 30]. As one example, Numba [2] compiles NumPy code into an intermediate representation (IR), and then to optimized CPU or GPU code. However, compilers trade off good performance for high complexity: they are difficult to implement and to integrate into existing libraries, and the generated code may not match the performance of heavily hand-optimized kernels such as linear algebra functions [23]. In contrast, annotation-based approaches such as split annotations achieved similar speedups to these compilers in many cases with substantially less developer effort (e.g., 10× less code than accelerating functions with Weld in the Mozart evaluation [23]) by leveraging individual, hand-written kernel functions and only optimizing the data movement across them. Like split annotations, OAs propose using expert-written kernels to offload computations rather than attempting to generating code that matches the performance of these kernels.

Several existing systems schedule tasks in a heterogeneous environment [16–19, 26, 32, 33]. Our system primarily aims to provide an interface to bridge existing CPU and GPU code. The algorithms presented in these systems are complementary, and can be used to schedule the task graphs produced by OAs.

Hardware-portable languages like OpenCL [29] provide a common interface to target both CPU and accelerators. However, they require end users to write custom code in these languages, whereas our goal is to leverage optimized CPU and accelerator kernels that have already been written by expert developers and automatically invoke these kernels in an application written using high-level APIs.

11 Conclusion

We have presented *offload annotations (OAs)*, a new approach for bridging existing CPU libraries with emerging GPU libraries with no library code changes. Annotators use OAs to specify an accelerator function for a corresponding CPU function, and to define how inputs to a function can be transferred between devices. Optionally, annotators can also annotate allocation functions and provide cost model estimators that assist the runtime in making scheduling decisions. Our runtime, Bach, uses the information encapsulated in OAs to automatically schedule functions in an end-user application across devices, manage data transfer, and page large datasets. We apply OAs to several existing to several existing CPU libraries and show that they can improve their by up to 1200× and a median of 6.3× by offloading work to a GPU, with little to no code changes. We also show that OAs enable workloads that could previously not fit in GPU memory to reap the benefits of hardware acceleration, without manual effort by the application developer.

Abstract

Deep Neural Network (DNN) models have continuously been growing in size in order to improve the accuracy and quality of the models. Moreover, for training of large DNN models, the use of heterogeneous GPUs is inevitable due to the short release cycle of new GPU architectures. In this paper, we investigate how to enable training of large DNN models on a heterogeneous GPU cluster that possibly includes whimpy GPUs that, as a standalone, could not be used for training. We present a DNN training system, *HetPipe* (*Het*erogeneous *Pipe*line), that integrates pipelined model parallelism (PMP) with data parallelism (DP). In HetPipe, a group of multiple GPUs, called a *virtual worker*, processes minibatches in a pipelined manner, and multiple such virtual workers employ data parallelism for higher performance. We also propose a novel parameter synchronization model, which we refer to as Wave Synchronous Parallel (WSP) to accommodate both PMP and DP for virtual workers, and provide convergence proof of WSP. Our experimental results on a given heterogeneous setting show that with HetPipe, DNN models converge up to 49% faster compared to the state-of-the-art DP technique.

1 Introduction

Deep Neural Networks have been popularly used to solve various problems such as image classification [16,29], speech recognition [17], topic modeling [3], and text processing [10]. The size of DNN models (i.e., the number of parameters) have continuously been increasing in order to improve the accuracy and quality of models and to deal with complex features of data [19,47,54,55]. The size of input data and batches used for training have also increased to achieve higher accuracy and throughput [19,26].

For training large DNN models, data parallelism [4, 31, 32, 50], which employs multiple workers using parameter servers or AllReduce communication, and model parallelism [12,28,30], which divides the network layers of a DNN model into multiple partitions and assigns each partition to a different GPU, have commonly been leveraged. Furthermore, to mitigate the critical issue of low GPU utilization of naive model parallelism, pipelined model parallelism, where minibatches are continuously fed to the GPUs one after the other and processed in a pipelined manner, has recently been proposed [19,38].

Table 1: Heterogeneous GPUs

	Year	Archi.	CUDA Core	Boost Clock (MHz)	Memory Size (GB)	Memory BW (GB/sec)
TITAN V	2017	Volta	5120	1455	12	653
TITAN RTX	2018	Turing	4608	1770	24	672
GeForce RTX 2060	2019	Turing	1920	1680	6	336
Quadro P4000	2017	Pascal	1792	1480	8	243

For training DNN models, the use of GPU clusters is now commonplace. In such an environment, the use of heterogeneous GPUs is inevitable due to the short release cycle of new GPU architectures [24]. Moreover, several types of GPUs targeted for high-end servers, workstations, and desktops are being released for purchase [39–42]. Due to their cost-effectiveness, less expensive GPUs targeted for desktops and workstations, rather than high-end servers are also commonly used for machine learning training, especially for small and medium size clusters [14,21,49,56,57,59]. Due to the same reason, spot instances with different types of GPUs that are offered by cloud service providers are being used [2,24,36]. Table 1 shows the hardware specifications for four different types of GPUs, along with their market release years, that we have purchased in our institution in the short span of the last three years. Each, at the time of purchase, was (close to) state-of-the-art affordable with what budget we could muster. With technology advancing in such rapid pace, these systems have become outdated. Some of the systems have become old technologies that, individually, are unable to run large DNN models that are common today. Such situations with clusters of heterogeneous GPUs should now be commonplace.

There are benefits to enabling DNN training with heterogeneous resources. First, it allows for large model training with lower-class GPUs. While unable to train individually due to their limited resources, aggregated together, they may be used for training. These GPUs, which likely would have been retired, become usable, possibly used to create (virtual) workers that show similar performance as high-class GPUs. Second, low-class GPUs can be used to improve the performance of even high-class GPUs by incrementally adding on the resources of the (old) lower class systems to the (new) high-class systems. We call a group of aggregated GPUs that could satisfy the resource constraint and be used for training a *virtual worker*. Internally, such a virtual worker could leverage pipelined model parallelism (PMP) to process a minibatch, while externally, a number of virtual workers could leverage data parallelism (DP) for higher performance.

In this paper, we explore the integration of PMP and DP to maximize the parallelism of DNN model training. In particular, we investigate a DNN model training system, which employs both PMP and DP, for a heterogeneous GPU cluster that possibly includes whimpy GPUs that, as a standalone, could not be used for training large models. Integrating DP to PMP may sound trivial, but in fact, it is quite challenging. In this setting, each virtual worker is continuously processing multiple minibatches in a pipelined manner and thus, all the virtual workers can be in different states. Thus, the key question here is, what weight version should be used by each virtual worker to synchronize with other virtual workers? Numerous questions need to be answered to answer this question: 1) How many new minibatches can start being processed while waiting for global updates from the parameter server? 2) Can synchronization occur at any point of processing the minibatches? 3) How can convergence be guaranteed when such synchronization occurs? 4) What version of parameters is used for the next minibatch while previous minibatches are still executing within each virtual worker? (This question is also considered to some extent in a prior work [38].) And so on. Furthermore, there are also many challenges that need to be overcome to ideally leverage a heterogeneous GPU cluster for DNN training: How are the heterogeneous GPUs to be divided and allocated into virtual workers? How do we reduce virtual worker stragglers when we consider DP? How do we partition the model to maximize the performance of PMP using heterogeneous GPUs?

While DP [4, 31, 32, 50], PMP [19, 38], and heterogeneity [24, 25, 33] for training have been considered separately, to the best of our knowledge, this is the first paper that tackles these issues together in attempting to answer *some* of the aforementioned questions. In this work, we design a DNN training system, *HetPipe* (*Het*erogeneous *Pipe*line), that integrates PMP of a virtual worker, which is composed of multiple (possibly whimpy) heterogeneous GPUs, with DP of virtual workers using parameter servers to enable and also speed up training of large models. HetPipe can aggregate heterogeneous resources from multiple GPUs to form a virtual worker such that the performance of each virtual worker is similar to each other, reducing the straggler problem. For HetPipe, we propose a novel parameter synchronization model, which we refer to as Wave Synchronous Parallel (WSP). WSP is adapted from the Stale Synchronous Parallel (SSP) model [18] to accommodate both PMP and DP for multiple virtual workers unlike existing synchronization models. We also prove the convergence of WSP. Note that while HetPipe would work in a homogeneous GPU cluster in training a large model that cannot be loaded into the memory of a single GPU, with the rapid turnaround of newer GPU architectures, it is more likely that one will end up with a cluster of heterogeneous GPUs. This is the environment that we target.

We implement HetPipe by modifying TensorFlow, a commonly used machine learning training system. We evaluate the performance of HetPipe for two DNN models using a heterogeneous GPU cluster composed of four different types of GPUs. Our experimental results demonstrate that the performance of HetPipe is better than that of the state-of-the-art DP via Horovod [50] that uses AllReduce communication [45]. This is because HetPipe mitigates the straggler problem, and also because it enables each virtual worker and the parameter server to intra-communicate for all parameter updates, significantly reducing communication overhead. Compared to Horovod, the convergence of VGG-19 with a large parameter set to a desired accuracy becomes 49% faster, and that of ResNet-152 which is too big to be loaded in four whimpy GPUs in our cluster becomes 39% faster by using all the GPUs (including whimpy ones).

Strategies to leverage PMP have been explored in previous studies [7, 19, 27, 38]. Compared to these, our study makes forward strides in three aspects. First, we generalize PMP of a virtual worker to be used together with DP of virtual workers, increasing the parallelism of DNN model training. Consequently, this results in speeding up training. Second, we consider a heterogeneous GPU cluster, which allows the use of GPUs, which otherwise, could not be used for training. Finally, we present a parameter synchronization model that guarantees convergence, of which we provide a proof, for training models using PMP with DP. We provide a more in-depth comparative discussion on these studies in Section 2.2.

2 Background

2.1 Data Parallelism

Training of a DNN model is processed by a *forward pass* followed by a *backward pass* for each *minibatch*, which is a subset of training samples, in a popularly used *stochastic gradient descent* (SGD) method. For each minibatch, the weight updates, i.e., *gradients*, are computed to update weights (or parameters) w of the model.

Data parallelism (DP) utilizes multiple workers to speed up training of a DNN model. It divides the training dataset into subsets and assigns each worker a different subset. Each worker has a replica of the DNN model and processes each minibatch in the subset, thereby computing the weight updates. Therefore, if a DNN model cannot be loaded into the memory of a single GPU, DP cannot be used.

Among the multiple workers, the parameters are synchronized using parameter servers [31] or AllReduce communications [32, 50]. For *Bulk Synchronous Parallel* (BSP) [1, 35], each worker must wait for all other workers to finish the current minibatch p before it starts to process the next minibatch $p+1$ so that it can use an updated version of the weights for minibatch $p+1$. For *Asynchronous Parallel* (ASP) [1, 48], each worker need not wait for other workers to finish minibatch p, possibly using a stale version of the weights. With BSP, which is possible for both the parameter servers and

AllReduce communications, the system may suffer from high synchronization overhead, especially in a heterogeneous GPU cluster where each worker with a different GPU provides different training performance [33]. On the other hand, while ASP, which is possible for the parameter servers, has no synchronization overhead, it is known that ASP does not ensure convergence [48, 58].

A method that takes the middle ground between BSP and ASP is *Stale Synchronous Parallel* (SSP) [18]. With SSP, each worker is allowed to proceed the training of minibatches using a *stale* version of the weights that may not reflect the most recent updates computed by other workers. Thus, workers need not synchronize with other workers whenever it finishes the processing of a minibatch. As such, parameter staleness can occur. However, this staleness is bounded as defined by the user and referred to as the *staleness threshold*. As SSP is beneficial when worker performance is varied, it has been explored especially in the context of heterogeneous systems [24].

In SSP, each worker periodically pushes the weight updates to the parameter server. This synchronization interval is called a *clock*. Thus, each worker increases its local clock by one for every iteration, which is the training period of a minibatch. For a given staleness threshold s where $s \geq 0$, each worker with clock c is allowed to use a stale version of the weights, which includes all the updates from iteration 0 to $c-s-1$ and, possibly, more recent updates past iteration $c-s-1$. That is, a worker can continue training of the next minibatch with parameters whose updates may be missing from up to the s most recent minibatches.

2.2 Model Parallelism and Pipeline Execution

Model parallelism (MP) is typically exploited for large DNN models that are too large to be loaded into memory of a single GPU. In particular, a DNN model composed of multiple layers is divided into k partitions and each partition is assigned to a different GPU. Each GPU executes both the forward and backward passes for the layers of the assigned partition. *Note that it is important to execute the forward and backward passes of a partition on the same GPU* as the activation result computed for the minibatch during the forward pass needs to be kept in the GPU memory until the backward pass of the same minibatch for efficient convergence, as similarly discussed by Narayanan and others [38]. Otherwise, considerable extra overhead will incur for managing the activation through either recomputation or memory management.

In the basic form of MP, k GPUs, individually, act as one *virtual worker* to process a minibatch as follows: For each minibatch, execution of the forward pass starts from GPU$_1$ up to GPU$_k$. When each GPU$_i$, where $1 \leq i < k$, completes the forward pass of the assigned partition, it sends the computed activations of *only the last layer in its partition* to GPU$_{i+1}$. Once GPU$_k$ finishes the forward pass of its partition, the backward pass of the minibatch is executed from GPU$_k$ down to GPU$_1$. When each GPU$_{i'}$, where $1 < i' \leq k$, finishes the backward pass, it sends the computed local gradients of *only the first layer in its assigned partition* to GPU$_{i'-1}$. This basic form of MP results in low GPU utilization as only one GPU is actively executing either the forward or backward pass. Nonetheless, MP allows execution of large DNN models that are too large for a single GPU.

Table 2: Comparison of HetPipe with GPipe and PipeDream

	GPipe	PipeDream	HetPipe
Heterogeneous Cluster Support	No	No	Yes
Target Large Model Training	Yes	No	Yes
Number of (Virtual) Workers	1	1	N
Data Parallelism	Extensible	Partition	Virtual Workers
Proof of Convergence	Analytical	Empirical	Analytical

To improve utilization of the GPUs in a virtual worker, minibatches can be processed in a pipelined manner. The subsequent minibatches are fed into the first GPU in MP (i.e., GPU$_1$) one by one once the GPU completes the processing of the previous minibatch. This allows for multiple GPUs to simultaneously execute either the forward or backward pass of their assigned layers for different minibatches. This is referred to as Pipelined Model Parallelism (PMP).

This PMP strategy has been investigated in previous studies [19, 38]. PipeDream exploits PMP of a single virtual worker to avoid the parameter communication overhead of DP [38]. Considering only homogeneous GPUs, when PipeDream partitions a model into stages to maximize pipeline performance, it does not take into account the memory requirement of a GPU that depends on the stage of a pipeline. Thus, PipeDream processes a limited number of minibatches, which is large enough to saturate the pipeline, to reduce memory overhead. PipeDream also provides a form of DP, but it considers DP within a virtual worker to speed up the execution of lagging layers. No proof of single pipeline convergence is provided in PipeDream. Note that without a parameter synchronization model such as WSP, it is not possible to properly run DP over multiple PipeDream virtual workers via parameter servers or AllReduce communication.

GPipe is a scheme that leverages PMP of a single virtual worker to support large DNN models, also in a homogeneous GPU cluster [19]. In GPipe, a minibatch is divided into multiple *microbatches* that are injected into the pipeline. Using the same weights, GPipe executes the forward passes for all the microbatches, and then executes the backward passes for them. When the backward pass of the last microbatch is done, it updates the weights all together for the minibatch. GPipe incurs frequent pipeline flushes, possibly resulting in low GPU utilization [38]. In GPipe, DP of multiple virtual workers can be done using existing synchronization schemes like BSP as a virtual worker processes one minibatch at a time. GPipe saves on GPU memory by recomputing the activations again in the backward pass instead of keeping the activations computed in the forward pass in memory. We do not use this optimization though there are no fundamental reasons forbidding it. A comparison of HetPipe with previous studies is given in Table 2.

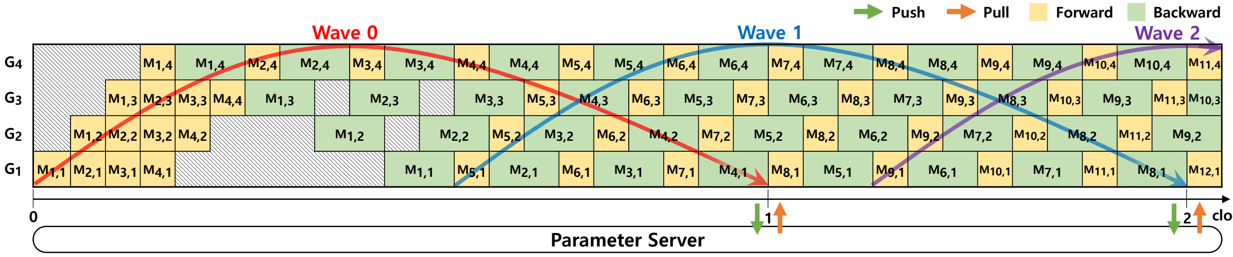

Figure 1: Pipeline execution of minibatches where $M_{p,k}$ indicates the execution of a minibatch p in partition k, which is executed in GPU$_k$ and the yellow and green colors indicate the forward and backward passes, respectively.

3 System Overview

The system that we propose focuses on training a large DNN model in a *heterogeneous GPU cluster* composed of various types of GPUs that have different computation capability and memory capacity. In such settings, for some types of GPUs in the cluster, the DNN model of interest may be too large to be loaded into the memory of a single GPU. The system that we propose in this paper leverages both pipelined model parallelism (PMP) and data parallelism (DP) to enable training of such large DNN models and, in the process, enhance performance as well as the utilization of the heterogeneous GPU resources of the cluster.

Figure 2 shows the architecture of the proposed cluster system composed of H nodes. Each node comprises a homogeneous set of GPUs, but the GPUs (and memory capacity) of the nodes themselves can be heterogeneous. Two key novelties exist in this architecture. First, DP is supported through a notion of a *virtual worker* (VW), which consists of k, possibly heterogeneous, GPUs, and encapsulates the notion of a worker in typical DNN systems. That is, a virtual worker is used to train the DNN model. In Figure 2, note that there are N virtual workers with 4 GPUs each, that is, $k = 4$, and that the GPUs comprising the virtual worker may be different for each virtual worker. While in this paper we consider k to be constant for each virtual worker, our design does not restrain it to be so; this is simply a choice we make for simplicity. The key aspect here is that a virtual worker allows DP by aggregating GPUs possibly even when individual GPUs may be resource limited.

The second novelty is that each virtual worker processes each minibatch based on model parallelism, in a pipelined manner, to fully utilize the GPU resources, as shown in Figure 1, to accommodate large DNN models. While PMP has been proposed before (which we compare in Section 2.2), to the best of our knowledge, we are the first to present PMP in a heterogeneous setting. We refer to our system as *HetPipe* as it is *het*erogeneous, in GPUs, across and, possibly, within virtual workers and makes use of *pipe*lining in virtual workers for resource efficiency.

To train DNN models based on pipelined model parallelism in virtual workers, the *resource allocator* first assigns k GPUs to each virtual worker based on a resource allocation policy (which will be discussed in Section 8.1). Note that for allocating the heterogeneous GPUs to the virtual workers, the resource allocation policy must consider several factors such as the performance of individual GPUs as well as the communication overhead caused by sending activations and gradients within a virtual worker, and synchronizing the weights among the virtual workers and the parameter server. Then, for the given DNN model and allocated k GPUs, the *model partitioner* divides the model into k partitions for the virtual worker such that the performance of the pipeline executed in the virtual worker can be maximized.

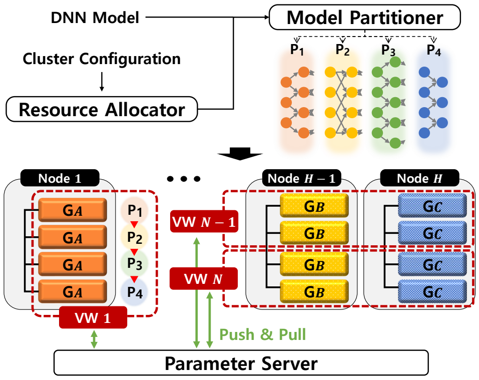

Figure 2: System architecture (VW: Virtual Worker)

As any typical DP, multiple virtual workers must periodically synchronize the global parameters via parameter servers or AllReduce communication; in HetPipe, parameter servers are used to maintain the global weights. Each virtual worker has a local copy of the global weights and periodically synchronizes the weights with the parameter server. Evidently, when managing the weights within a virtual worker and across virtual workers, two types of staleness, *local staleness* and *global staleness*, need to be permitted to improve the performance of DNN training. Local staleness refers to staleness within a virtual worker. As each virtual worker processes minibatches in a pipelined manner, there are multiple minibatches that are being processed in parallel. Thus, staleness is inevitable as weights seen by a minibatch may not reflect the updates of all of its previous minibatches.

Global staleness, on the other hand, is similar to the staleness notion introduced by Ho et al. [18]. That is, the system needs to reduce communication overhead between the parameter server and (virtual) workers, and, in our case, also mitigate the synchronization overhead caused by possibly heterogeneous virtual workers. Therefore, similarly to SSP [18], each virtual worker should be allowed to proceed training without querying the global weights for every minibatch, unless its local copy is so old such that there are too many missing recent updates made by other virtual workers. Note that such staleness condition is set by the user [18].

For our system, we propose the *Wave Synchronous Parallel* (WSP) model to synchronize the weights. A *wave* is a sequence of minibatches that are processed concurrently in a virtual worker. Let the number of minibatches in a wave be N_m. Within a wave, processing of the i-th minibatch is allowed to proceed without waiting for the preceding minibatchs i' to be completed, where $1 < i \leq N_m$ and $1 \leq i' < i$. That is, there is no dependency among the weights used by minibatches in the same wave. As the virtual worker does not enforce the updates even from the first minibatch in a wave to be reflected in the weights used by the last minibatch, the local staleness threshold in WSP is $N_m - 1$. Moreover, *each virtual worker only pushes the aggregated updates from all the minibatches in a wave, instead of for every minibatch, to the parameter server.* This results in considerable reduction in communication overhead.

As it is important that the results generated through our proposed system configuration are correct [18, 24, 60], we show the convergence of our methodology in Section 6.

Note that HetPipe uses parameter servers, which may incur synchronization and communication overhead. However, HetPipe mitigates such overhead by permitting global staleness among virtual workers and executing the pipeline in each virtual worker such that it continues to process minibatches that have already been injected while waiting for the parameter update. We believe HetPipe can be further optimized by taking decentralized approaches, but leave this for future work.

4 Pipelined Model Parallelism Within a VW

Number of Minibatches in the Pipeline: In our system, each virtual worker processes up to N_m minibatches concurrently in a pipeline manner so that the executions of the minibatches can overlap. Given a DNN model and k GPUs, the maximum number of minibatches executed concurrently in the virtual worker, Max_m, is basically determined by the memory requirement for training the model. For a model that requires a huge amount of memory for output activations and weights, Max_m may be less than k. Note that in such cases, the utilization of each GPU is unlikely to be high.

N_m, the actual number of minibatches in the pipeline will be $N_m \leq Max_m$ and basically determined by considering the throughput of the pipeline. Note that N_m must be the same in every virtual worker, and thus, N_m is set to the minimum Max_m among all the virtual workers. N_m will affect the local staleness that we discuss later in this section.

Model Partitioning: To train a DNN model, a set of k GPUs is allocated to a virtual worker by a resource allocation policy, which we discuss in Section 8.1. For now, let us assume that k, the number of possibly heterogeneous GPUs, and N_m are given. Then, a partitioning algorithm is employed to divide multiple layers of the model into k partitions, assigning them to the k different GPUs. The goal of the partitioning algorithm is to maximize the performance of the pipeline, while satisfying the memory requirement of each partition to process N_m minibatches.

In particular, in this study, for memory, we consider the fact that the actual memory requirement will vary depending on the stage of the pipeline that the GPU is used for. For example, contrast GPU$_4$ and GPU$_1$ in Figure 1. GPU$_4$, the GPU that handles the last stage of the pipeline, handles only one minibatch at a time and is immediately done with the minibatch as exemplified by the yellow (forward pass) and green (backward pass) M$_{i,4}$ pairs for $i = 1, 2, ...,$ that are side-by-side. In contrast, for GPU$_1$, the yellow and green M$_{i,1}$ pairs are far apart, meaning that the forward pass M$_{i,1}$ needs to hold up memory until the backward pass M$_{i,1}$ is finished with its execution. Thus, with GPU$_1$, the memory requirement is high as it needs to hold on to the results of the forward pass for all stages of the pipeline. This variance in memory requirement is considered in partitioning the layers.

Execution time must also be considered when partitioning the layers. To do so, we calculate the execution time of a partition to be the sum of the computation time of all the layers in the partition and the communication time needed for receiving the activations (in the forward pass) and local gradients (in the backward pass). Our partitioning algorithm attempts to minimize the maximum execution time of the partitions within the bounds of satisfying the memory requirement.

Partition Scheduling: Once the partition is set, the partitions need to be scheduled for each of the GPUs. Each GPU$_q$ responsible for partition q may have multiple forward pass and backward pass tasks to schedule at a time. Each GPU schedules a task by enforcing the following conditions:

1. A forward pass task for a minibatch p will be executed only after a forward pass task for every minibatch p' is done where $1 \leq p' < p$.
2. Similarly, a backward pass task for a minibatch p will be executed only after a backward pass task for every minibatch p' is done where $1 \leq p' < p$.
3. Among multiple forward and backward pass tasks, a FIFO scheduling policy is used.

Note that in the last partition, for a minibatch, processing a forward pass immediately followed by a backward pass is executed as a single task.

Considering Staleness: Given the description of pipelining, the question of staleness of weights used needs to be considered. That is, as a minibatch is scheduled, it may be that the layers are not using the most up-to-date weights. For example, in Figure 1, when the forward pass M$_{2,1}$, the second minibatch, begins to be processed, it must use stale weights as the first minibatch has not completed and hence, the changes in the weights due to the first minibatch have not yet been appropriately reflected, which is in contrast with typical processing where minibatches are processed one at a time. We now discuss how this staleness issue is considered.

Let *local staleness* be the maximum number of missing updates from the most recent minibatches that is allowed for a minibatch to proceed in a virtual worker. As training with N_m minibatches can proceed in parallel in a virtual worker, the local staleness threshold, s_{local}, is determined as $N_m - 1$, where $1 \leq N_m \leq Max_m$. If $N_m = 1$, the behavior is exactly the same as naive model parallelism. Larger N_m may improve the performance (i.e., throughput) of the pipeline as a larger number of concurrent minibatches are executed, but local staleness increases, possibly affecting the convergence of training. In a real setting, typically, N_m will not be large enough to affect convergence as it will be bounded by the total amount of GPU memory of a virtual worker.

Such local staleness also exists in PipeDream [38]. As PipeDream basically employs weight stashing that uses the latest version of weights available on each partition to execute the forward pass of a minibatch, a different version of weights is used across partitions for the same minibatch. Unfortunately, PipeDream only shows empirical evidence of convergence when weight stashing is used. Note that PipeDream also discusses vertical sync, which is similar to HetPipe, but it excludes vertical sync in its evaluations [38].

Now let w_p be the weights used by minibatch p. Then, initially, we can assume that w_0, the initial version of weights, is given to the virtual worker. Then, the first $(s_{local} + 1)$ minibatches are processed in a pipelined manner with $w_0 = w_1 = \cdots = w_{s_{local}} = w_{s_{local}+1}$.

To accommodate staleness in our system, when processing of minibatch p completes, the virtual worker updates the local version of the weights, w_{local} as $w_{local} = w_{local} + u_p$, where u_p is the updates computed by processing minibatch p. Therefore, in HetPipe, weights are not updated layer by layer and w_{local} is a consistent version of weights across partitions. When the virtual worker starts to process a new minibatch, it makes use of the latest value of w_{local} without waiting for the other minibatches to update their weights. For example, once the virtual worker is done for minibatch 1 and updates w_{local} with u_1, it will start to process minibatch $s_{local} + 2$ by using the updated weights without waiting for minibatches 2 up to $s_{local} + 1$ to be completed. Similarly, when the virtual worker is done with minibatch $s_{local} + 1$ and updates w_{local} with $u_{s_{local}+1}$, it will start to process minibatch $2 \times (s_{local} + 1)$ without waiting for the previous most recent s_{local} minibatches to be completed. Therefore, except for the initial minibatches 1 to $s_{local} + 1$, for minibatch p the virtual worker will use the version of the weights that reflects (at least) all the local updates from minibatches 1 to $p - (s_{local} + 1)$. Note that for every minibatch p, w_p must be kept in GPU memory until the backward pass for p is executed.

Note that staleness in SSP is caused by the different processing speed of minibatches among multiple workers. Thus, in SSP, staleness is used as a means to reduce the synchronization and communication overhead. However, local staleness in HetPipe is caused inherently as minibatches are processed in a pipelined manner within a virtual worker.

5 Data Parallelism with Multiple VWs

In this section, we discuss data parallelism (DP) with virtual workers. The first and foremost observation of DP being supported with virtual workers is that the virtual workers may be composed of (whimpy) heterogeneous GPUs. While it is well known that DP helps expedite DNN execution, DP, in typical systems, is not possible if individual GPUs, that is, workers, do not have sufficient resources to handle the DNN model, in particular, large DNNs. By allowing a virtual worker to be composed of multiple GPUs that are lacking in resources, our system allows DP even with whimpy GPUs. The other key observation in properly supporting DP with virtual workers is that each virtual worker now retains local staleness as discussed in Section 4. Making sure that, despite such individual staleness, we understand and show that the results obtained from DP among virtual workers (globally) converge is an important issue that must be addressed. The rest of the section elaborates on this matter.

Workings of WSP: As stated in the system overview, HetPipe uses parameter servers. We assume that such synchronization occurs in *clock* units, a notion taken from SSP [18]. Precisely, a clock unit is defined as the progress of completing one wave. Recall from Section 3 (and Figure 1) that a wave is a sequence of $s_{local} + 1$ minibatches concurrently executed such that a virtual worker is allowed to process a later minibatch in a wave without updates from an earlier minibatch in the same wave.

Similarly to SSP (which, however, considers the staleness of weights only in DP), each virtual worker maintains a local clock c_{local}, while the parameter server maintains a global clock c_{global}, which holds the minimum c_{local} value of all the virtual workers. Initially, the local clocks and the global clock are 0. At the end of every clock c, each virtual worker completes the execution of all the minibatches in wave c. At this point, the virtual worker computes the aggregated updates from minibatch $c \times (s_{local} + 1) + 1$ to minibatch $(c+1) \times (s_{local} + 1)$ and pushes the updates $\tilde{u}$ to the parameter server. We see that, similar to in SSP [18], $\tilde{u}$ is synchronized with a clock value c. For example, as shown in Figure 1 where $s_{local} = 3$, at the end of clock 0, the virtual worker pushes the aggregated updates of wave 0, which is composed of minibatches from 1 to 4, and at the end of clock 1, the aggregated updates of wave 1, which is composed of minibatches from 5 to 8, and so on. It is important to note that in WSP, the virtual worker pushes $\tilde{u}$ to the parameter server for every wave, instead of pushing $\tilde{u}$ for every minibatch, which will significantly reduce the communication overhead.

When the parameter server receives the updates ũ from the virtual worker, the parameter server updates the global version of the weights as $w_{global} = w_{global} +$ ũ. Note that the parameter server updates its c_{global} to $c+1$ only after every virtual worker has pushed the aggregated updates of wave c.

In WSP, each virtual worker is allowed to proceed training without retrieving the global weights for every wave. Thus, the virtual worker may use a weight version that, from a global standpoint, may be stale, as the most recent updates received by the parameter servers may not be reflected in its local version of the weights. We discuss how global staleness among the virtual workers is bounded.

Global Staleness Bound: Let *clock distance* be the difference in c_{local} between the fastest and slowest virtual workers in the system. Therefore, a virtual worker with local clock c, where $c \geq D+1$, must use a version of the weights that includes all the (aggregated) updates from wave 0 up to $c-D-1$. Also, the weight version may include some recent global updates from other virtual workers and some recent local updates within the virtual worker beyond wave $c-D-1$.

When a virtual worker pulls the global weights at the end of clock c to maintain this distance, it may need to wait for other virtual workers to push their updates upon completion of wave $c-D$. However, while a virtual worker waits for other virtual workers to possibly catch up at the end of clock c, local processing is allowed to proceed with s_{local} minibatches of wave $c+1$ as the minibatches are executed in a pipelined manner. Take, for example, the case when $D=0$ and $s_{local}=3$ in Figure 3 (and Figure 1). As a virtual worker, VW1, completes minibatch 4, it computes the aggregated updates ũ for wave 0 (composed of minibatches 1 to 4) and pushes ũ to the parameter server. VW1 now waits for the other virtual workers to complete wave 0 before proceeding with minibatch 8. However, note that as shown in the figure, VW1 has already started to process minibatches 5, 6 and 7, which belong to wave 1, while its local clock is still 0. Similarly, once it completes minibatch 8, it pushes the aggregated updates ũ for wave 1 (composed of minibatches 5 to 8) to the parameter server; in the meantime, it has already started processing minibatches 9, 10, and 11, which belong to wave 2, while its clock is still 1.

Note that this processing of local minibatches in the virtual worker does not violate the local staleness bound. Note also that when $D=0$, each virtual worker must wait for each other at the end of every clock to synchronize the weights for every wave, which is BSP-like behavior with pipelined execution in each virtual worker.

Now let us define the *global staleness bound*, s_{global}, to be the maximum number of missing updates from the most recent minibatches, *globally computed by all the other virtual workers in the system*, that is allowed for a minibatch to proceed in a virtual worker. We want to identify s_{global} based on our discussion so far. This will allow each virtual worker to determine whether it can proceed with its current minibatch.

Initially, all virtual workers start processing the first $(D+1)$ waves without querying the global weights from the parameter server. Furthermore, they can start to process up to s_{local} minibatches of the next wave before receiving the global weights that include the recent updates as discussed above. Therefore, for those initial minibatches, the virtual worker uses w_0 or a weight version that may include some recent local updates.

Figure 3: Local and global staleness with WSP

For any minibatch p thereafter, that is, where $p > (D+1) \times (s_{local}+1) + s_{local}$, p must use a weight version that reflects, at the very least, all the global updates from all the other virtual workers from minibatch 1 to minibatch $p - (s_{global}+1)$, where $s_{global} = (D+1) \times (s_{local}+1) + s_{local} - 1$. The first term of this equation is due to the fact that a virtual worker is allowed to proceed with the next $(D+1)$ waves (i.e., $(D+1) \times (s_{local}+1)$ minibatches), and the second term is due to the additional s_{local} minibatches that can be started because of pipelined execution. Continuing with the example in Figure 3, where $D=0$ and $s_{local}=3$, VW1 proceeds the training of minibatch 11 without the global and/or local updates from wave 1 (minibatches 5 to 8) or the two local updates from minibatches 9 and 10 (i.e., having $s_{global}=6$). Thus, it must have a version of the weights that includes all the global updates from minibatches 1 to 4. Actually, the weight version used for minibatch 11 includes three local updates from minibatches 5, 6, and 7, along with all the global updates from wave 0. In case of minibatch 12, it cannot start the training until global updates up to minibatch 8 are received.

6 Convergence Analysis

In this section, we discuss the convergence property of the WSP model. Let N be the number of virtual workers and $u_{n,p}$ be the update of worker n at minibatch execution p. Let $s_g = s_{global}$ and $s_l = s_{local}+1$, and following the analysis of [18], the noisy weight parameter[1] $\tilde{w}_{n,p}$ for worker n at minibatch execution p, is decomposed into

$$\tilde{w}_{n,p} = w_0 + \left[\sum_{n'=1}^{N} \sum_{p'=1}^{p-s_g-1} u_{n',p'}\right] + \left[\sum_{p' \in \mathcal{C}_{n,p}} u_{n,p'}\right] + \left[\sum_{(n',p') \in \mathcal{E}_{n,p}} u_{n',p'}\right]. \quad (1)$$

[1] In this section, we use the term 'weight parameter' to denote all weights of a network. Thus, the weight parameters refer to a set of weights of networks.

Here w_0 refers to the initial parameter, and the noisy weight parameter has three other terms which respectively include

1. updates of all workers (guaranteed to be included) to process minibatch execution p,
2. $\mathcal{C}_{n,p} \subseteq [p-s_g, p-1]$: the index set of the latest updates of the querying worker n in the range of current global staleness bound, and
3. $\mathcal{E}_{n,p} \subseteq ([1,N] \backslash \{n\}) \times [p-s_g, p+s_g+s_l]$: the index set of extra updates of other workers in the range of the current global staleness bound. When execution p is not at a synchronization point, $\mathcal{E}_{n,p} = \emptyset$.

We define $\{u_t\}$ as the sequence of updates of each virtual worker after processing each minibatch and $\{w_t = w_0 + \sum_{t'=0}^{t-s_l N} u_{t'}\}$ as the reference sequence of weight parameters, where $u_t := u_{t \bmod N, \lfloor t/N \rfloor + t \bmod s_l}$, in which we loop over the workers ($t \bmod N$) and over each update after a minibatch execution inside a worker ($\lfloor t/N \rfloor + t \bmod s_l$). Here, $s_l N$ ($= s_l \times N$) is the number of total minibatch updates in one wave from all virtual workers. Since a virtual worker uses a version of the weight parameter that reflects all the local updates from minibatch 1 to $p - s_l$ for worker p, the reference and noisy sequences at iteration t are updated up to $t - s_l N$. The set $\mathcal{E}_t$ and the noisy weight parameter $\tilde{w}_t$ are defined similarly and the difference between w_t and $\tilde{w}_t$ is $\tilde{w}_t = w_t - \left[\sum_{i \in \mathcal{R}_t} u_i\right] + \left[\sum_{i \in \mathcal{Q}_t} u_i\right]$ where $\mathcal{R}_t$ is the index set of missing updates in the reference weight parameter but not in noisy weight parameter, and $\mathcal{Q}_t$ is the index set of extra updates in the noisy weight parameter but not in reference weight parameter.

After T updates, we represent the target function as $f(w) := \frac{1}{T}\sum_{t=1}^{T} f_t(w)$, the regret of two functions with $\tilde{w}_t$, the parameter learned from the noisy update, and w^*, the parameter learned from the synchronized update is $R[W] := \frac{1}{T}\sum_{t=1}^{T} f_t(\tilde{w}_t) - f(w^*)$.

Thus, when we bound the regret of the two functions, we can bound the error of the noisy updates incurred by the distributed pipeline staleness gradient descent. We first bound the cardinality of $\mathcal{R}_t$ and $\mathcal{Q}_t$ in the following lemma.

Lemma 1. *The following two inequalities, $|\mathcal{R}_t| + |\mathcal{Q}_t| \leq (2s_g + s_l)(N-1)$ and $\min(\mathcal{R}_t \cup \mathcal{Q}_t) \geq \max(1, t - (s_g + s_l)N)$, hold.*

Proof. Since $\mathcal{Q}_t \subseteq \mathcal{E}_t$ and $\mathcal{R}_t \subseteq \mathcal{E}_t \backslash \mathcal{Q}_t$, $|\mathcal{R}_t| + |\mathcal{Q}_t| \leq |\mathcal{E}_t| \leq (2s_g + s_l)(N-1)$. The second claim follows from $\mathcal{E}_t \supseteq \mathcal{R}_t \cup \mathcal{Q}_t$. □

With the following two assumptions, the proof of convergence generally follows Qirong et al. [18][2]

Assumption 1. ***(L-Lipschitz components)*** *For all t, the component function f_t is convex and has bounded subdifferential $\|\nabla f_t(w)\| \leq L$, in which $L > 0$ is a constant.*

Assumption 2. ***(Bounded distances)*** *For all w, w', the distance between them is bounded $D(w\|w') \leq M$, in which $M > 0$ is a constant.*

We also denote $\frac{1}{2}\|w - w'\|^2$ as $D(w\|w')$. Then, we can bound the regret of the function trained with our noisy distributed, pipeline update as in Theorem 1.

Theorem 1. *Suppose w^* is the minimizer of $f(w)$. Let $u_t := -\eta_t \nabla f_t(\tilde{w}_t)$ where $\eta_t = \frac{\sigma}{\sqrt{t}}$ with $\sigma = \frac{M}{L\sqrt{(2s_g+s_l)N}}$, in which M, L are the constants defined in the assumptions. Then the regret is bounded as $R[W] \leq 4ML\sqrt{\frac{(2s_g+s_l)N}{T}}$.*

Our theoretical results are similar with existing work on non pipelined version of staleness update [18, 24]. However, we reflect the new characteristics of distributed pipeline staleness update in Lemma 1, and thus in Theorem 1.

7 Partitioning Algorithm

Recall that the goal of our partitioning algorithm is to minimize the maximum execution time of the partitions within the bounds of satisfying the memory requirement. To obtain a performance model to predict the execution time of each layer of a model in a heterogeneous GPU, we first profile the DNN model on each of the different types of GPUs in a cluster, where we measure the computation time of each layer of the model. For GPU memory usage, we measure the usage of each layer (by using the logging feature of TensorFlow) on only one GPU type (as it is roughly the same for all GPU types). For profiling the memory usage on a whimpy node, we measure the memory usage of each layer using a small batch size and then multiply it for the target batch size. To compute the memory requirement for a given partition, we take into account the total memory usage to store the data to process the layers as well as the maximum number of minibatches concurrently assigned to the partition.

For communication time between layers in the model, we first derive the amount of input data for each layer in the forward and backward pass from the model graph. For the given data size, we predict intra-node communication based on the PCI-e bandwidth, then multiply it by a scaling-down constant (which is similarly done in Paleo [46]), since in practice, it is not possible to utilize the peak bandwidth. The scaling-down constant is derived by running a synthetic model that sends various sizes of data from one GPU to another GPU in the same node. For inter-node communication (via InfiniBand), we use linear regression to estimate the communication time for the given data size. To build a prediction model, we collect 27 samples by training two DNN models, used in our experiments, with arbitrary partitions. Note that in this work, the heterogeneity of network performance such as slow network links is not considered (as in [33]). However, for such cases, we can extend our partitioning algorithm to consider different network performance between two nodes when estimating the communication time. Also, a model that estimates the memory requirement for each stage more accurately will be helpful in partitioning a DNN model in a more balanced manner.

[2] The full proof is omitted due to space, but can be found in [44].

To find the best partitions of a DNN model, we make use of CPLEX, which is an optimizer for solving linear programming problems [20]. The memory requirement for each partition on the pipeline to support N_m concurrent minibatches is provided as a constraint to the optimizer. The algorithm will return partitions for a model with a certain batch size only if it finds partitions that meet the memory requirement for the given GPUs. Also, the optimizer checks all the different orders of the given heterogeneous GPUs for a single virtual worker to partition and place layers of the DNN model on them.

8 Experimental Results

8.1 Methodology

Heterogeneous GPU cluster: In our experiments, we use four nodes with two Intel Xeon Octa-core E5-2620 v4 processors (2.10 GHz) connected via InfiniBand (56 Gbps). Each node has 64 GB memory and 4 homogeneous GPUs. Each node is configured with a different type of GPU as shown in Table 1. Thus, the total number of GPUs in our cluster is 16. Each GPU is equipped with PCIe-3×16 (15.75 GB/s). Ubuntu 16.04 LTS with Linux kernel version 4.4 is used. We implement HetPipe based on the WSP model by modifying TensorFlow 1.12 version[3] with CUDA 10.0 and cuDNN 7.4.

DNN models and datasets Our main performance metric is throughput (images/second) of training a DNN model. We use ResNet-152 [16], and VGG-19 [51] with ImageNet [13]. For each DNN model, batch size of 32 is used. For all other hyperparameters, we use the default settings as specified in the benchmark [52] of ResNet-152 and VGG-19.

Resource allocation for virtual workers: Given any heterogeneous GPU cluster, there can be many ways of allocating the resources to the multiple virtual workers. For our experiments, we consider allocation policies within the bounds of our platform. Thus, given the 16 GPUs, HetPipe employs four virtual workers, each of which is configured with four GPUs, along the following three allocation policies.

Node Partition (NP): This policy assigns a node per virtual worker. Thus, each virtual worker is composed of homogeneous GPUs. Consequently, as the nodes are heterogeneous, partitioning of layers for a DNN model is different for each virtual worker. NP results in minimum communication overhead within each virtual worker as communication between GPUs occurs within the same node via PCI-e, rather than across multiple nodes where communication is via InfiniBand. On the other hand, as the performance of each virtual worker varies, a straggler may degrade performance with DP.

Equal Distribution (ED): This policy evenly distributes GPUs from each node to every virtual worker. Thus, every virtual worker is assigned four different GPUs, but every virtual worker has the exact same resources. Thus, model partitioning is the same, and thus, performance will be the same across the virtual workers, which mitigates the straggler problem. However, ED results in high communication overhead within each virtual worker.

Table 3: Resource allocation for the three policies considered

	Node Partition	Equal Distribution	Hybrid Distribution
VW1	VVVV	VRGQ	VVQQ
VW2	RRRR	VRGQ	VVQQ
VW3	GGGG	VRGQ	RRGG
VW4	QQQQ	VRGQ	RRGG

Hybrid Distribution (HD): This policy is a hybrid of NP and ED. For our cluster, a combination of two GPU types are allocated to each virtual worker such that their performances in terms of aggregated computation capability and amount of GPU memory are similar to each other. This choice is made to mitigate the straggler problem while reducing the communication overhead within each virtual worker. As, in terms of computation power, V > R > G > Q and, in terms of the amount of the GPU memory, R > V > Q > G, two virtual workers are allocated VVQQ, while the other two are allocated RRGG, where V, R, G and Q refers to TITAN V, TITAN RTX, GeForce RTX 2060, and Quadro P4000, respectively.

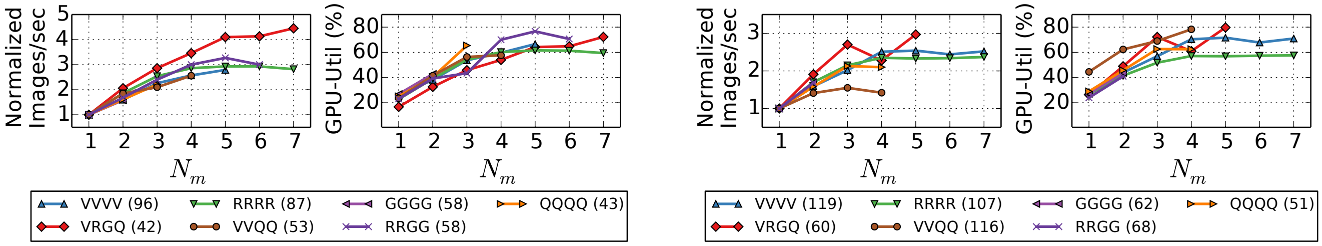
Table 3 shows the resource allocation of each virtual worker for the three resource allocation policies.

Parameter Placement: In our experiments, for DP, we locate the parameter servers, each of which only handles a portion of the model parameters, over all the nodes. For the *default* placement policy, which can be used with all three of our resource allocation policies, we place layers of the model in round-robin fashion over all the parameter servers as in TensorFlow [53]. For ED, however, another policy is possible, which we refer to as 'ED-local'. With 'ED-local', we place the layers of a partition on the parameter server running on the same node, incurring no actual network traffic across the nodes for parameter synchronization. This is possible as the same partition of the model can be assigned *locally* to the GPU on the same node for every virtual worker. For all results reported hereafter, the 'default' policy is used, except for 'ED-local'.

8.2 Performance of a single virtual worker

We first investigate the performance of the 7 different individual virtual workers that are possible according to the allocation schemes in Table 3. Figure 4 shows the throughput over various values of N_m, which is the number of minibatches executed concurrently, in the virtual worker normalized to that of when $N_m = 1$ and the maximum average GPU utilization among the four partitions for ResNet-152 and VGG-19. The numbers shown (in the box) along with the allocation policy are the absolute throughput (images/sec) when $N_m = 1$. Note that some results for larger N_m are not shown. This is because the GPU memory cannot accommodate such situations and hence, cannot be run.

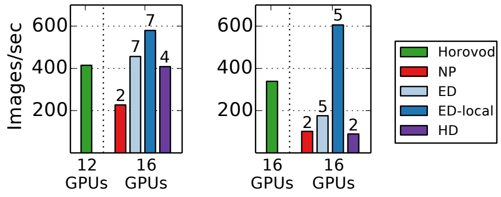
[3] Modified LOC is ~1.5K in the TensorFlow framework and TensorFlow benchmark codes, where most features are added as independent functions.



(a) ResNet-152

(b) VGG-19

Figure 4: Normalized throughput and the maximum average GPU utilization among partitions in a single virtual worker for various resource allocation policies as N_m is varied. The number in parenthesis is absolute throughput (images/sec) when $N_m = 1$ (which is equivalent to the naive MP) for each policy.



(a) ResNet-152

(b) VGG-19

Figure 5: Performance with the three allocation policies when D=0 (The number on bar represents N_m)

From the results, we can see that as N_m increases, normalized throughput of a virtual worker as well as the maximum GPU utilization generally increases. Note that, though not shown, the total GPU memory utilization tends to increase as N_m increases. However, depending on the resource allocation scheme (which results in different partitions of a model) as well as the DNN model, the effect of having larger N_m varies. When a virtual worker is configured with homogeneous GPUs, the average GPU utilization of each partition is similar to each other. However, when it is configured with heterogeneous GPUs, there is a tendency that the GPU utilization of the first or last partition is higher than those of the other partitions. For this configuration, different computation capabilities and memory capacity of the GPUs are considered when partitioning a model. As it is possible that only a small number of layers are assigned to some GPUs, the overall GPU utilization may turn out to be low.

8.3 Performance of multiple virtual workers

Figure 5 shows the throughput of training each model with the three resource allocation policies, where "Horovod" indicates the state-of-the-art DP via Horovod that uses AllReduce communication[4]. In these experiments, for each resource allocation policy, N_m is set such that performance is maximized while every virtual worker uses the same value of N_m as this is the assumption behind HetPipe. For ResNet-152, the whole model is too large to be loaded into a single GPU with G type, and thus, Horovod uses only 12 GPUs.

Table 4: Performance improvement of adding whimpy GPUs (The number in parenthesis presents the total number of concurrent minibatches in HetPipe)

Model	Single GPU [V]	Method	4 GPUs 4[V]	8 GPUs 4[VR]	12 GPUs 4[VRQ]	16 GPUs 4[VRQG]
VGG-19	159	Horovod	164	205	265	339
		HetPipe	300(5)	530(16)	572(20)	606(20)
ResNet-152	112	Horovod	233	353	415	X
		HetPipe	256(5)	516(20)	538(24)	580(28)

The results in Figure 5 show that the performance of DNN training is strongly affected by how heterogeneous GPUs are allocated to virtual workers. From the results, we can make the following observations: First, for VGG-19 whose parameter size is 548MB, the performance of Horovod, which reduces communication overhead for parameter synchronization, is better than those of NP, ED, and HD. However, for ResNet-152 whose parameter size is 230MB, ED and HD, which utilize virtual workers with similar performance, show a bit better or similar performance to Horovod (with 12 GPUs). Second, with NP, training performance of ResNet-152 and VGG-19 is low as N_m is bounded by the virtual worker with the smallest GPU memory. Third, with ED-local, intra-communication occurs between each GPU and the parameter server, significantly reducing communication overhead across the nodes, especially for VGG-19, the model with a large parameter set. For VGG-19, the amount of data transferred across the nodes per minibatch with ED-local (i.e., 103MB) is much smaller than that with Horovod (i.e., 515MB). Thus, the performance of ED-local (which also mitigates the straggler problem) is 1.8× higher than Horovod. For ResNet-152, the amount of data transferred with ED-local (i.e., 298MB) is larger than that with Horovod (i.e., 211MB) because the sizes of output activations to be sent between partitions are large, even though the parameter size is relatively small. However, the throughput of ED-local is still 40% higher than Horovod. This is because Hetpipe allows each virtual worker to process a large number of minibatches concurrently. Compared to NP and HD, ED-local (or ED) usually has larger N_m in each virtual worker, improving throughput.

[4] We use the same minibatch size for all workers of Horovod as the minibatch size is one of the critical factors to the final performance of a trained DNN and adaptive batch sizing will affect convergence [5].

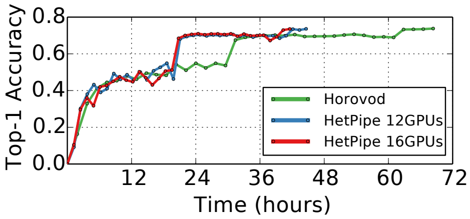


Figure 6: ResNet-152 top-1 accuracy

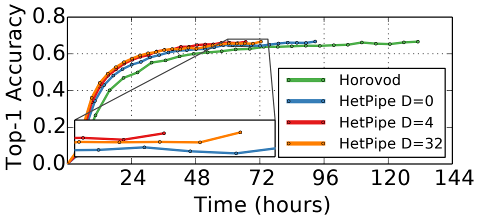

Figure 7: VGG-19 top-1 accuracy

Next, we investigate how the throughput is improved when whimpy GPUs are additionally used for training. Table 4 shows the throughput of VGG-19 and ResNet-152 when DP via Horovod and HetPipe with ED-local are used over different sets of heterogeneous GPUs, and also when a single V GPU is used. For these experiments, HetPipe is configured to use four virtual workers, except for '4 GPUs' where a single virtual worker is used. In the table, the number and type of GPUs used for each experiment are also given. From the results, we can see that the performance of both Horovod and HetPipe increases when additional whimpy GPUs are used for training. With additional GPUs, HetPipe can increase the total number of concurrent minibatches processed, having up to 2.3 times speedup. This scenario can be thought of as an answer to when new, higher end nodes are purchased, but one does not know what to do with existing nodes. The results show that making use of the whimpy systems allows for faster training of larger models.

8.4 Convergence

Our HetPipe based on the WSP model is guaranteed to converge as proven in Section 6. In this section, we analyze the convergence performance of HetPipe with ED-local using ResNet-152 and VGG-19. For our experiments, the desired target accuracy of ResNet-152 and VGG-19 is 74% and 67%, respectively.

Figure 6 shows the top-1 accuracy of ResNet-152 with Horovod (12 GPUs), HetPipe (12 GPUs), and HetPipe (16 GPUs), where D is set to 0 for HetPipe. For the experiments with 12 GPUs, the 4 G type GPUs are not used. When the same set of GPUs are used, convergence with HetPipe is 35% faster than that of Horovod by reducing the straggler problem in a heterogeneous environment and exploiting both PMP and DP. Furthermore, by adding four more whimpy G GPUs, HetPipe improves training performance even more, converging faster than Horovod by 39%.

Figure 7 shows the top-1 accuracy of VGG-19 with Horovod and HetPipe as we vary D to 0, 4, and 32. For the experiments, all 16 GPUs are used. The figure shows that convergence with the BSP-like configuration (i.e., $D = 0$) of HetPipe is roughly 29% faster than that with Horovod. As we increase D to 4, the straggler effect is mitigated and the communication overhead due to parameter synchronization is reduced. Thus, convergence is faster by 28% and 49% compared to $D = 0$ and Horovod, respectively. In this experiment with ED-local (where the training speed of each virtual worker is similar), when D becomes very large (i.e., 32), the throughput remains similar but the convergence performance degrades by 4.7%, compared to $D = 4$. This is because it is unlikely that the clock distance between the fastest and slowest virtual workers becomes as large as 32, but higher global staleness can degrade the convergence performance (similarly discussed in [18]). Note that though not shown, using larger D has a greater effect for HetPipe with NP, ED and HD resource allocation, and the different resource allocations only affect the set of heterogeneous GPUs used for each virtual worker and do not affect the convergence behavior.

We also analyze the synchronization overhead as D is varied. We find that as D increases, the waiting time of a virtual worker to receive the updated global weights decreases. In our experiments, the average waiting time with $D = 4$ is found to be 62% of that with $D = 0$. Furthermore, the actual idle time is only 18% of the waiting time as the virtual worker can continue to proceed in the pipeline while waiting.

9 Discussion

Comparison to PipeDream PipeDream [38], which is the closest related study, optimizes PMP of a single virtual worker, only employing DP for lagging layers within a virtual worker in homogeneous environments. To be adapted to heterogeneous environments, its partitioning algorithm must be extended to consider the different performance and memory sizes of heterogeneous GPUs, various orders of heterogeneous nodes used for a pipeline, and the memory requirement of the GPUs for partitions.

We run the training of ResNet-152 using PipeDream, which is implemented on PyTorch [37], in our heterogeneous GPU cluster described in Section 8.1. Since the partitioning algorithm does not consider heterogeneous GPUs, for each GPU type, we profile ResNet-152, then generate partitions of the model assuming that our cluster is configured with homogeneous GPUs with that type, and finally, measure the throughput of PipeDream with the partitions. All the computed configurations of the pipeline result in a large number of (i.e., 12 or 14) partitions. For example, with Q, the configuration is 4-2-1-1-1-1-1-1-1-1-1-1 indicating that the model is divided into 12 partitions where the first partition is executed by four GPUs with DP, the second one is executed by two GPUs with DP, and so on. For these configurations, we run experiments with various orders of the four different nodes and test using several batch sizes. (Note that we could not run training for some configurations due to out of memory errors.) The best throughput measured using PipeDream is 158. Recall that the throughputs of Horovod (with 12 GPUs) and HetPipe are 415 and 580, respectively. In this case, the performance of PipeDream for ResNet-152 is found to be low as a large number of partitions cause high network overhead, in addition to the sub-optimal partitions. Therefore, with PMP alone (i.e., single virtual worker), the performance benefit may become limited when a model is divided into numerous partitions. Instead of increasing partitions, running DP with multiple virtual workers like HetPipe can improve the parallelism of training and further improve performance in such cases.

Effect of imbalanced partitions Our partitioning algorithm attempts to balance partitions while satisfying the memory requirements. However, depending on the DNN model, computed partitions may be imbalanced. For example, for a model composed of a small number of layers, if one layer takes much longer to execute compared to other layers, the partitions may end up having different execution times. In this case, the performance of the pipeline will be degraded as in any other pipeline-based systems. Note that running DP for the slow partition to have a similar processing rate across all the partitions like PipeDream [38] will be a possible extension of HetPipe.

10 Related Work

Pipelining has been leveraged to improve the performance of machine learning systems [6, 7, 19, 32, 38]. A pipelining scheme is employed to handle expensive backpropagation [7]. Pipe-SGD pipelines the processing of a minibatch to hide communication time in AllReduce based systems [32]. A weight prediction technique is proposed to address the staleness issue in pipelined model parallelism [6]. Detailed comparisons of HetPipe with PipeDream [38] and GPipe [19] are provided in Section 2.2. Note that the feature of overlapping computation and communication, presented in PipeDream [38], will also improve the performance of our system. PipeDream employs the one-forward-one-backward scheduling algorithm for pipeline execution. Sophisticated schedulers that consider various factors such as heterogeneous configurations, the number of partitions, and the number of concurrent minibatches within a virtual worker, can potentially improve the performance of HetPipe. Techniques to optimize learning rates have been studied [15], which can also be applied to HetPipe to help converge faster.

Decentralized training systems that consider heterogeneous environments have also been studied [33, 34]. However, these techniques do not consider integration of DP with PMP, which allows support for large models that do not fit into single GPU memory. In AD-PSGD, once a mini-batch is processed, a worker updates the parameters by averaging them with only one neighbor which is randomly selected [33]. This is done asynchronously, allowing faster workers to continue. In theory, the convergence rate of AD-PSGD is the same as SGD. In principle, the contribution of AD-PSGD is orthogonal with the contributions of HetPipe in that we can extend our HetPipe further by adapting the idea of asynchronous decentralized update in AD-PSGD when there is a bottleneck in the parameter server. When it comes to the experimental evaluations, the performance of AD-PSGD is evaluated for DNN models whose sizes are 1MB, 60MB, and 100MB, which are smaller than the models we consider in HetPipe. For a decentralized training system, Hop [34] considers the bounded staleness and backup workers, and uses CIFAR-10 for performance evaluation on a CNN model.

There have been earlier efforts to employ DP and/or MP for model training. Project Adam uses both DP and MP to train machine learning models on CPUs [8]. Pal et al. combine DP and MP in a similar way as our system, but do not consider pipelining nor heterogeneous GPUs [43]. STRADS leverages MP to address the issues of uneven convergence of parameters and parameter dependencies [27]. FlexFlow considers utilizing parallelism in various dimensions such as sample, operator, attribute and parameters to maximize parallelization performance [23]. Bounded staleness has been explored where Jiang et al. present heterogeneity-aware parameter synchronization algorithms based on the SSP model [24], while Cui et al. analyze the effects of bounded staleness [11].

Hierarchical AllReduce performs the AllReduce operation in two levels [22]. This technique does not solve the straggler problem in a heterogeneous GPU cluster, as master GPUs in the second level will have different GPU types. BlueConnect is an efficient AllReduce communication library considering heterogeneous networks [9]; unfortunately, it also cannot handle stragglers caused by heterogeneous GPUs.

11 Conclusion

In this paper, we presented a DNN training system, HetPipe, that integrates pipelined model parallelism with data parallelism. Leveraging multiple virtual workers, each of which consists of multiple, possibly whimpy, heterogeneous GPUs, HetPipe makes it possible to efficiently train large DNN models. We proved that HetPipe converges and presented results showing the fast convergence of DNN models with HetPipe.

Abstract

Although machine learning (ML) and deep learning (DL) provide new possibilities into optimizing system design and performance, taking advantage of this paradigm shift requires more than implementing existing ML/DL algorithms. This paper reports our years of experience in designing and operating several production learning-augmented systems at Microsoft. AutoSys is a framework that unifies the development process, and it addresses common design considerations including ad-hoc and nondeterministic jobs, learning-induced system failures, and programming extensibility. Furthermore, this paper demonstrates the benefits of adopting AutoSys with measurements from one production system, Web Search. Finally, we share long-term lessons stemmed from unforeseen implications that have surfaced over the years of operating learning-augmented systems.

1 Introduction

Learning-augmented systems represent an emerging paradigm shift in how the industry designs modern systems in production today [33]. They refer to systems whose design methodology or control logic is at the intersection of traditional heuristics and machine learning. Due to the interdisciplinary nature, learning-augmented systems have long been widely considered difficult to build and require a team of engineers and data scientists to operationalize. To this end, this paper reports our years of experience in designing and operating learning-augmented systems in production at Microsoft.

The need of learning-augmented system design stems from the fact that heterogeneous and complex decision-makings run through each stage of the modern system lifecycle. These decisions govern how systems handle workloads to satisfy user requirements under a particular runtime environment. Examples include in-memory cache eviction policy, query plan formulation in databases, routing decisions by networking infrastructure, job scheduling for data processing clusters, document ranking in search engines, and so on.

Most of these decision-makings have been solved with explicit rules or heuristics based on human experience and comprehension. However, while heuristics perform well in general, they can be suboptimal as modern systems evolve. First, since many heuristics were designed at the time when computation and memory resources were relatively constrained, their optimality was often traded for execution cost. Second, since heuristics are typically designed for some presumably general cases, hardware/software changes and workload dynamics can break their intended usage or assumptions. Third, many modern systems have grown in complexity and scale beyond what humans can design heuristics for.

Recent advances in machine learning (ML) and deep learning (DL) have driven a shift in system design paradigm. Various efforts [6, 7, 16, 28, 34, 36, 48] have found success in formulating certain system decision-makings into ML/DL predictive tasks. Conceptually, from past benchmarks, ML/DL techniques can learn factors that impact the system behavior. For example, Cortez et al. [16] reported an 81% accuracy in predicting average VM CPU utilization, which translates to $\sim 6\times$ more opportunities for server oversubscription; Alipourfard et al. [7] reported near-optimal cloud configurations being predicted for running analytical jobs on Amazon EC2.

AutoSys is a framework that unifies the development process of several learning-augmented systems at Microsoft. AutoSys has driven decision-makings with ML/DL techniques, for several critical performance optimization scenarios. These scenarios range from web search engine, advertisement delivery infrastructure, content delivery network, to voice-over-IP client. Not only do these scenarios allow us to gain insights into the learning-augmented design, but they also reveal common design considerations that AutoSys should address.

Contributions. This paper makes the following key contributions, through reporting our years of experience in designing

This work was done when Lifei Zhu, Zhao Lucis Li, and Zibo Wang were interns at Microsoft Research.

and operating learning-augmented systems.

First, Section 2 analyzes the need for adopting the learning-augmented design, with concrete observations from modern systems in production. Due to its architectural similarities to most modern systems, this paper uses web search infrastructure (*Web Search*) as the target system scenario for performance optimization. We characterize sources of system complexity and operation complexity in modern systems, to contribute an understanding of the emergence of learning-augmented system design in industry.

Second, Section 3 describes the AutoSys framework that formulates a system decision-making as an optimization task. AutoSys incorporates proven techniques to address common design considerations in building learning-augmented systems. ***(1)*** To support scenario-specific decision-making, AutoSys employs a hybrid architecture – decentralizing inference plane for system-specific interactions such as actuations and exploration, and centralizing training plane for hosting an array of ML/DL algorithms with generalized abstractions. ***(2)*** To handle ad-hoc and nondeterministic jobs spawned by an optimization task, AutoSys employs a cross-layer solution – prioritizing jobs based on their expected gains towards solving the given optimization task and executing jobs in a container to satisfy heterogeneous job requirements in a resource-sharing environment. ***(3)*** To handle learning-induced system failures due to inference uncertainties, AutoSys incorporates a rule-based engine with hard rules authored by experts to check an inferred actuation's commands and assumptions.

Third, we report long-term lessons stemmed from the years of operations, and these lessons include higher-than-expected learning costs, pitfalls of human-in-the-loop, generality, and so on. Prior to sharing these lessons in Section 5, Section 4 quantifies benefits of the learning-augmented design, on Web Search's key application logic and data stores. Compared to years of expert tuning, Web Search exhibits an 11.5% reduction in CPU utilization for a keyword-based selection engine, 3.4% improvement in relevance score for a ranking engine, 16.8% reduction in key-value lookups for a datastore cluster, and so on. The core of AutoSys is open-sourced on GitHub (*https://github.com/Microsoft/nni*).

2 Background and Motivations

As system performance drives end-user experience and revenue, many modern systems are supported by large teams of engineers and operators. This section shares concrete observations in production, which have motivated the industry to transit to the learning-augmented system design. Particularly, we deep dive into one large-scale cloud system – the web-scale search service, or *Web Search*. Web Search is architecturally representative of modern systems, with fundamental building blocks of networking, application logic, and data stores.

2.1 Overview of Web-Scale Search

This section describes the Web Search design with respect to the fundamental building blocks of modern systems.

Distributed and Pipelined Infrastructure. Web Search realizes a multi-stage pipeline of networked services (c.f. Figure 1), to iteratively refine the list of candidate documents for a user search query. The first stage is *Selection service* which selects relevant documents from massive web indexes as candidates for subsequent Ranking service. It relies on both keyword-based and semantics-based matching strategies, i.e., KSE and SSE. Then, *Ranking service* orders these documents according to their expected relevance to the user query, by running the RE ranking engine. Finally, *Re-ranking service* adds additional web contents that are relevant to the user query, and it re-ranks search results. These additional contents are from sources such as stock and weather, and verticals such as news and images. Suppose the user query contains celebrity names, search results will likely have relevant news and images.

Application Logic. We present three applications implemented with rules, heuristics, and ML-based logic.

First, Selection service's Keyword-based engine (KSE) matches keywords in user queries and web documents, by looking up inverted web indexes. Queries are first classified into pre-specified categories. Each category corresponds to a physical execution plan, or a hand-crafted sequence of sub-plans to specify the document evaluation criteria. For example, one sub-plan can specify whether a query keyword should appear in the web document title/body/URL, and how many documents should be retrieved. Sub-plan knobs determine the trade-offs between search relevance and latency.

Second, Selection service's semantics-based engine (SSE) selects web documents with keywords semantically similar to the user query. The problem can be formulated as Approximate Nearest Neighbor (ANN) search [14, 47] in the vector space where keywords that share similar semantics are located in close proximity. The search strategy is an iterative process, and each step can take on one of the three possible actions: ***(1)*** identifying some anchors in the vector space by looking up the tree, ***(2)*** marking anchors' one-hop neighbors in the neighborhood graph as new anchors, and ***(3)*** terminating and returning the best anchors that we have seen. The action sequence determines how fast SSE returns semantically relevant document candidates.

Third, Ranking service's ranking engine (RE) implements a ranking algorithm based on high-performance LambdaMART [12], which uses Gradient Boosted Decision Trees (GBDT) [20]. GBDT is one of the sophisticated ranking algorithms hosted by Web Search, and each targets different query types, document types, languages, and query intentions. Since GBDT combines a set of sub-models to produce the final results, tuning RE requires data scientists to reason about how tuning each sub-model would impact the overall performance.

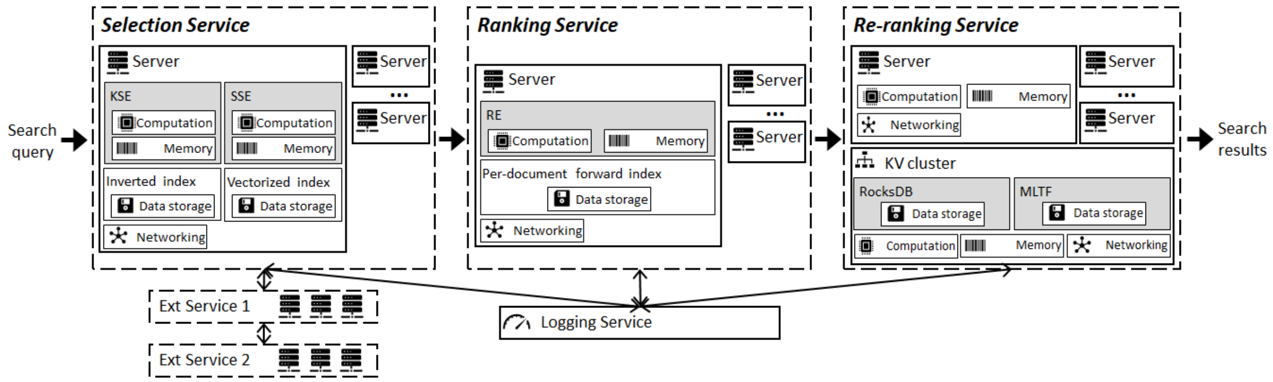

Figure 1: AutoSys drives transitions of several critical engines in Web Search to the learning-augmented design. These engines include *KSE* (Keyword-based Selection Engine), *SSE* (Semantics-based Selection Engine), *RE* (Ranking Engine), *RocksDB* key-value store engine, and *MLTF* (Multi-level Time and Frequency) key-value store engine. Since Web Search is architecturally similar to modern systems in general, AutoSys has also been applied to other production systems at Microsoft.

Data Store. One common data structure of web indexes is the key-value store. Web Search employs both open-sourced RocksDB, and customized solutions such as Multi-level Time and Frequency key-value store (MLTF). MLTF takes key access time and frequency as signals to decide cache evictions.

The index of SSE engine is organized in a mixed structure of space partition tree and neighborhood graph. Space partition tree is used to navigate the search to some coarse-grained subspaces while the neighborhood graph is used to traverse the keywords in these subspaces.

2.2 Sources of System Complexity

Heterogenous Classes of Decisions. Decision-makings in systems can be grouped into three classes: application logic, system algorithms, and system configurations. Each class requires human experts with different skill sets and experience.

First, application logic implements features that fulfill user requirements, so its decision-making process should adapt to user usage. In the case of Web Search, Ranking service hosts hundreds of lightweight and sophisticated ranking algorithms for different user query types and document types. Optimizing these ranking algorithms requires data scientists to have a deep understanding of how different ML/DL capabilities can be combined to match user preferences.

Second, the infrastructure implements system algorithms to better support application requirements with available resources. In the case of Web Search, Selection service has algorithms responsible for compiling user queries into physical execution plans that are specific to underlying hardware capabilities. Optimizing algorithms requires system designers to consider the relationship between application requirements and infrastructure capabilities.

Third, system configurations are knobs for operators to customize systems. Optimizing knobs requires a deep understanding of their combined effects on system behavior [50].

Multi-Dimensional System Evaluation Metrics. Optimizing multiple metrics can be non-trivial if they have different (and potentially conflicting) goals. For instance, Selection service has tens of metrics in different categories: resource usage, response latency, throughput, and search result relevance. Reasoning about the trade-offs among multiple metrics quickly becomes painstaking for humans, as the number of evaluation metrics increases. In some cases, system designers follow a rather conservative rule: improving some metrics without causing other metrics to regress. In fact, any software update in Web Search that can cause search quality degradation should not be deployed, even if it improves some crucial metrics such as the query latency for top queries.

Modern systems can also have meta-metrics that aggregate a set of metrics or measurements over a time period. One example is the "weekly user satisfaction rate" of Ranking service. To optimize these aggregated metrics, system operators need to understand their compositions.

End-to-End and Full-Stack Optimization. Modern systems are constructed with subsystems and components to achieve separation of concerns. Since the end-to-end system performance represents an aggregated contribution of all components, optimizing one component should consider how its outputs would impact others. For example, we have observed that Selection service may increase the number of potentially relevant pages returned, at the risk of increasing spam pages. If the subsequent Ranking service does not consider the possibilities of spam pages, it can hurt user satisfaction.

2.3 Sources of Operation Complexity

Environment Diversity and System Dynamics. While hardware upgrades and infrastructure changes can offer new capabilities, they potentially alter the existing system behavior. An example is how we altered the in-memory caching mechanism design, according to I/O throughput gaps between memory and mass storage medium for different data sizes. Furthermore, hardware upgrades might be rolled out in phases [41], and server resources can be shared with co-located tenants. Therefore, it is possible that instances of a distributed system face different resource budgets.

Modern systems have increasingly adopted tighter and more frequent software update cycles [39]. These software updates range from architecture, implementation, to even data. For example, Selection service has bi-annual major revisions to meet the increasing query volume and Web documents size, or even to adopt new relevance algorithms. And, Re-ranking service can introduce new data structures for new data types, or new caching mechanisms for the storage hierarchy. Finally, software behavior can change with periodic patches, bug fixes [54], and even the monthly index refresh.

Workload Diversity and Dynamics. Interestingly, there can be non-trivial differences among the workloads that individual system components actually observe. The reason is that subsystems can target different execution triggers, or depend on the outputs of others. For example, the list of candidate documents returned by Selection service predominately dictates the workload of Ranking service. And, if a large number of user queries do not have hits in web indexes, Ranking service would have low utilization. The same observation is applicable to the Re-ranking service.

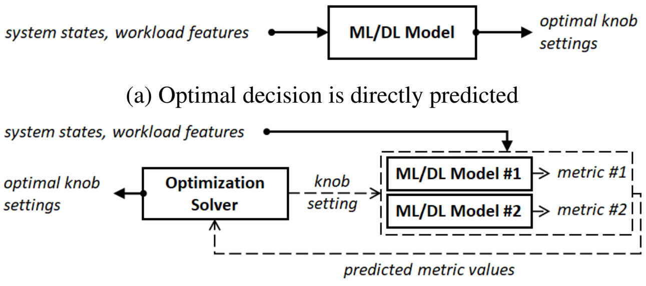
Furthermore, the workload can have temporal dynamics that are predictable and unpredictable, and an example is where the search keyword trend can shift with national holidays and breaking news, respectively.

Non-Trivial System Knobs. Modern systems can expose a large number of controllable knobs to system operators. These knobs include software logic parameters, hardware configurations, actions of an execution sequence, engine selections, and so on. Operation complexity arises from the following observations. A set of knobs can have dependencies [54], i.e., the effect of one knob depends on the setting of another knob. In addition, knobs should be set with the prior knowledge of runtime workloads and system specifications [52]. In the presence of system and workload dynamics, operators need to periodically adjust knob settings for optimal performance. Finally, software parameters can take values of several types: continuous numbers (e.g., 0 - 1,000), discrete numbers (e.g., 1 and 2), and categorical values (e.g., `ON` and `OFF`).

3 AutoSys

We introduce the *AutoSys* framework to unify the development of learning-augmented systems. While AutoSys has driven performance optimization for several production systems at Microsoft, our discussions here focus on Web Search.

Optimization Tasks. In AutoSys, a system decision-making is formulated as an optimization task. In the case of system performance optimization, the output of an optimization task contains optimal values of system knobs. The input consists of system and workload characteristics (e.g., traffic arrival rate). During execution, an optimization task can trigger a sequence of jobs of the following types: ***(1)*** system exploration jobs, ***(2)*** ML/DL model training and inferencing jobs, and ***(3)*** optimization solver. Next, Figure 2 illustrates two use cases of optimization tasks.



(a) Optimal decision is directly predicted

(b) Optimal decision is indirectly predicted

Figure 2: Heterogenous classes of decision-makings can be formulated as ML/DL optimization tasks. This figure illustrates two common realizations of optimization tasks.

Figure 2a illustrates the first case where AutoSys predominately learns from human experts, who handcraft the training dataset containing preferable knob settings for some system states and workloads. In this case, the model takes in system states and workload features as inputs, and directly infers the optimal knob settings. As one example implementation, AutoSys can assign a high reward for these preferable knob settings, and the model can implement value functions to find a policy that maximizes the reward for unforeseen inputs.

Figure 2b illustrates the second case where AutoSys predominately learns from interactive explorations with the target system. By automatically generating system benchmark candidates, AutoSys collects measurements to train models. In this case, the model takes in a knob setting and predicts the expected value of performance metrics. Based on these model predictions, an optimization solver can infer optimal knob settings. An example implementation of model and solver is regression models and gradient descent. For cases where a sequence of step-wise actions is necessary such as Selection service's search query plans, the solver can be based on reinforcement learning.

3.1 Design Principles

AutoSys follows the design principles below, to address common considerations in building learning-augmented systems.

To support scenario-specific decision-makings, AutoSys implements a hybrid architecture. Specifically, a centralized training plane is shared across all target systems, and decen-

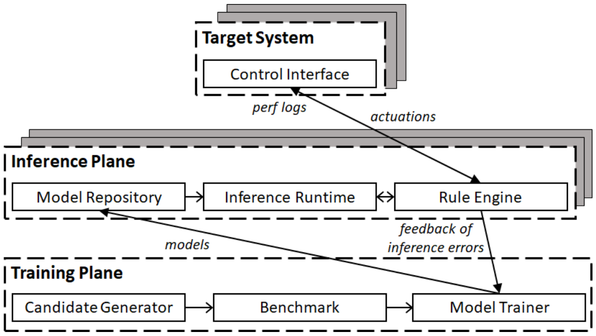


Figure 3: AutoSys framework. It centralizes training plane which hosts an array of ML/DL algorithms, and decentralizes inference plane for system-specific interactions such as actuations and exploration.

tralized inference planes are deployed for each target system. We observe that a centralized training plane promotes sharing data and trained models among scenarios – for example, this can help bootstrapping model training by initializing neural network weights and model hyper-parameters. Decentralized inference planes help distribute inference loads that grow with the system scale, and they also allow scenario-specific customizations such as verification rules.

To manage computation resources, AutoSys implements a cross-layer solution. Specifically, AutoSys abstracts scenarios as optimization tasks, and allows target systems to prioritize jobs spawned by their tasks. Unifying learning-augmented scenarios allows computation resources to be flexibly shared, especially since tasks are ad-hoc and non-deterministic. First, tasks are triggered in response to system dynamics, which might not exhibit a regular pattern. Second, jobs are determined at runtime according to the optimization task progress.

To handle learning-induced system failures, AutoSys implements a rule-based engine to validate actuations. Since most models mathematically encode knowledge learned, existing verification tools might not be applicable. On the other hand, rules are human-readable and human-verifiable.

3.2 Framework Overview

AutoSys executes an optimization task by spawning a number of jobs: ***(1)*** system exploration jobs, ***(2)*** ML/DL model training and inferencing jobs, and ***(3)*** optimization solver. Figure 3 shows the overall AutoSys framework to support these jobs.

Training Plane. The training plane implements features to support both system exploration jobs and ML/DL training jobs. Figure 4 shows the training plane workflow. The first step is candidate generation, which generates knob values to benchmark for the purpose of building up the training dataset. Considering the costs of running system benchmarks, the key is to balance the number of candidates and the model accuracy. Generation algorithms are wrapped in Tuner instances, and we

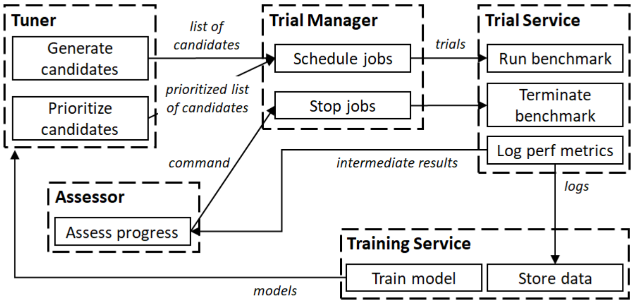

Figure 4: Workflow of training plane. System exploration jobs are wrapped in a Trial object, which collects system benchmark outputs for training models in the Training Service.

have implemented algorithms based on TPE [9], SMAC [26], Hyperband [30], Metis [31], and random search.

The second step is to benchmark configuration candidates. Trial Manager abstracts each system benchmark as a Trial object – the Trial object has fields holding ***(1)*** knob configurations, ***(2)*** execution meta-data: the command to run binaries and even ML/DL models (e.g., RE's hyper-parameter tuning), and metrics to log, ***(3)*** resource requirements (e.g., the number of GPU cores). In the case of KSE, SSE, MLTF, RocksDB engines, their Trial instances point to both the system executable and workload replay tool. The replay tool feeds a pre-recorded workload trace to the executable. In contrast, RE engine has a different goal of optimizing a ranking model's hyperparameters, its Trial instance contains the model and the dataset location. And, invoking `updateConfigs` updates model hyperparameters.

Table 2 presents the Trial Manager API. Invoking `startTrial` submits a Trial instance to Trial Service. At any time, `updateConfigs` can be called to change knob settings, and `getMetrics` can be called to retrieve metric measurements. A Trial can optionally assess its intermediate benchmark results, to decide whether it should terminate the benchmark early. To do so, Trial sends intermediate results to an Assessor instance implementing early-stopping criteria. If the criteria is met, Assessor can invoke Trial Manager's *stopJob*.

The third step is model training. Upon the completion of Trial instances, `getMetrics` outputs are merged with the corresponding knob settings to form a tabular dataset, for Training Service to train models. Historical results are optionally stored in data store, for model re-training or data sharing among similar scenarios.

Inference Plane. The inference plane implements features to support ML/DL inferencing jobs and optimization solver. Taking the current system states and workload characteristics as inputs, these jobs infer optimal actuations. These jobs are typically triggered by events, which are predefined by system operators to support service level agreements. For example, if the target system's workload changes (e.g., an increase in search queries per second), performance drops (e.g., a drop

Name	Description
`tuner.updateSearchSpace(args)`	Specify search space. *args* is a list of system knobs' names, value types, and value ranges.
`candidates = tuner.generateCandidates()`	Generate and return a list of configuration candidates.
`tuner.generateModel()`	Train the Tuner instance's model.

Table 1: Tuner instance API

Name	Description
`trial = submitTrial(args)`	Submit and deploy a benchmark trial. *args* include a configuration candidate, execution meta-data, and scheduling meta-data.
`trial.startTrial()`	Start a benchmark trial.
`trial.stopJob()`	Stop a benchmark trial.
`trial.updateConfigs(args)`	Update a trial's configuration candidate. *args* is a configuration candidate.
`measurements = trial.getMetrics()`	Return perf measurements of a trial.

Table 2: Trial Manager API

in tail latencies), or models update, inference plane initiates optimization tasks to make system tuning decisions. Furthermore, inference plane can be configured to directly actuate the target system, or simply inform system operators as suggestions. Finally, the inference plane can relay online system performance measurements to the training plane, for training.

3.3 Ad-hoc and Nondeterministic Jobs

In contrast to traditional systems, learning-augmented systems introduce jobs that are difficult for system operators to provision beforehand. First, optimization tasks are *ad-hoc* – they are triggered in response to adapting to system and workload dynamics, which might not exhibit a regular pattern. Second, optimization tasks have *nondeterministic* requirements – they spawn system exploration jobs and ML training jobs according to the optimization progress at runtime. To this end, AutoSys implements mechanisms to prioritize, schedule, and execute these jobs.

Job Prioritization. The tuner can prioritize the list of candidates in `generateCandidates`, to highlight benchmarks that are expected to subsequently improve model accuracy the most. Unnecessary benchmarks waste time and resources, especially for systems that require warm-up (e.g., in-memory cache warm-up). In this mode, training plane iterates between candidate generation, candidate prioritization, and model training.

We illustrate some of the candidate prioritization strategies that AutoSys Tuners have implemented. First, since the Metis Tuner uses Gaussian process (GP) regression model, it leverages GP's capability to estimate the confidence interval of its inference. A larger confidence interval represents lower inference confidence. And, it prioritizes candidates by sorting their confidence interval in descending order. Second, the TPE Tuner maintains two mixture models to learn the distribution of top-performing knob combinations [9]. It computes how likely a candidate belongs to this distribution, and prioritizes by sorting likelihood scores in descending order.

Job Scheduling. Trial Manager schedules Trials according to priorities and available resources, and passes this information to underlying infrastructure [3, 49]. Trials can impose heterogeneous resource requirements to support their corresponding decision-making scenarios. Taking system exploration jobs as an example – benchmarking ML/DL-learned system components in RE benefits from access to ML/DL acceleration hardware such as GPUs, but benchmarking MLTF KV engine must take place with SSDs. We note that scheduling learning jobs also have similar considerations. For learning approaches based on neural networks, their training jobs can be scheduled to machines with GPUs and TPUs [1] for acceleration. Some learning approaches such as Metis maintain a collection of ML models, and their training and inference time can significantly benefit from multiple CPU cores.

Job Execution. In addition to natively running system exploration jobs (i.e., Trial instances) on real machines, AutoSys also supports containers such as Docker [2]. The container image packages a Trial's software dependencies including the target system's binaries and libraries. Containers benefit AutoSys in the following ways. First, containers can be started and stopped to share hardware resources among multiple target systems. Second, previous efforts reported that containers exhibit a much lower overhead than virtual machines [19]. This improves the benchmark fidelity, hence AutoSys's training data quality. Second, the capability of deploying an image on heterogeneous machines easily enables benchmarking a target system under different hardware environments.

In addition to allocating short-lived containers that run only one benchmark, AutoSys also offers long-lived containers. For Trials with multiple benchmarks, long-lived containers effectively amortize the cost of initializing and loading the image. Furthermore, if consecutive benchmarking jobs need to share states (e.g., warmed-up caches) and data (e.g., weight sharing for tuning ML/DL model hyperparameters), contents in memory can be retained and reused.

3.4 Learning-Induced System Failures

Being stochastic in nature, ML/DL inference exhibits some degrees of uncertainty, and this uncertainty can lead to learning-induced system failures or suboptimality. While failures are not unique to learning-augmented systems [8], handling them requires a different approach for the following reasons. First, ML/DL models mathematically encode knowledge learned from the training data, the meaning of their internal weights is not interpretable to humans and common formal verification techniques. Second, as models autonomously learn from the training data, it is difficult to assess whether a dataset would guarantee a model to fully learn a particular concept.

Since it is hard to formally verify ML/DL correctness, AutoSys opts to validate ML/DL outputs with a rule-based engine. These validation rules are authored by operators, and the rule engine functions as a blacklist. Each rule specifies conditions of a violation to catch, and it has the following format: $(Predicate_1 \ AND|OR \ Predicate_2 ...)$. A predicate is one variable value comparison with operators such as $==$, $!=$, $>=$, $>$, $<=$, and $<$. Conceptually, AutoSys maintains the following two rulesets for each target system.

First, ruleset validates ML/DL actuations, or inference runtime outputs as illustrated in Figure 5. In addition to validating parameter value constraints, if certain system states have been known to cause failures (from either past experience or bug reports), system operators can prevent those configurations from being applied. Rules can also encode knob dependencies – an example is the multi-tenant setup where the total memory allocated to all tenants must not exceed a budget, and the blacklist rule can be written as $capacity_1 + capacity_2 > 1024$.

Second, ruleset checks the actuation feedback, or target system outputs as illustrated in Figure 5. One use case in our deployments is to check discrepancies between actual system states and ML/DL inference. Specifically, if the predicted performance (of an actuation) significantly differs from the actual performance measurement, this feedback is relayed to the training plane as additional training data. An example rule is $|perf.latency - perf_p red.latency| > 10$ in Figure 5.

3.5 Extensibility

Since tuning scenarios can vary in requirements, we design AutoSys to be extensible through the Tuner abstraction. Tuner is agnostic to specific candidate generation algorithms, and it provides APIs to wrap the underlying ML/DL details (c.f. Table 1). After a Tuner instance is instantiated, users can specify its search space by invoking `updateSearchSpace` method. The method argument is a list of system knobs' names, value types, and value ranges. Invoking `generateCandidates` generates a list of configuration candidates to be benchmarked for model training. Then, after benchmarks complete, AutoSys invokes `generateModel` to train and update the Tuner instance's model in Training Service.

We have implemented Tuners based on algorithms including TPE [9], SMAC [26], Hyperband [30], Metis [31], and random search. Our implementation of `updateSearchSpace` allows system operators to specify each parameter's expected value type: `choice` (e.g., categorical values for KSE engine's `RankingStreams` parameter), `uniform` (e.g., continuous number within a range for RE engine's `LearningRate`), `randint` (e.g., integers between within a range for RocksDB engine's `WriteBufferSize` parameter), and so on. Finally, for model-less algorithms such as random search, it is not necessary to implement `generateModel`.

3.6 Implementation

Our current implementation comprises ~18,205 lines of Python code (Tuner: 5,427, Assessor: 1,392, Trial Manager: 35, Trial Service: 28), ~12,852 lines of TypeScript code (Trial Manager: 3,283, Trial Service: 6,638), and ~13,344 lines of code in other languages. We have implemented Tuners for an array of popular optimization algorithms such as TPE (Tree-structured Parzen Estimator) [9], SMAC (Sequential Model-based Algorithm Configuration) [26], Hyperband [30], Metis [31], anneal, naïve evolution, grid search, and random search. We have also implemented two early-stopping algorithms based on median stop [23] and curve fitting [18]. Our current implementation supports the following Trial Service realizations: local machine, remote servers, several Kubernetes-based platforms, and several internal experimental platforms. We have open-sourced the core of AutoSys on GitHub (*https://github.com/Microsoft/nni*).

4 Production Deployment Measurements

This section presents production measurements of Web Search, and Table 3 summarizes key results. The goal is to

	Search space size	**Tuning time**	**Key results (vs. long-term expert tuning)**
Keyword-based Selection Engine (KSE)	$O(1000^n)$	1 week	Up to 33.5% and 11.5% reduction in 99-percentile latency and CPU utilization, respectively
Semantics-based Selection Engine (SSE)	Action sequences	1 week	Up to 20.0% reduction in average latency
Ranking Engine (RE)	$O(10^n)$	1 week	3.4% improvement in NDCG@5
RocksDB key-value cluster (RocksDB)	$O(100^n)$	2 days	Lookup latency on-par with years of expert tuning
Multi-level Time and Frequency key-value cluster (MLTF)	$O(100^n)$	1 week	16.8% reduction on avg in 99-percentile latency

Table 3: Summary of adopting learning-augmented design to tune various systems of Web Search (c.f. Section 2.1). We compare key results to the previous practice of manual tuning by human experts over the years. n represents the number of parameters.

quantify benefits of adopting learning-augmented system design in terms of ***(1)*** tuning effort reduction and ***(2)*** system performance improvement.

4.1 Tuning Application Logic

This subsection considers both cases of tuning application logic in a single step and in a sequence of step-wise actions. Specifically, we present measurements from Selection service's KSE engine and SSE engine.

Performance Gain for KSE Engine. KSE engine exposes the following key knobs. Each execution plan consists of a hand-crafted sequence of sub-plans. Each sub-plan has a categorical parameter, *RankingStreams* (`title`, `body`, `anchor`, and `URL`), that specifies document fields that a query keyword should appear in. In addition, it has an integer parameter, *MaxSeekCount* (1 - 1000), that dictates the maximum number of documents the sub-plan should examine. These parameters determine the trade-off between Selection service effectiveness and latency – while a large *MaxSeekCount* potentially increases the number of document candidates for ranking, it also increases the Selection service latency. Depending on the number of execution plans, there can be up to 20 controllable knobs and parameters.

Metrics of interests include per-query latency, CPU utilization, and relevance. As Selection outputs an un-ranked list, we use the popular NCG (Normalized Cumulative Gain) score to quantify the overall relevance, and this is a variant of NDCG [5] that does not consider position-based discounting. Importantly, the higher the NCG, the more likely users will click the corresponding search result. For KSE, the optimization target is to reduce latency and CPU utilization, while keeping relevance score the same.

We optimized KSE for the image and video domain. Web Search divides the image and video domain into several segments: generic, tail (e.g., lower popularity), regions (e.g., US market), and so on. With production workloads, we ran the TPE (Tree-structured Parzen Estimator) Tuner for a week, on a machine with 2.1 GHz CPU (with 8 cores) and 16 GB RAM. Compared to years of expert-tuning, we highlight the following improvements. For the image domain, AutoSys lowered KSE 99-percentile latency by another 16.9% - 33.5%, and CPU utilization by another 9.0% - 11.0%. For the video domain, compared to expert-tuned configurations, AutoSys lowered KSE 99-percentile latency by another 19.4% - 29.7%, and CPU utilization by another 10.1% - 11.5%. These improvements represent a Selection latency reduction up to 33 msec; for reference, many companies have reported an ~1.0% revenue gain from reducing the end-to-end search engine latency by 100 msec.

Performance Gain for SSE Engine. SSE engine optimization concerns with deciding the action for each step of the execution sequence. In contrast to other engines in Web Search, SSE requires a correct ordering of actions. The problem can be formulated as the Approximate Nearest Neighbor (ANN) search [14, 47] in the vector space. As we mentioned before, given a user query, each step of SSE chooses one of the three possible actions: ***(1)*** identifying some anchors in the vector space by looking up the tree, ***(2)*** making anchors' one-hop neighbors in the neighborhood graph as new anchors, and ***(3)*** terminating and returning the best anchors that we have seen. At each step, SSE provides the following system states and environment features for the decision-making: the number of distance calculations between candidates and the query so far, the number of tree searches so far, whether top K candidates have been updated in the last T actions, and the average distance between current top K candidates and the query.

We implemented a reinforcement learning Tuner with tabular based models (Q-tables). Reinforcement learning excels in discovering the action sequence that would maximize the overall reward. We define the reward of step t as a trade-off between relevance gain and latency cost: $R_t = \alpha \times relevance\_gain_t - \beta \times latency\_cost_t$ (α and β are hyperparameters). Under Web Search production workload, we observed that learned execution sequences are able to achieve an average of 20.0% reduction in latency while keeping the relevance score the same.

Additional Consideration: Actuation Granularity. While setting up AutoSys for KSE, we encountered the question of actuation granularity – *should AutoSys generate coarse-grained actuations (i.e., one actuation for all system instances) or fine-grained actuations (i.e., one actuation for each system instance, user segment, region, and so on)*? Coarse-grained actuations impose less computation loads, but fine-grained actuations potentially offer higher performance gains. Unfortunately, the real-world value of learning-augmented design diminishes with either high learning cost

	RS	MS_1	MS_2	MS_3	MS_4
Image-generic	`U,T,B`	300	6	9,00	160
Image-tail	`U,T,B`	484	10	6,30	130
Image-US	`U,T,B,C`	245	50	4,80	90
Video-generic	`U,T,C`	220	160	6,50	10
Video-tail	`U,T,C`	125	30	6,40	180

Table 4: Optimal decisions should vary with workload diversity. This table illustrates the optimal configuration of key KSE knobs for several segments of the image and video search domain. *RS* and *MS* are the abbreviated name for *RankingStreams* and *MaxSeekCount* parameters, respectively.

or low performance gain.

To balance the trade-off, we experimented with three levels of granularity: system-wide, per-instance, and per-search-segment. Due to restrictions imposed by the production environment, we performed exploration jobs on a random selection of 3 instances in each search segment. Results suggested that per-search-segment granularity best balances the trade-off for KSE. Table 4 illustrates the best-performing knob configurations for five popular segments, and there is a noticeable variance in their knob settings.

4.2 Tuning ML Algorithms

This subsection considers tuning system components that host ML/DL algorithms. Specifically, we present measurement from Ranking service's RE engine.

Performance Gain for RE Engine. RE engine runs a set of decision trees, or random forest. Its key controllable knobs include *LearningRate*, *NumberOfLeaves*, *MinimumDocsPerLeaf*, *NumberOfTrees*, and so on. *LearningRate* takes a continuous number (0.01 - 0.99), for adjusting gradient descent speed that trades off between learning convergence time and accuracy. *NumberOfLeaves* takes an integer (10 - 5,000), for adjusting the maximum number of base tree leaves, which relates to the model's learning capability. *MinimumDocsPerLeaf* takes an integer (5 - 1,000), for adjusting the minimum number of documents in a leaf. *NumberOfTrees* takes an integer (5 - 100), for adjusting the number of decision trees. In total, there are approximately 5×10^8 possible parameter combinations in the configuration space.

The optimization metric is NDCG (c.f. Section 4.1), and we ran the TPE (Tree-structured Parzen Estimator) Tuner in AutoSys for one week, on a machine with 2.1 GHz CPU (with 8 cores) and 16 GB RAM. Compared to years of expert-tuning, we highlight the following improvements (evaluated on a production workload containing 150K queries and 2.5M URLs): AutoSys improved NDCG@1 (i.e., top 1 result's NDCG score) by another 2.9%, NDCG@2 (i.e., top 2 results' NDCG score) by another 3.4%, NDCG@3 by another 3.4%, NDCG@4 by another 3.4%, and NDCG@5 by another 3.4%. We note that ranking relevance has a direct correlation with conversion rate (e.g., ads clicking).

Additional Consideration: Human-in-the-Loop. We note that solving the combinatorial optimization from a total of 5×10^8 possibilities is theoretically doable, but it might not be practically feasible. With RE, we took advantage of human knowledge of the engine design, and reduced the value range of several parameters during the process. Interestingly, we have encountered cases where information from humans unintentionally misled learning or caused unexpected consequences, and Section 5 shares these cases.

4.3 Tuning Data Store

Through both RocksDB engine and MLTF engine in Reranking service, we demonstrate data store optimization.

Performance Gain for RocksDB Engine. From years of operation, Web Search operators selected the following key knobs to optimize RocksDB read and write throughputs (in MB per second): *WriteBufferSize* (1 - 96 MB), *BlockSize* (128 - 2,000 KB), *Level0FileNumCompactionTrigger* (2 - 64), and *MaxBackgroundJobs* (1 - 45). Details of these knobs are available online [4]. We used the Metis Tuner because gaussian process models have been shown to be effective for tuning databases [6].

We allocated a two-day computation budget (on an 8-core 2.1 GHz CPU), for AutoSys to search for the optimal configuration with respect to a 5-day trace of production Web Search traffic. AutoSys improves the maximum write throughput to 50.36 MB per second, which matches the throughput achieved by Web Search operators' years of manual tuning. This result demonstrates that AutoSys can significantly reduce the amount of human efforts.

Performance Gain for MLTF Engine. MLTF (Multi-level Time and Frequency) KV engine has the following key knobs. There are *NumCacheLevels* (1 - 10) cache levels. A cached object can move up a level if it has been queried *CachePromotionThreshold* (1 - 1,000) times. Top *NumInevictableLevels* (0 - 9) cache levels can be specified as being inevictable. Furthermore, MLTF does not immediately admit large keys with an object size larger than *AdmissionThreshold* (1 - 1,000) bytes, but it first holds them in a shadow buffer of *ShadowCapacity* (1 - 10) MB. Then, keys in the shadow buffer are moved to the cache only if they have been queried more than *ShadowPromotionFreq* (1 - 1,000) times. The dataset partition on each server is divided into *NumShards* (1 - 64) shards. The metric of interests is the 99-percentile query latency. Due to the noise in latency measurements, we used the Metis Tuner. We collected measurements from one production cluster whose servers have a 512 MB in-memory cache and SSD.

With measurements from a 14-day window, we try to answer the question, *can AutoSys continuously maintain optimal system performance over time?* AutoSys generated a new configuration every two hours to adapt to workload dynamics.

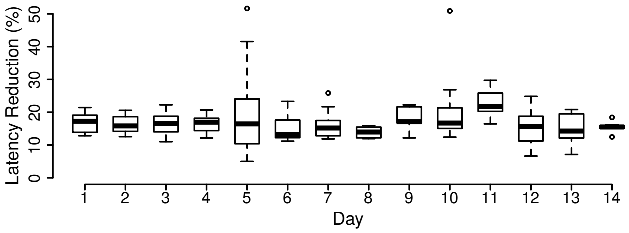

Figure 6: The figure summarizes the 99-percentile latency reduction over a 14-day window, as compared to the static default configuration. AutoSys periodically tuned MLTF every two hours, so we have 12 actuation feedbacks per day.

Figure 6 summarizes the latency reduction for each day, as compared to the default configuration from human operators. We highlight the following observations. First, AutoSys lowered the 99-percentile latency by an average of 16.8%. Second, if the workload changes too frequently, AutoSys might not be able to always update the system configure in time.

Additional Consideration: System Measurement Quality. Noise and outliers are the common factors that system engineers typically consider in terms of measurement quality. In fact, as mentioned above, they are the reason that we used the Metis Tuner for MLTF. Interestingly, while setting up AutoSys for RocksDB, we encountered another factor of system measurement quality – imbalanced measurements. In imbalanced datasets, data points are not roughly equally distributed among all classes of behavior (e.g., read vs. write requests). For example, in one RocksDB scenario, the workload trace is significantly skewed, and writes significantly dominate reads. As a result of using this trace for training, AutoSys optimization tasks frequently produced actuations that sacrificed read throughput for write throughput. These actuations might not be acceptable in the real world.

5 Long-Term Lessons Learned

Although AutoSys addresses common design considerations (c.f. Section 3), unforeseen implications have surfaced over years of operation. They reveal roadblocks in the transition to learning-augmented system design, from the perspective of system operators.

5.1 Higher-Than-Expected Learning Costs

While we anticipated model training would incur some costs, these costs sometimes exceed our expectations due to how operators set up models. The common approach is to model an entire system deployment as one black box. Since ML/DL models directly learn from the observed system execution behavior, operators are freed from worrying about non-trivial component interactions and resource contentions within the deployment. This benefit of simplicity is attractive because interactions and contentions are unavoidable in modern systems – if multiple service instances are deployed on the same server, they would contend for computation and I/O resources, especially on over-subscribed servers. Even for single-instance servers, instances share network resources, job dispatcher, etc.

The first unapparent trade-off of modeling an entire system deployment as one black box is *re-training cost*. Compared to traditional systems, most modern systems are designed to be elastic. Individual instances can be created and destroyed on demand, and they can run on heterogeneous hardware as required. Unfortunately, any changes to the deployment setup would invalidate model assumptions and cause the trained model to be irrelevant. In our example above, system setup changes include the number of co-located instances on a server and instance migration. Re-training models for modern systems can be costly. Complex systems require complex ML/DL models, which tend to be difficult to train and require a large amount of training data.

The second unapparent trade-off of modeling an entire system deployment as one black box is *exploration cost*. Considering optimizing the job completion time for a cluster of hundreds (or even thousands) workers and job dispatchers, if we consider individual nodes' CPU utilization, the model would already have hundreds of inputs to learn. Furthermore, preparing training datasets for this model scale can be challenging: ***(1)*** testbeds rarely match the target system's hyper scale in the real world, and ***(2)*** exploratory actuations on critical systems in production are prohibitive.

To mitigate higher-than-expected learning costs, one ongoing effort is to take advantage of the target system's software modularity [40]. Software modularity emphasizes separating code functionality to promote maintainability. Similarly, instead of modeling an entire system deployment with a monolithic model, we modularize the learning task into composable units of learning assignments. One realization is to dedicate a model to learn a subsystem or a component. Considering a content-aggregation application that queries two local key-value stores for images and videos in series, we can have separate latency-predicting models for these stores, M_{image} and M_{video}. And, the end-to-end latency can be computed by aggregating outputs of M_{image} and M_{video}. Due to the separation, each model has less to learn and can be re-trained independently. Furthermore, if the application is updated to aggregate new content types, additional models (e.g., M_{text}) can be added without updating M_{image} and M_{video}.

We acknowledge that software design modularity might not always be the appropriate level of modularity, especially that software modularity is typically based on the criteria of code functionality and maintainability, rather than learning complexity. This process is currently a manual trial-and-error process for individual systems, and we are accumulating experience to standardize the methodology.

5.2 Pitfalls of Human-in-the-Loop

Senior engineers and operators likely have a wealth of knowledge and experience on the target system, which can guide AutoSys optimization tasks. This subsection describes cases where information from humans unintentionally misled learning or caused unexpected consequences.

First, human experts can inject biases into training datasets, by providing a large number of labeled data points for certain search space regions. This is possible if human experts are already familiar with these regions. As a result, models would exhibit an uneven distribution of uncertainties. For optimization algorithms that tend to exploit regions with lower uncertainties, e.g., Expected Improvement (EI) [44], decisions would likely lean towards regions labeled by human experts. While the academic community has investigated data bias in the context of classification (e.g., images [46]), learning-augmented systems also rely on regression. Our current practice is to advise operators to mix human-labeled datasets with random exploration.

Second, human experts can write conflicting specifications for optimization tasks. Specifically, human experts can help AutoSys narrow down the search space by specifying the *valid* value ranges of each configuration knob, and an example is RE described in Section 4.2. At the same time, they can specify *invalid* configurations for the rule engine to check optimization task outputs. Due to human errors, if the invalid space completely covers the valid space, any outputs would effectively be rejected by AutoSys. Our current practice is to run a tool to check this overlapping condition.

5.3 Closed-Loop System Control Interfaces

We have worked with many production systems that lack closed-loop control interfaces. The closed loop refers to how AutoSys actuates a system to achieve optimality, based on the current system feedback. To this end, not only do modern systems need interfaces to accept external actuations, but they should also have well-defined interfaces that abstract system measurements and logs in a way of facilitating learning.

We describe common issues that motivate this need. First, some systems distribute configurable parameters and error messages over a set of not-well documented configuration files and logs [42]. And, directly modifying configuration files means that the system can not enforce value checks or provide immediate feedbacks. Second, parsing raw logs can be time-consuming, especially if system components disagree on a unified logging format or excessively log [27]. Third, many system feedbacks are not natively learnable, e.g., stack traces and core dumps.

To this end, we have been customizing closed-loop control interfaces for individual systems. Our current practice consists of the following steps. We ensure interfaces contain accessors for all configurable knobs and also accessors for system metrics. The latter output system measurements in the format of time-series values, which capture system measurements since the last AutoSys actuation. Furthermore, control interfaces implement mechanisms to remove system-specific data outliers (e.g., Gaussian noise and spikes), to improve the quality of system benchmark measurements as training data.

5.4 Applicability to Other Systems

This subsection summarizes our experience in applying AutoSys to systems other than Web Search. AutoSys works extremely well in a well-controlled learning environment where high-quality workload traces can be easily collected from the target system, and training can take place offline on high-fidelity testbeds or simulators. Interestingly, many critical scenarios already have the infrastructure to satisfy these strict requirements for debugging purposes.

Many target systems have a more relaxed learning environment. First, real-time exploration can be slow, especially for systems that require warm-up (e.g., in-memory cache). For Tuners based on Bayesian optimization or reinforcement learning, training can take a long time. Our current practice is to run multiple Trials for multiple concurrent benchmarks, at each iteration of exploration. Second, online in-situ exploration with production systems can be restricting and even prohibitive. our current practice is to construct base models offline by running exploration on testbeds or simulators, and then fine-tune models online with live traffic. This practice is useful, especially for systems where individual instances exhibit different workload characteristics. Finally, Section 5.1 discusses cases of frequent model retraining, due to various types of dynamics.

6 Related Work

There are efforts on exploring and demonstrating the potential of learning in solving certain system challenges. Building on these efforts, AutoSys takes a step towards unifying the development of learning-augmented systems. Anticipating growing system scale and complexity, Self-* [22] stated a vision of autonomic computing that satisfies a collection of "self-*" properties, and proposed a conceptual model. Recent efforts include learning index structures and memory access patterns [25, 28], optimizing data query evaluations [37], system performance tuning [7, 31], database configuration tuning [6, 13], placing deep learning computational graphs onto hardware device [35, 36], anomaly detection [21, 29, 55], etc.

There are efforts on building general-purpose predictive service. Resource Central [16] is a predictive service to drive Azure's VM scheduler, and it builds random forest and XGBoost models from past VM telemetry, rather than interactive explorations. Vizier [23] is a general-purpose black-box optimization service, and it has enabled tasks such as parameter tuning at Google. Vizier implements Bayesian optimization to learn the search space through interactive explorations. Clipper [17] is a general-purpose low-latency prediction serving system which introduces a modular architecture to simplify model deployment across frameworks. However, these efforts do not consider some of the challenges in operationalizing learning-augmented systems such as interactive explorations, learning-induced system failures, and so on.

Some AutoSys components are inspired by decades of research and experience in the system community. Many efforts heavily focus on system challenges to support learning tasks [15, 38, 49], and Berkeley shared their views of system challenges for artificial intelligence (AI) [45]. Related to control interfaces, interfaces and methods for controlling and exploring systems state are used for implementation-level model checking (e.g., MaceMC [24] and Modist [51]). One approach to drive automating system performance tuning is interactive exploration. Fuzz testing has been effectively used in generating inputs to induce unexpected software behavior [10, 32, 53], and there is a rich literature on software testing and system debugging. Inspired by the idea of composable AI [45], we are exploring how assembling previously trained models can scalably model large-scale systems.

Finally, some AutoSys components are inspired by research in the ML/DL community. Examples include online learning [11], continual learning [43], and so on.

7 Conclusion

This paper reports our years of experience in designing and operating learning-augmented systems at Microsoft. To unify the development process of these systems, we introduce the AutoSys framework that addresses common design considerations. Furthermore, we present production measurements and discuss long-term lessons learned from operating one such system, Web Search. Going forward, we will study how learning-augmented systems should evolve models over time, and how end-to-end and full-stack system optimization can be safely carried out in practice.

Acknowledgments

We thank anonymous reviewers and our shepherd, Prof. Ana Klimovic, for their extensive comments and suggestions. We also thank our colleagues at Microsoft, for their help in deploying AutoSys: Mingqin Li (Bing Platform), Wei Li (Bing Platform), Haidong Wang (Bing Platform), Yuanchi Yan (Bing Platform), Chao Zhang (Bing), Qiang Zhang (Bing), and Wenjin Zhang (Bing).

Daydream: Accurately Estimating the Efficacy of Optimizations for DNN Training

Hongyu Zhu[†], *Amar Phanishayee*[⋆], *Gennady Pekhimenko*[†]
[†]*University of Toronto & Vector Institute* [⋆]Microsoft Research

Abstract

Modern deep neural network (DNN) training jobs use complex and heterogeneous software/hardware stacks. The efficacy of software-level optimizations can vary significantly when used in different deployment configurations. It is onerous and error-prone for ML practitioners and system developers to implement each optimization separately, and determine which ones will improve performance in their own configurations. Unfortunately, existing profiling tools do not aim to answer predictive questions such as "How will optimization X affect the performance of my model?". We address this critical limitation, and proposes a new profiling tool, Daydream, to help programmers efficiently explore the efficacy of DNN optimizations. Daydream models DNN execution with a fine-grained dependency graph based on low-level traces collected by CUPTI [49], and predicts runtime by simulating execution based on the dependency graph. Daydream maps the low-level traces using DNN domain-specific knowledge and introduces a set of graph-transformation primitives that can easily model a wide variety of optimizations. We show that Daydream is able to model most mainstream DNN optimization techniques and accurately predict the efficacy of optimizations that will result in significant performance improvements.

1 Introduction

Recent years have witnessed the co-evolution of deep neural network (DNN) algorithms and the underlying hardware and software design. ML researchers have developed many important models [20, 26, 27, 73] at a rapid pace, creating a huge demand for computation power [69]. To meet the demand for fast DNN computation, computer architects respond with new, AI-optimized GPUs (e.g., NVidia Turing architecture [56]) and various domain-specific hardware accelerators from FPGAs (e.g., Microsoft Catapult [64]) to ASICs (e.g., Google TPU [34], Amazon Inferentia [70]). However these accelerators might not be effective in improving performance without proper software optimizations across the full systems stack [84]. As a result, systems researchers have proposed many optimizations, targeting different bottlenecks across the system stack – for example, improving memory utilization [29, 67], better overlapping of communication with computation [25, 30, 83], and increasing communication efficiency [16]. Moreover, researchers have also developed workload-centric optimizations to exploit the stochastic nature of DNN computation. For example, precision reduction [18, 23, 42] aims to reduce runtime as well as memory consumption, and gradient compression [40, 41] aims at reducing the communication overhead in distributed training.

Despite these advances, the benefits of many proposed optimizations cannot be fully exploited due to two main reasons. First, the efficacy of many proposed performance optimizations can drastically change when applied to different ML models and deployment configurations. The hardware deployments that practitioners use might be completely different from the hardware configurations used by optimization and model inventors. Differences in DNN models, accelerator type, compute capabilities, available memory, networking capabilities, and software library versions can all shift the major runtime bottlenecks. Second, it is onerous for programmers to implement and evaluate various optimizations to identify the ones that actually work for their models. As a result, it is common for users to ask *what-if* questions such as:

Why did my DNN training workload run slowly? Will optimization X improve the performance of my model? Does GPU memory capacity limit the performance of my model? Would upgrading to a faster network improve training throughput? How will my workload scale with the number of GPUs?

The central focus of this paper is to answer the following general question for DNN training workloads: *Given a model and a deployment scenario, how can we efficiently explore the efficacy of potential solutions*? Systems researchers have tried to explore the impact of different potential performance bottlenecks (e.g., CPU, network, IO) in many non-ML contexts [5, 17, 43, 59, 60, 74]. The basic approaches to explore the what-if questions are similar: decompose the workloads into atomic tasks, profile runtime statistics for each task, model the what-if question, and use simulation to estimate performance.

These systems typically address what-if questions of the form: "How does runtime change if a task T is N times (or even infinitely) faster?" [17, 60]. Such questions can be simply modeled by shrinking task runtime. While this basic approach seems sufficient to address the central question above for ML workloads, the **diversity of DNN optimizations** introduces three key requirements unique to these workloads, thus motivating the need for a novel solution.

First, we need to **track dependencies at a kernel-level abstraction** i.e., one GPU kernel corresponds to one task (the smallest unit of execution in the dependency graph). Such fine-grained abstraction is necessary because optimizations that improve hardware utilization typically target individual compute kernels (e.g., mixed precision [42]). Meanwhile, accurate performance estimation has to consider both CPU and GPU runtime. Certain optimizations, e.g., kernel fusion, require potentially removing existing CPU and GPU tasks from the dependency graph. Existing tools do not provide such dependency tracking. It is therefore important to track kernel-level dependencies among concurrently executing tasks.

Second, we need to **map tasks to DNN layers**. In contrast to prior works that explore what-if questions in non-ML contexts, predicting the performance of DNN optimizations requires domain knowledge about DNNs to properly model them. For example, MetaFlow [33] and TASO [32] fuse DNN layers. Modeling them requires a mapping from tasks to specific DNN layers. However, collecting kernel-level traces on accelerators requires generic vendor-provided tools (e.g., NVProf [48], CUPTI [49]), which have no application specific knowledge. We therefore need to have the ability to map low-level tasks to DNN layers.

Third, we need the **ability to easily model diverse DNN optimizations**. Modeling a DNN optimization might involve not just scaling or shrinking task durations, but also complicated transformations to the dependency graph. For example, TicTac [25] reschedules communication tasks, BlueConnect [16] replaces the communication primitives to utilize parallel network channels, and the optimization proposed by Jung *et al.* [35] restructures the GPU kernel implementations. Manually manipulating the kernel-level dependency graph could be extremely intricate and error-prone. The system should enable users to flexibly and effectively model such diverse optimizations with minimal effort.

We introduce *Daydream*, a new system that fulfills all three requirements described above, and achieves our goal of answering potential what-if questions for DNN workloads. Constructing dependencies among potentially thousands of low-level tasks is not an easy problem: tasks can be spread across multiple execution threads (including both CPU threads and GPU streams), thus even for simple DNN workloads, this results in thousands of tasks to be tracked. The intricacy comes from identifying dependencies across threads. We make a key observation about DNN training workloads: despite the large number of tasks that need to be tracked, the number of concurrently executing threads is surprisingly quite limited. Based on this observation, Daydream constructs the low-level dependency graph, which provides a realistic model of overlapping among CPU, GPU, and communication runtimes in a DNN training workload. It uses a synchronization-free approach to map GPU tasks onto appropriate higher-level DNN layer abstractions. We also introduce a set of graph-transformation rules, allowing programmers to effectively model various performance optimizations. After modeling the optimization, Daydream simulates the execution based on the new dependency graph to predict the overall runtime. In our evaluation, we show that Daydream is able to distinguish effective DNN optimizations from those that will bring limited improvements by accurately predicting their performance speedups.

In summary, we make the following key contributions:

- We make the observation that fine-grained tasks in DNN training workloads are highly sequential. This greatly simplifies dependency graph construction, over thousands of tasks, as we only need to identify a limited number of inter-thread dependencies.
- Daydream introduces the abstraction of a kernel-granularity dependency graph that contains mappings back to DNN specific abstractions (layers), by collecting profiling data, instrumenting DNN frameworks, and exploiting information from vendor-provided tools like CUPTI. Daydream also provides primitives to mutate the dependency graph in the form of simple graph transformations. Taken together this enables programmers to both (i) model a diverse set of popular optimizations spanning kernel- and layer-level enhancements by using simple graph-transformation primitives, and (ii) estimate the efficacy of optimizations by simulating execution time based on optimization-induced graph mutations.
- We extensively evaluate Daydream, with *five* different optimizations on *five* DNN models across *three* distinct applications. We show that Daydream can effectively detect which optimizations provide improvements and also accurately predict their magnitude for different DNN models and deployments. For example, we estimate that using mixed precision will improve the iteration time of training BERT$_{\text{LARGE}}$ model by 17.2% (with <3% error), while the kernel fusion technique can improve it by 38.7% (with <7% error). We can also accurately predict performance in distributed training with different number of workers and variable network bandwidth, based on runtime profiles collected from a single-GPU setting.

2 DNN Training Optimizations and Tools

DNN training is an iterative algorithm, in which one iteration consists of three phases: (i) *forward*, (ii) *backward*, and (iii) *weight update*. The *forward* phase takes training data samples as input and produces output based on current weights

Optimization Goal	Strategy	Technique Examples

	Improving Communication Efficiency/Overlap	***Wait-free Backprop*** [83], ***P3*** [30], **BlueConnect** [16], TicTac [25], BytePS [62], Xue *et al.* [80]

Table 1: Representative optimizations for DNN training. We show how we can accurately estimate the performance of optimizations (shown in ***italics***) in Section 6, and can effectively model many other optimizations (shown in **bold**) in Section 5.

(or parameters). The error between the *forward* output and the input data labels is fed to the *backward* phase, which computes the gradients of weights with respect to the input data. The *weight update* phase then uses the gradients to update weights accordingly. In each iteration, the input data samples are randomly selected [11], forming a *mini-batch* of input.

2.1 DNN Training Optimizations

Modern DNNs have millions of parameters [24], resulting in training times of days or even weeks [38]. To improve DNN training performance, researchers have proposed various strategies focusing on different optimization goals. To understand the potential what-if questions and how to design a system to answer them, we study a list of software-level techniques that speedup DNN training from top systems and ML conferences in recent years. Table 1 shows our summary.

Exploiting computation power of hardware accelerators. ML programmers often use large mini-batches, within the memory budget, for better hardware utilization and faster convergence. This motivates strategies that reduce the memory footprint of DNN training and hence enables training with larger mini-batch sizes [14, 29, 67]. Researchers have also proposed some generic strategies to increase hardware utilization, including precision reduction [18, 23, 42], kernel/layer fusion [10, 32, 33], and improving low-level kernel implementation [13, 35, 37, 72]. Meanwhile, libraries such as cuDNN [15], cuBLAS [45], MKL [75], Eigen [1], and NCCL [46] are also constantly evolving to provide operations and primitives that can better utilize underlying hardware.

Scalable distributed training. Data parallelism [11] is a simple and effective strategy to improve training performance. Using multiple accelerators significantly reduces DNN training time to hours or even minutes [44]. This success is mainly based on the techniques that guarantee model convergence under extremely large mini-batch size [7, 22, 81]. One of the major performance bottlenecks for distributed training is communication, which can be optimized by compressing traffic [40, 41, 76, 78], increasing network utilization [16, 80], or increasing the overlap between communication and computation [25, 30, 83]. Exploring the efficacy of these optimizations without prediction requires a multi-machine cluster. Our proposed design, Daydream, avoids the potential cost of cluster setup (i.e. extra machines, accelerators, high-speed communication), by predicting distributed training performance with profiles collected from a single-worker environment.

2.2 Profiling Tools for DNNs

As the full ML system stack is constantly evolving, profiling tools play a key role in helping programmers identify the performance bottlenecks under different system configurations.

Hardware profiling tools. Modern DNN training heavily relies on hardware accelerators such as GPUs [56] and TPUs [34]. To help programmers develop highly efficient applications, hardware vendors provide profiling tools that can expose hardware performance counters. For example, NVProf [48] provides programmers with information including start/end time, core utilization, memory throughput, cache miss rate, along with hundreds of other hardware counters for every GPU kernel. CUPTI [49] enables programmers to extract and manipulate these counters at runtime. Nsight [47] aims to provide details on the state of more fine-grained counters for recent GPU architectures [56]. Our proposed system, Daydream, relies on CUPTI to collect low-level traces for further analysis.

Framework built-in tools. For more intuitive profiling results, it is often desirable for a profiler to show runtime statistics for framework operations, or even DNN layers. DNN frameworks have built-in tools to achieve this goal by correlating the hardware counters with runtime information collected in frameworks. TensorFlow [3], coupled with the Cloud TPU Tool [21], can provide an execution timeline and runtime statistics for each TensorFlow operation. Similarly, other mainstream frameworks (e.g., MXNet [12] and PyTorch [61]) provide built-in tools that can extract per-layer or per-operation runtime from both the CPU and the GPU. The framework built-in tools render intuitive results for pro-

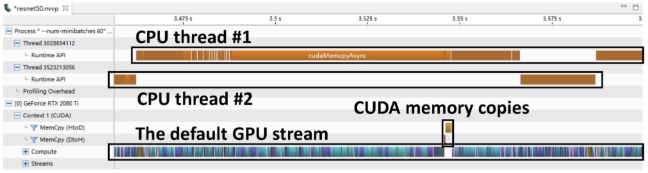

Figure 1: NVProf timeline example of training ResNet-50.

grammers, but omit important details (for example, the CPU runtime). We show in our work that such information is crucial in building an accurate runtime predictor.

3 Key Ideas

In this section we highlight the key ideas and observations behind the Daydream design.

Constructing kernel-granularity dependency graph. The neural network topology is a natural graph structure in which nodes are DNN operators or layers. Most mainstream DNN frameworks [12, 61] provide built-in tools to record the layer-level runtime profile. The layer-level abstraction is intuitive for programmers to understand the "where time goes" question, but hides important information about the parallel execution of the CPU functions, GPU kernels, and memory transfers. This information is crucial for accurate performance predictions. For example, optimizations that reduce numerical precision will change the duration of GPU kernels while the CPU runtime remains unchanged, and optimizations like vDNN [67] will inject CUDA memory copies, without changing the duration of GPU kernels. It is extremely hard to predict how duration of each layer changes when applying these optimizations if lacking low-level details about CPU and GPU runtime. To accommodate optimizations that target fine granularity tasks (such as GPU kernels), our proposed system, Daydream chooses to model the training workloads using a kernel-level dependency graph (i.e., each GPU kernel has one corresponding task in the graph), incorporating detailed traces of CPU, GPU and communication runtime.

With a large number of kernel-level tasks that are spread across several threads and CUDA streams, the complexity of constructing the dependency graph comes mainly from identifying the inter-thread dependencies [74]. Existing tools do not provide such dependency tracking. We make the following key observations about the DNN training workloads to overcome this general challenge of dependency tracking in concurrent systems. First, for the implementations in the mainstream frameworks [12, 61], once a mini-batch has been prepared by data loading threads, only one or two CPU threads are involved in the control flow of computation.[1] Second, there is a very limited number of concurrent GPU kernels. Such serialization of GPU kernels is due to two main reasons: (i) GPU kernels in the modern cuDNN library achieve high GPU core utilization; (ii) ML frameworks usually invoke only one CUDA stream. Figure 1 shows the NVProf profiles of one training iteration of ResNet-50. There are two CPU threads involved, but no CPU tasks run concurrently. The high serialization of low-level traces is not a unique phenomenon for just convolutional networks. We observe a similar phenomenon in most DNN training workloads.

Based on these insights, Daydream constructs the kernel-level dependency graph in three major steps. First, Daydream uses CUPTI to extract traces of all GPU kernels, CUDA memory copies, and CUDA APIs. Second, Daydream captures the dependencies between CPU and GPU tasks, caused by CUDA synchronizations and GPU kernel launches. Third, when predicting performance for distributed training, Daydream adds communication tasks to the dependency graph.

Synchronization-free task-to-layer mapping. In distributed training, mainstream frameworks implement the wait-free backpropagation strategy [83] to overlap communication with computation. This strategy immediately transfers gradients once they are computed by corresponding backward layers. To properly add dependencies related to communication tasks, we need the task-to-layer mapping to know when the computation of each layer ends. Meanwhile, accurately modeling DNN optimizations by changing the graph potentially requires this task-to-layer mapping to determine which tasks are involved and how to change them.

Unfortunately, vendor-provided tools like CUPTI do not have the required knowledge about these applications and building such a mapping requires extra DNN framework instrumentation. A naïve approach to achieve this mapping is to compare the start and stop timestamps of GPU kernels and DNN layers. This requires additional CUDA synchronization calls for each layer since GPU kernels are launched asynchronously. However, such synchronizations might significantly alter the execution runtime by adding additional dependencies from GPU to CPU tasks. Hence, we design a synchronization-free procedure to achieve this mapping by instrumenting timestamps for each layer in the frameworks, and utilizing the correlations between CPU and GPU tasks.

Representing complex optimizations with simple graph-transformation primitives. As shown in Table 1, DNN optimizations target a wide range of performance bottlenecks with various approaches. Unlike prior dependency graph analysis in non-ML contexts [17, 59, 60], where users can model most what-if questions by simply shrinking and scaling task runtime, accurately modeling DNN optimizations with the low-level dependency graph might require complicated changes to the dependency graph. Manually changing the kernel-level graph to model optimizations could be both complicated and error-prone, and the programmers might simply opt to rather directly implement the optimizations.

To address this problem, we propose a small set of graph-transformation primitives, so that popular optimization techniques can be effectively represented as a combination of

[1] Our approach can be generalized to frameworks that use more concurrent CPU threads.

these primitives. These primitives include (i) task insertion/removal, (ii) task selection and update, and (iii) changing the policy for scheduling tasks. The proposed primitives are simple yet powerful enough to represent many different optimizations as we will show in Section 5. They play a key role in realizing our goal of efficiently exploring what-if questions.

In summary, Daydream introduces the abstraction of a kernel-granularity dependency graph that contains mappings back to DNN specific abstractions (layers). It tracks dependencies by collecting profiling data as well as instrumenting DNN frameworks. Daydream also provides primitives to mutate the dependency graph in the form of simple graph transformations. Altogether this enables programmers to both (i) model a diverse set of popular optimizations spanning kernel- and layer-level enhancements by using simple graph-transformation primitives, and (ii) estimate the efficacy of optimizations by simulating execution time based on optimization-induced graph mutations.

4 Design

We describe Daydream's design with an emphasis on how to construct Daydream's proposed graph abstraction: the kernel-granularity dependency graph with mappings back to DNN layers. We also describe the primitives for mutating this graph to model different optimizations and how Daydream uses the graph to estimate the efficacy of various DNN optimizations.

4.1 Overview of Daydream

Figure 2 shows the workflow of performance prediction in Daydream. It consists of the following four phases:

Phase 1: Trace collection. Constructing a kernel-level dependency graph requires low-level details for all tasks. These details are extremely massive, differ across ML frameworks, and can be obtained by profiling a baseline workload. Daydream collects low-level profiling data using CUPTI [49], a tool which provides details for all CPU/GPU tasks including name, start time, duration, CUDA stream ID, thread ID, etc. We manually augment three popular frameworks (Caffe, MXNet, PyTorch) for use with CUPTI and modify the layer modules of these frameworks to collect timestamps of each layer, which will be used for task-to-layer mapping, described in Section 4.3. Through our instrumentation, we also collect the necessary information (e.g., size of gradients) to construct the dependency graph of distributed training via a profile collected in a single worker setting.

Phase 2: Dependency graph construction. Daydream constructs the dependency graph with details of tasks provided by the first phase. A dependency could be induced by domain knowledge (e.g., a GPU task triggers a communication task), or by hardware/software implementation (e.g., a cudaLaunchKernel API triggers the corresponding GPU task). Based on our analysis, we identify five different types of dependencies (described in Section 4.2.2), which are sufficient for Daydream to accurately simulate baseline execution.

Phase 3: Graph transformation. To estimate the efficacy of a given optimization, Daydream models the optimization by transforming the dependency graph. Daydream provides a set of primitives (e.g. selection, insertion/removal) to represent these transformations. We design these primitives in a way such that they are succinct (easy to use), flexible (able to depict a wide range of optimizations), and accurate (being able to achieve high prediction accuracy).

Algorithm 1: Daydream's Simulation Algorithm

```
Input  : Dependency graph: $G(V,E)$
Output : The start time of each task $u \in V$
$F \leftarrow \emptyset$ // initialize the frontier task set
$P \leftarrow \{0\}$ // initialize thread progress
foreach task $u \in V$ do
    $u.ref \leftarrow |\{u'sparents\}|$
    if $u.ref = 0$ then
        $F \leftarrow F \cup \{u\}$
end
while $F \neq \emptyset$ do
    $u \leftarrow schedule(F)$ // pick a task to exec.
    $t \leftarrow u.ExecutionThread$
    $F \leftarrow F - \{u\}$
    $u.start \leftarrow max(P[t], u.start)$
    $P[t] \leftarrow u.start + u.duration + u.gap$
    foreach $c \in u.children$ do
        $c.ref \leftarrow c.ref - 1$
        $c.start \leftarrow$
          $max(c.start, u.start + u.duration + u.gap)$
        if $c.ref = 0$ then
            $F \leftarrow F \cup \{c\}$
        end
    end
end
```

Phase 4: Runtime simulation. Daydream simulates the execution of optimizations to predict runtime based on the dependency graph. Algorithm 1 shows the simulation process, which traverses the dependency graph and puts tasks into execution threads. In each iteration, Daydream picks one task from the execution frontier (i.e. tasks that are ready to execute), dispatches it to its corresponding execution thread, and updates the thread progress. The simulation determines the start time of each task and records the total execution time.

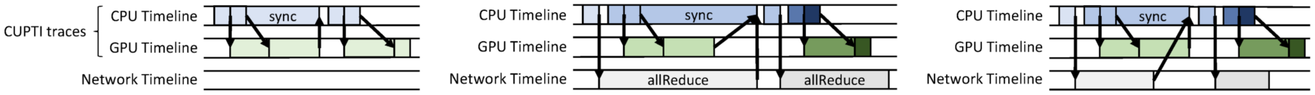
4.2 Dependency Graph Construction

Constructing the dependency graph is essential to determine the node (task) set and edge (dependency) set.

4.2.1 Task

Daydream's kernel-level dependency graph contains the following four types of tasks:

GPU tasks. Each GPU task in the graph corresponds to one GPU kernel. Daydream also views CUDA memory copies as



(a) Constructing the dependency graph based on CUPTI traces (the black arrows represent task dependencies).

(b) Mapping each task to DNN layers (shown in different colors in the figure), then inserting communication tasks based on mapping and instrumentation.

(c) Predicting "what if network bandwidth is 2×" by shrinking allReduce duration by 2× and simulating the new dependency graph.

Figure 2: An example showing Daydream's overall workflow for predicting runtime assuming network bandwidth doubles.

GPU tasks, because each memory copy is associated with a specific CUDA stream, and therefore has dependencies with other GPU kernels. The runtime of all these tasks can be collected using CUPTI.

CPU tasks. To model the concurrency and dependencies between CPU runtime and the GPU runtime, Daydream generates CPU tasks based on CPU traces collected by CUPTI. One of the limitations of CUPTI is that it can only expose CUDA-related traces. Instead of adding massive instrumentation to the framework, Daydream captures the non-CUDA runtime by recording the lengths of gaps between consecutive CPU tasks (shown in line 13 of Algorithm 1).

Data loading tasks. One data loading task corresponds to loading one mini-batch from disk/flash to CPU memory. We include data loading tasks for completeness, even though data loading in most DNN training workloads is not a performance bottleneck. In Daydream's implementation, we treat all data loading tasks as CPU tasks.

Communication tasks. A communication task corresponds to one communication primitive, e.g., a push/pull operation in parameter-server based frameworks [39], or an all-reduce operation in decentralized frameworks. When predicting distributed training performance, Daydream automatically adds communication tasks to the dependency graph based on a single-worker profile. We notice that in PyTorch, gradients from multiple layers can be grouped and sent with a single allReduce primitive [2]. Thus, properly adding communication tasks to a PyTorch profile requires additional instrumentation to extract knowledge about gradients grouping.

Given the types of tasks in the graph, Daydream collects and maintains the following information for each task, which is later used in what-if analysis and simulation:

ExecutionThread. Depending on the type of a task, its execution thread can be on of the following: (i) a CPU process, (ii) a GPU stream, and (iii) a communication channel. A data loading task is executed in a CPU process. A CPU process has a process ID, a GPU stream has a stream ID, and a communication channel could be send/receive when using parameter server primitives, or a unified one when using collective primitives. This field is used in line 10 of Algorithm 1.

Duration. This field specifies how long a task takes to execute. The duration of a CPU/GPU task is collected by CUPTI. The runtime of data loading tasks is measured by injecting timestamps to the framework. Daydream aims to predict distributed training performance based on profiling in a single-GPU configuration. Hence we calculate the duration of all communication task based on the size of gradients, the communication type (push/pull/all-reduce), and the network bandwidth. These numbers can be obtained based on knowledge of the DNN model and framework implementation.

Gap. The duration of low-level CUDA APIs (e.g., `cudaMalloc`) might be only tens of microseconds, which is of the same magnitude as the runtime of their non-CUDA equivalent C functions (e.g., `malloc`), or the runtime of the call stack from Python front-end to C back-end. NVidia-provided tools cannot expose non-CUDA traces, but they are indispensable to simulation accuracy. The non-CUDA CPU runtime is usually not a target for optimization in DNN models, hence, we do not need to define and measure corresponding tasks. Instead, for each CPU task in our current definition, we measure the gap between its end and the start of the next task in the same execution thread, and simulate these gaps in Algorithm 1.

Layer. This field refers to which DNN layer a task belongs to, which is necessary information for programmers to transform the graph and model optimizations. Daydream uses a synchronization-free approach to map a task to DNN layers. We will describe the details of this approach in Section 4.3.

4.2.2 Dependency

Based on our discussion in Section 3, we identify the following five types of dependencies for accurate simulations.

Sequential order of CPU tasks in the same thread. CPU tasks in the same thread are serialized. The order that CPU tasks are executed in is determined by the framework and does not change in two separate executions. We add a dependency between each two consecutive CPU tasks in the same thread.

Sequential order of GPU tasks in the same CUDA stream. GPU kernels belonging to the same CUDA stream are executed sequentially. Similar to CPU tasks, the order of GPU tasks in the same stream does not change between executions. Hence, two consecutive GPU tasks in the same CUDA stream have a dependency between them.

Correlation from CUDA APIs to GPU kernels. Each GPU kernel or CUDA memory copy has a corresponding CPU-sided CUDA API (`cudaLaunch`, `cudaMemcpy`, or `cudaMemcpyAsync`) that triggers the GPU task. CUPTI provides a correlation ID for every CUDA API and GPU kernel. A GPU kernel is dependant on a CUDA API if they share the same correlation ID.

CUDA Synchronization. A CUDA synchronization API

Figure 3: The mapping of GPU kernels to a layer. CUPTI provides correlations between CUDA launches and GPU kernels.

(e.g., `cudaDeviceSynchronize`) is invoked on CPU, and returns after GPU kernels (or CUDA memory copies) that are launched before this synchronization complete. A CUDA synchronization therefore generates dependency from a GPU task to a CPU task. Similar to CUDA synchronizations, even though a `cudaMemcpyAsyncDtoH` call returns before a memory copy completes, we found it still blocks the CPU until all previous GPU kernels on the same stream are completed.

Communication. Mainstream frameworks including PyTorch and MXNet implement the wait-free backpropagation strategy [83] to schedule gradient communication. Here, a communication primitive is launched as soon as the weight gradients are ready, thus overlapping communication with the backward phases of subsequent layers. Hence, we need to know the runtime of DNN layers (not just kernels) to determine which tasks trigger communication.

4.3 Mapping Tasks to Layers

The task-to-layer mapping enables Daydream to construct the dependency graph for distributed training, and provides necessary domain knowledge for Daydream to model DNN optimizations. Figure 3 shows how Daydream determines which tasks belong to a certain layer. Let L be the forward phase of a DNN layer. Daydream collects the CPU and GPU runtime information using CUPTI [49], as well as timestamps before and after the forward, backward, and weight update phases for each layer. The start and end timestamps of L will determine the CPU runtime of L (denoted by C_L). To determine the GPU runtime of L, Daydream gathers all CUDA launch calls invoked during C_L. With CUPTI providing the correlations between CUDA launch calls and corresponding GPU kernels, Daydream can identify all the GPU kernels launched during C_L, and map these kernels to L. This process can also be applied to the backward or weight update phases of any layers, and can be further generalized to any code region of interest in the framework or user-level programs.

4.4 Graph Transformation

What-if analysis by transforming the graph and simulating the execution requires input about the optimizations from programmers. Daydream provides a set of primitives for programmers to model DNN optimizations by modifying the graph. Like most what-if analysis in non-ML contexts, modeling DNN optimizations requires potentially shrinking or scaling the duration of tasks (the `shrink/scale` primitives). We carefully study common DNN optimization techniques and identify the following primitives (besides the `shrink/scale` primitives), which are sufficient for programmers to describe those optimizations.

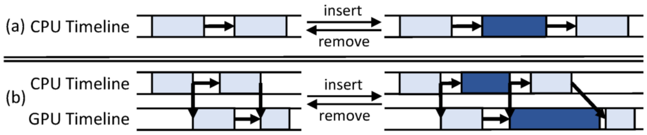

Figure 4: Insert/Remove a (a) CPU task; (b) GPU task.

Insert/Remove a task. Inserting a task to an execution thread just involves an appending of a node to a linked list. Figure 4 shows how this process works. When inserting a GPU task, we need to insert the corresponding CPU tasks that launch it. Which CPU tasks to insert and their duration depend on the framework implementation, and can be inferred based on collected traces.

Select. This operation allows users to select tasks of interest for further operations. One potentially useful selection criterion is select-by-layer, as many optimizations are depicted based on DNN layers. Another potentially useful criterion is to select by keywords in task names, based on knowledge of the software library (e.g., cuDNN [50]). For example, kernels with keywords such as `elementwise` or `PointwiseApply` in the names are element-wise arithmetic operations. These kernels are typically *not* compute-bound, and could be much shorter than their corresponding CUDA launch calls. Similarly, kernels with `sgemm` string in names are compute-bound matrix-multiplications.

Schedule. The `schedule` function picks one task from a set of frontier tasks that are ready to execute (line 9 in Algorithm 1). By default, it picks the task with the earliest start. Programmers can override this function and implement any custom scheduling policy. which is useful to model optimizations that increase computation-communication overlap.

5 Modeling Optimizations

To demonstrate that Daydream is able to estimate the performance of the most common optimizations in DNN training, we select ten techniques from Table 1 with different optimization goals. We show that we can easily model these optimizations using the primitives Daydream provides. [2]

5.1 Optimizations for Evaluation

We select the following five DNN optimizations, which we are able to acquire the implementations, to evaluate Daydream's prediction accuracy. We use implementations from the authors of these optimizations in cases where they were not readily available.

Automatic Mixed Precision (AMP). We aim to predict the efficacy of the AMP optimization [42], implemented using NVidia's Apex package [51]. We expect that AMP will

[2] We show pseudo code for AMP in this section. Refer to our arxiv version [85] for the pseudo code of all examples shown in Section 5.

improve memory-bounded GPU kernels by 2× because the number of transferred bits is halved. With Tensor Cores in the Volta and Turing architectures, AMP empirically yields up to 3× speedup on the most compute-intensive workloads [58]. To predict AMP performance, we simply `select` all the compute-intensive (e.g., `sgemm`, `conv`) kernels and memory-bounded (e.g., `elementwise`, `batchnorm`, `RELU`) kernels, and `shrink` their duration by 3× and 2× respectively. We show the pseudo code for modeling AMP in Algorithm 3.

Algorithm 2: What_If_AMP

```
Input  : Dependency graph: $G(V,E)$
Output : A modified graph $G(V,E)$ to model AMP
$GPUTasks \leftarrow \{G.Select(funcPtr(IsOnGPU))\}$
foreach $u \in GPUTasks$ do
    if "sgemm" in u.Name or "scudnn" in u.Name then
        $u.duration \leftarrow u.duration/3$
    else
        $u.duration \leftarrow u.duration/2$
    end
end
```

FusedAdam Optimizer. We use the FusedAdam optimizer [52] implemented in NVidia's Apex package [51] as an example for the kernel fusion optimization. This optimizer fuses all kernels in one weight update phase into one unified kernel. It is applicable to the models that use the Adam optimizer (e.g., GNMT, BERT). Daydream uses the kernel-to-layer mapping to identify the CPU/GPU tasks that belong to a weight update phase. We `remove` all these tasks, then `insert` a new GPU task whose duration is roughly estimated by the sum of all removed compute-intensive kernels.

Reconstructing Batchnorm. Recently Jung et al. [35] proposed a technique that optimizes non-convolutional layers in state-of-the-art CNNs. It first splits each batch normalization layer into two sub-layers, then fuses the first sub-layer with the previous convolutional layer, and the second sub-layer with the following activation and convolutional layers. We `remove` the affected activation kernels when estimating performance, since they are memory-bound kernels now fused with compute-intensive convolutional kernels. For the batch nomalization layers, we estimate that the GPU kernels will be improved by 2× since this optimization halves the amount of input data that these layers load from GPU memory.

Distributed Training. Using Daydream we can accurately predict distributed training performance with the profile based on the single-GPU environment. We evaluate Daydream's prediction based on PyTorch, which uses collective communication primitives from the NCCl library [46]. PyTorch groups gradients from multiple layers into buckets before transferring them. Hence, to predict distributed training performance, we need to `insert` one allReduce task for every bucket. The dependencies of the inserted tasks are determined based on the layer-to-bucket mapping (which requires additional instrumentation to the PyTorch framework).

Priority-Based Parameter Propagation (P3). P3 [30] is a technique that optimizes communication overhead by slicing and prioritizing. We evaluate Daydream's prediction of P3 based on MXNet, which uses the parameter-server mechanism [39]. In order to model parameter slicing, we `insert` multiple push task and pull tasks between the backward and the forward GPU tasks for each layer. The duration of the push/pull task is calculated from the slice size and the network bandwidth. To model the priority scheduling, we override the `schedule` function with a priority queue.

5.2 Modeling Additional Optimizations

In addition to the above optimizations, we show that Daydream is capable of modeling an additional set of diverse DNN optimizations.

BlueConnect. BlueConnect [16] optimizes communication by decomposing the allReduce primitives into a series of reduce-scatter and all-gather primitives. These primitives run concurrently as they use parallel communication channels. To predict the performance of BlueConnect, instead of `insert`ing regular allReduce or push/pull tasks, we need to `insert` reduce-scatter and all-gather tasks, and assign them to corresponding network channels (the duration can be estimated according to formulas shown in [57]).

MetaFlow. MetaFlow [33] is a layer-fusion technique to optimize DNN training by fusing DNN layers to simplify the DNN topology. We `select` the GPU kernels of substituted layers, `remove` them, and `insert` GPU kernels of new layers to predict the performance of MetaFlow in Daydream. The new layers are mostly existing layers with different dimensions; their GPU kernel durations can be inferred by profiling.

vDNN. Virtualized DNN [67] reduces GPU memory consumption by temporarily offloading intermediate data from GPU memory to CPU memory. The offloaded data needs to be prefetched back to GPU to perform execution, which causes potential performance overhead due to PCIe traffic or late prefetching. To predict the performance overhead using Daydream, we only need to `insert` additional CUDA memory copies, and override the `schedule` function to implement a custom prefetching policy.

Gist. Gist [29] reduces GPU memory consumption by storing encoded intermediate data and decoding before the data is used. The encoding and decoding introduces performance overhead. We `insert` extra encoding and decoding GPU kernels (along with `cudaLaunchKernel` calls in CPU) to estimate the performance overhead in Daydream. The duration of the inserted encoding/decoding kernels can be estimated using existing element-wise kernels.

Deep Gradient Compression (DGC). DGC [40] is a technique that reduces communication overhead by compressing the gradients. To estimate performance, we: (i) `scale` the duration of communication; (ii) `insert` the GPU tasks of compression and decompression. The duration of inserted

GPU tasks can be estimated according to the compression rate and duration of existing element-wise GPU kernels.

6 Evaluation

6.1 Methodology

We implement Daydream based on three mainstream DNN frameworks: PyTorch [61], MXNet [12], and Caffe [31]. We add CUPTI [49] support to each framework to obtain traces of CUDA APIs and GPU kernels. We also add instrumentation to the frameworks to acquire layer-wise timestamps for the kernel-to-layer mapping process, and communication information such as the size of each allReduce call and their dependencies with other layer-wise computation.

Infrastructure. We evaluate Daydream's runtime prediction on a cluster of four machines. Each machine contains one AMD EPYC 7601 16-core processor [9], and four 2080Ti GPUs [55] with 11GB GDDR6 memory each, connected through PCIe 3.0 [6]. Our experiments are based on Ubuntu 16.04, CUDA v10.0 [53], cuDNN v7.4.1 [54], and NCCL v2.4.2 [46]. Our software implementation is based on PyTorch v1.0, MXNet v1.1, and Caffe v1.0.

Models. Table 2 shows the DNN models and datasets we use to evaluate Daydream. We select five DNN models from three different applications, covering a diverse set of DNN models. For the BERT model, we evaluate both "base" and "large" versions. The difference between these versions is that the "base" version contains 12 "Transformer blocks" (the main layer type in BERT) where as the "large" version contains 24.

6.2 Automatic Mixed Precision (AMP)

We evaluate Daydream's prediction accuracy of AMP [42], which is implemented in NVidia's Apex package [51] based on the PyTorch framework. Figure 5 shows the performance of using AMP and the corresponding performance prediction given by Daydream. Our predictions have errors below 13% for all the models we evaluate.

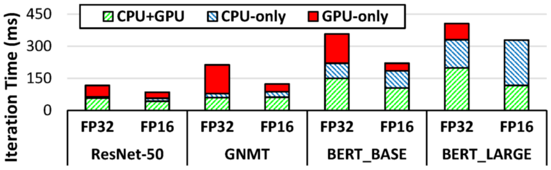

Figure 6: Runtime breakdown of the baseline (FP32) and mixed precision (FP16).

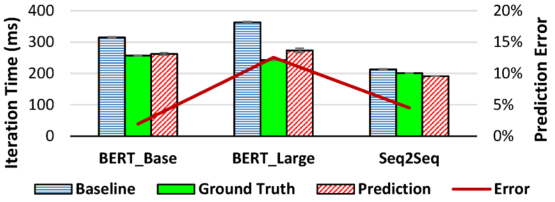

Figure 7: FusedAdam - comparing baseline (FP32), ground truth with FusedAdam, and predictions by Daydream.

Our experiments show that using AMP brings speedups generally less than 2× – much less than the theoretical boost of using AMP for individual kernels (e.g., 3×). To understand how AMP improves performance, we break down the overall runtime into the following three components:

CPU-only runtime. This component refers to the runtime when the CPU is busy, but the GPU is not executing any kernels. It is straightforward to calculate this runtime by simply subtracting all GPU kernel runtime from the total runtime.

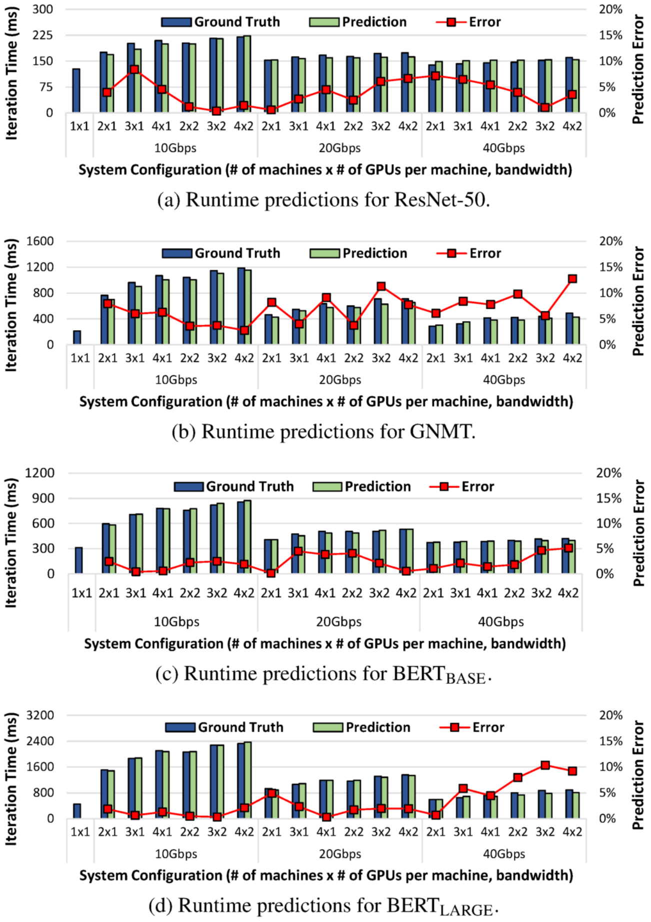
GPU-only runtime. This component refers to the runtime when the CPU is waiting for the GPU kernels to complete. It includes not only the duration of CUDA synchronization APIs, but also the `cudaMemcpyAsync` calls of all the device-to-host CUDA memory copies.

CPU+GPU parallel runtime. This component refers to the runtime when both CPU and GPU are busy. We calculate this part of runtime by deducting the CPU-only and GPU-only parts from the total runtime.

Figure 6 shows the runtime breakdown of the models we evaluated. CPU runtime generally becomes the new performance bottleneck in the models that incur limited speedups (e.g., $\text{BERT}_{\text{LARGE}}$). When applying AMP, the CPU bottleneck increases, because the GPU runtime becomes shorter and part of the CPU+GPU parallel runtime is shifted to the CPU-only runtime. The overall runtime improvement comes mostly from the reduction of GPU-only runtime while CPU runtime barely changes. This demonstrates the necessity of the kernel-level abstraction when predicting performance.

6.3 FusedAdam Optimizer

We apply the FusedAdam optimization to the BERT and GNMT models as they use the Adam optimizer. Figure 7 shows the performance of using the FusedAdam optimizer. Our predictions are within 13% of the ground truth runtime.



(a) Runtime predictions for ResNet-50.

(b) Runtime predictions for GNMT.

(c) Runtime predictions for BERT$_{\text{BASE}}$.

(d) Runtime predictions for BERT$_{\text{LARGE}}$.

Figure 8: The error between Daydream's runtime predictions and the baseline with synchronization before each allReduce under various system configurations.

There are two reasons why the FusedAdam optimizer substantially improves the performance of BERT models. First, unlike most DNN training workloads, the weight update phase is a significant proportion of a BERT model's iteration runtime (around 30% for BERT$_{\text{BASE}}$ and 45% for BERT$_{\text{LARGE}}$). Second, the weight update phase consists of very many element-wise GPU kernels (2633 for BERT$_{\text{BASE}}$, 5164 for BERT$_{\text{LARGE}}$). Thus, the CUDA launch calls on the CPU become the main bottleneck. The FusedAdam optimizer almost eliminates all CPU kernel launch overhead in the weight update phase by fusing all GPU kernels into one single GPU kernel. Compared to BERT models, the GNMT model spends less than 10% of its iteration time on the weight update phase, explaining the lower speedup improvements.

6.4 Reconstructing Batchnorm

We evaluate our performance prediction for the optimization of reconstructing batch normalization [35] based on the Caffe implementation of DenseNet-121 [28]. Using Daydream, we predict that reconstructing batchnorm will yield a moderate performance improvement of 12.7% compared to the baseline. This suggests that reconstructing batchnorm in our configuration is less promising than the paper claims (17.5% speedup). We verify this conclusion by testing the ground truth implementation of reconstructing batchnorm, and find out that this optimization yields even lower 7% speedup.

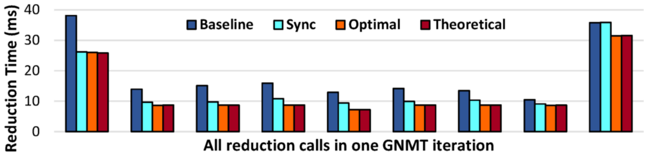


Figure 9: Comparison of all individual reduction runtimes in one training iteration of GNMT. **Baseline**: runtime measured in regular training; **Sync**: runtime measured with an additional CUDA synchronization before each reduction; **Optimal**: runtime measured when executing exclusively; **Theoretical**: runtime calculated using the formula [57].

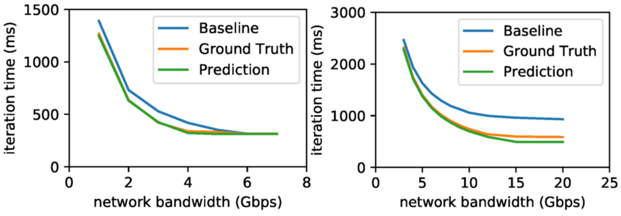
We notice that there are two main reasons for the difference between our prediction and the ground truth. First, the ground truth uses a completely new implementation of the batchnorm layers, and it is hard to precisely predict the runtime of newly implemented kernels. Second, the ground truth implementation introduces new CUDA memory copies and allocations, which add performance overhead. Obtaining a very precise estimate would require us to understand not just the high-level idea from the paper, but also the detailed implementation of the user-level programs and the Caffe framework.

6.5 Distributed Training

Next we evaluate distributed training using PyTorch with the NCCL [46] library. Figure 8 shows the comparisons between runtimes predicted by Daydream and the measured ground truth runtimes, for each DNN model under different system configurations. We evaluate the prediction accuracy for Ethernet and InfiniBand connecting multi-machine systems under different network bandwidths (10, 20, 40 Gbps). In most of the configurations, Daydream predicts distributed runtime with at most 10% prediction error, with a few exceptions for the 20Gbps and 40Gbps configurations.

The prediction errors of the overall iteration times are mainly due to inaccurate estimates of individual NCCL primitives. Figure 9 shows the comparisons of NCCL allReduce calls between the ground truths and predictions. The ground truths are on average 34% higher than the theoretical values.

An NCCL primitive is both a communication primitive and a GPU kernel, suggesting that it could be bottlenecked by two types of hardware resources: (i) the network bandwidth, and (ii) GPU resources (e.g., memory bandwidth, streaming multiprocessors). Figure 9 shows that the predicted values are very close to the runtimes measured when running NCCL primitives exclusively. This suggests that the ground truth is slower because they compete for GPU resources with other GPU kernels. Based on this insight, we try to reduce this interference by adding CUDA synchronizations before invoking NCCL



(a) ResNet-50.

(b) VGG-19.

Figure 10: Daydream's prediction for how the P3 optimization will help under different network bandwidths.

primitives. As shown in Figure 9, adding synchronizations improve the NCCL primitives by 22.8% on average when compared to the baseline.

We also verify the impact to the overall iteration time when adding synchronizations before NCCL primitives. We run the experiments on all the configurations shown in Figure 8. We find that this simple approach does not lead to performance degradation in any configuration. Instead, it could bring an improvement of up to 22%.

6.6 Priority-Based Parameter Propagation

We evaluate Daydream's prediction accuracy of applying Priority-Based Parameter Propagation (P3) to VGG-19 and ResNet-50. To reproduce the performance speedups of P3, we use a cluster of four machines with one P4000 GPU per machine (which is consistent with the evaluation setup of the P3 paper [30]). We use MXNet v1.1, and have one worker process and one parameter server process on each machine.

Figure 10 shows the iteration time of the baseline, ground truth, and prediction using Daydream under different bandwidths. Our prediction faithfully reflects the trend of P3 speedups when the network bandwidth increases. The prediction error is at most 16.2% among all the configurations we tested, and lower in most of the configurations.

We overestimate the speedup of P3, especially when training VGG-19 with a 15 or 20 Gbps network bandwidth. The reason is similar to our previous insight about NCCL primitives: when bandwidth is higher, a communication task is increasingly bottlenecked by non-network resources. In the case of MXNet, this overhead could be caused by the server processes, or the control flow of the worker processes.

7 Discussion

In this section, we discuss the adaptability, potential extensions, and some limitations of Daydream.

Why Not Simply Run the Optimizations? The main problem many ML developers face is that not all optimizations are readily available on all platforms. In fact, we are only able to evaluate the prediction accuracy of optimizations with the implementations already available (see Table 1); for the remaining ones, we highlight the flexibility of Daydream by showing that they can be represented succinctly. Most newly proposed optimizations do not have open-source implementations on **all** DNN frameworks available right away; it would be unreasonable to expect researchers to open-source their implementations and port their optimizations on all platforms. Therefore, analyzing if these optimizations can help in a deployment setting, using Daydream, can still precede the programming effort to port the optimizations. Furthermore, Daydream's profiling can be performed just once, and using that profile on a given platform, one can answer questions for many different optimizations.

Adaptability of Daydream Daydream requires support from hardware profilers. The current implementation of Daydream utilizes GPU-based profilers, and it relies on CUPTI to provide: (i) CPU and GPU traces and (ii) information about which CPU call triggered the launch of a specific GPU kernel. Adapting our design to other architectures (e.g., TPUs), would require hardware vendor profilers to provide similar traces for this new hardware.

Daydream can be also easily adapted to other ML frameworks (e.g., MXNet and TensorFlow). We built Daydream based on PyTorch, and then post-process the dumped traces to make predictions. The post-processing scripts are framework-independent. To add framework instrumentation, we need to: (i) add CUPTI (or similar tool) support, (ii) insert per-layer timestamps, and (iii) gather the gradient-to-bucket mappings for injecting the communication primitives to the dependency graph (required for PyTorch). Such instrumentation is relatively light-weight and can be easily adapted to other mainstream frameworks such as TensorFlow [3] and MXNet [12].

Training Accuracy Prediction In addition to improving iteration time, some optimizations may also affect training accuracy (e.g., AMP [42], DGC [40]); predicting the impact of optimizations on accuracy is currently outside of Daydream's scope. We leave this interesting and challenging problem for future work.

Kernel Runtime Prediction Estimating the effect of optimizations that alter existing GPU kernels or introduce new ones requires predicting the runtime of new/changed GPU kernels. When estimating performance of AMP, our estimation of kernels that use half-precision kernels was based on findings/observations from NVIDIA [42]. This generalization above for all kernels (in contrast to identifying how each kernel in isolation is affected by AMP), still leads to the low prediction errors we observe in Figure 5.

However, optimizations such as DGC [40], Reconstructing Batchnorm [35], and Gist [29] introduce newly-implemented kernels to the runtime. Accurately predicting runtime for new kernels is a challenging problem. Daydream estimates the overall runtime based on existing kernel implementations, or using guidelines from studies that highlight quantitative improvements for the proposed kernels. But if the estimated runtimes for such new kernels are inaccurate, it may lead to relatively high prediction error (Section 6.4). How much a kernel's runtime estimation error contributes to the overall prediction error depends on the training workload itself. Due to this limitation, it is hard for Daydream to accurately model algorithmic innovations (e.g., BPPSA [77] or 2nd Order Optimizations [68]), because these innovations use new GPU kernels at a massive scale, making the performance estimation with Daydream less accurate. Estimating new GPU kernels runtime is beyond the current scope of Daydream.

While Daydream cannot predict individual kernel runtime, it provides a high-level structure for kernel developers to estimate the overall performance. Developers can profile their individual kernels, and then input the profiling results into Daydream to accurately estimate the overall runtime. This approach saves the engineering effort of porting the kernel implementation into the DNN frameworks.

Concurrent Kernels Existing GPU profilers such as CUPTI usually serialize GPU kernel execution, removing all concurrency, making our performance estimation somewhat conservative. Despite this, we observe that the runtime for models with concurrent execution (e.g., GNMT) can still be predicted with high accuracy (§ 6.2). This is because the majority of computation time goes to fully connected layers (including embedding layers), which have no concurrent kernels executed in parallel with them. We leave a complete solution for concurrent kernels, requiring better support from profiling tools, as a part of future work.

8 Related Work

To help programmers understand the performance of the hardware accelerators and develop highly efficient applications, hardware vendors provide profiling tools (e.g., NVProf [48], Nsight [47], and vTune [66]) that can reveal low-level performance counters (e.g., cache hit rate, memory speed or clock rate). These tools are usually designed with general applications in mind, and expose hundreds of low-level performance counters. The fundamental limitation of all these tools is that they do not utilize application-specific knowledge.

The new generation of profiling tools feature the *application-aware* property, enabling them to deliver domain-specific (e.g., ML-specific) insights about performance to programmers. The Cloud TPU Tool [21] is an example of such a profiling tool. It correlates low-level TPU metrics with the DNN structure, and shows the performance for each DNN layer. Similarly, MXNet [12] and PyTorch [61] also have their own built-in profiling tools. These domain-specific tools can highlight performance hotspots, but are less efficient in finding optimization opportunities. In contrast, Daydream is not only *application-aware*, but also *optimization-aware*, enabling Daydream to quantitatively estimate the efficacy of different optimizations without fully implementing them.

Prior works have tried to explore what-if questions in other contexts by using low-level traces. Curtsinger *et al.* proposed a causal profiler (COZ [17]) to identify potentially unknown optimization opportunities by running performance simulation with certain functions being virtually speed-up. Unlike Daydream, COZ does not require dependencies among functions because it does not consider the cases where functions can be added or deleted (which is the case for many ML optimizations). Pourghassemi *et al.* uses the idea of COZ to analyze the performance for web browser applications [63]. For data analytic frameworks, such as Spark [82], Ousterhout *et al.* use dependency analysis to understand the overhead caused by I/O, network, and stragglers [59,60]. Daydream is designed to address a more diversified set of what-if questions, and hence requires more powerful modeling.

Prior works address what-if questions of the form "What if we can speedup task T by N times (or infinity)?", but they do not study whether existing optimizations can deliver this speedup. In the ML context, given an optimization, accurately predicting the performance of individual tasks in the dependency graph, is still an open problem. It requires additional knowledge about the kernel implementation and the architecture design. Currently Daydream can not automatically estimate the runtime of new GPU kernels. However, as we show in Section 6, even with rough estimates of per-kernel duration based on domain knowledge and reasonable assumptions, we can still achieve high overall prediction accuracy.

9 Conclusion

The efficacy of DNN optimizations can vary largely across different DNN models and deployments. Daydream is a new profiler to effectively explore the efficacy of a diverse set of DNN optimizations. Daydream achieves this goal by using three key ideas: (i) constructing a kernel-level dependency graph by utilizing vendor-provided profiling tools, while tracking dependencies among concurrently executing tasks; (ii) mapping low-level traces to DNN layers in a synchronization-free manner; (iii) introducing a set of rules for programmers to effectively describe and model different optimizations. Our evaluation shows that using Daydream, we can effectively model (i.e. predict runtime) the most common DNN optimizations, and accurately identify both optimizations that result in significant performance improvements as well as those that provide limited benefits or even slowdowns.

ALERT: Accurate Learning for Energy and Timeliness

Chengcheng Wan, Muhammad Santriaji, Eri Rogers, Henry Hoffmann, Michael Maire, Shan Lu
The University of Chicago

Abstract

An increasing number of software applications incorporate runtime Deep Neural Networks (DNNs) to process sensor data and return inference results to humans. Effective deployment of DNNs in these interactive scenarios requires meeting latency and accuracy constraints while minimizing energy, a problem exacerbated by common system dynamics.

Prior approaches handle dynamics through either (1) system-oblivious DNN adaptation, which adjusts DNN latency/accuracy tradeoffs, or (2) application-oblivious system adaptation, which adjusts resources to change latency/energy tradeoffs. In contrast, this paper improves on the state-of-the-art by coordinating application- and system-level adaptation. ALERT, our runtime scheduler, uses a probabilistic model to detect environmental volatility and then simultaneously select both a DNN and a system resource configuration to meet latency, accuracy, and energy constraints. We evaluate ALERT on CPU and GPU platforms for image and speech tasks in dynamic environments. ALERT's holistic approach achieves more than 13% energy reduction, and 27% error reduction over prior approaches that adapt solely at the application or system level. Furthermore, ALERT incurs only 3% more energy consumption and 2% higher DNN-inference error than an oracle scheme with perfect application and system knowledge.

1 Introduction

1.1 Motivation

Deep neural networks (DNNs) have become a key workload for many computing systems due to their high inference accuracy. This accuracy, however, comes at a cost of long latency, high energy usage, or both. Successful DNN deployment requires meeting a variety of user-defined, application-specific goals for latency, accuracy, and often energy in unpredictable, dynamic environments.

Latency constraints naturally arise with DNN deployments when inference interacts with the real world as a consumer—processing data streamed from a sensor—or a producer—returning a series of answers to a human. For example, in motion tracking, a frame must be processed at camera speed [40]; in simultaneous interpretation, translation must be provided every 2–4 seconds [56]. Violating these deadlines may lead to severe consequences: if a self-driving vehicle cannot act within a small time budget, life threatening accidents could follow [53].

Accuracy and energy requirements are also common and may vary for different applications in different operating environments. On one hand, low inference accuracy can lead to software failures [67, 80]. On the other hand, it is beneficial to minimize DNN energy or resource usage to extend mobile-battery time or reduce server-operation cost [41].

These requirements are also highly dynamic. For example, the latency requirement for a job could vary dynamically depending on how much time has already been consumed by related jobs before it [53]; the power budget and the accuracy requirement for a job may switch among different settings depending on what type of events are currently sensed [1]. Additionally, the latency requirement may change based on the computing system's current context; e.g., in robotic vision systems the latency requirement can change based on the robot's latency and distance from perceived pedestrians [18].

Satisfying all these requirements in a dynamic computing environment where the inference job may compete for resources against unpredictable, co-located jobs is challenging. Although prior work addresses these problems at either the application level or system level separately, each approach by itself lacks critical information that could be used to produce better results.

At the application level, different DNN designs—with different depths, widths, and numeric precisions—provide various latency-accuracy trade-offs for the same inference task [26, 39, 42, 77, 85]. Even more dynamic schemes have been proposed that adapt the DNN by dynamically changing its structure at the beginning of [22, 61, 84, 89] or during [34, 35, 49, 52, 82, 86, 88] every inference tasks.

Although helpful, these techniques are sub-optimal without considering system-level adaptation options. For example, under energy pressure, these application-level adaptation techniques have to switch to lower-accuracy DNNs, sacrificing accuracy for energy saving, even if the energy goal could have been achieved by lowering the system power setting (if there is sufficient latency budget).

At the system level, machine learning [4, 14, 15, 51, 63, 68, 69, 79] and control theory [32, 37, 44, 45, 62, 70, 74, 93] based techniques have been proposed to dynamically assign system resources to better satisfy system and application constraints.

Unfortunately, without considering the option of application adaptions, these techniques also reach sub-optimal solutions. For example, when the current DNN offers much higher accuracy than necessary, switching to a lower-precision DNN may offer much more energy saving than any system-level adaptation techniques. This problem is exacerbated because, in the DNN design space, very small drops in accuracy enable dramatic reductions in latency, and therefore system resource requirements.

A cross-stack solution would enable DNN applications to meet multiple, dynamic constraints. However, offering such a holistic solution is non-trivial. The combination of DNN and system-resource adaptation creates a huge configuration space, making it difficult to dynamically and efficiently predict which combination of DNN and system settings will meet all the requirements optimally. Furthermore, without careful coordination, adaptations at the application and system level may conflict and cause constraint violations, like missing a latency deadline due to switching to higher-accuracy DNN and lower power setting at the same time.

1.2 Contributions

This paper presents ALERT, a cross-stack runtime system for DNN inference to meet user goals by simultaneously adapting both DNN models and system-resource settings.

Understanding the challenges We profile DNN inference across applications, inputs, hardware, and resource contention confirming there is a high variation in inference time. This leads to challenges in meeting not only latency but also energy and accuracy requirements. Furthermore, our profiling of 42 existing DNNs for image classification confirms that different designs offer a wide spectrum of latency, energy, and accuracy tradeoffs. In general, higher accuracy comes at the cost of longer latency and/or higher energy consumption. These tradeoffs offered provide both opportunities and challenges to holistic inference management (Section 2).

Run-time inference management We design ALERT, a DNN inference management system that dynamically selects and adapts a DNN and a system-resource setting together to handle changing system environments and meet dynamic energy, latency, and accuracy requirements[1] (Section 3).

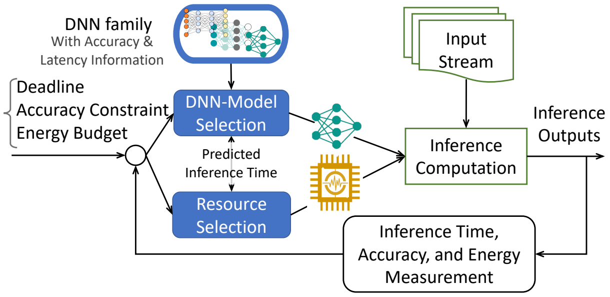

Figure 1: ALERT inference system

ALERT is a feedback-based run-time. It measures inference accuracy, latency, and energy consumption; it checks whether the requirements on these goals are met; and, it then outputs both system and application-level configurations adjusted to the current requirements and operating conditions. ALERT focuses on meeting constraints in *any* two dimensions while optimizing the third; e.g., minimizing energy given accuracy and latency requirements or maximizing accuracy given latency and energy budgets.

The key is estimating how DNN and system configurations interact to affect the goals. To do so, ALERT addresses three primary challenges: (1) the combined DNN and system configuration space is huge, (2) the environment may change dynamically (including input, available resources, and even the required constraints), and (3) the predictions must be low overhead to have negligible impact on the inference itself.

ALERT addresses these challenges with a *global slow-down factor*, a random variable relating the current runtime environment to a nominal profiling environment. After each inference task, ALERT estimates the global slow-down factor using a Kalman filter. The global slow-down factor's mean represents the expected change compared to the profile, while the variance represents the current volatility. The mean provides a single scalar that modifies the predicted latency/accuracy/energy for *every* DNN/system configuration—a simple mechanism that leverages commonality among DNN architectures to allow prediction for even rarely used configurations (tackle challenge-1), while incorporating variance into predictions naturally makes ALERT conservative in volatile environments and aggressive in quiescent ones (tackle challenge-2). The global slow-down factor and Kalman filter are efficient to implement and low-overhead (tackle challenge-3). Thus, ALERT combines the global slow-down factor with latency, power, and accuracy measurements to select the DNN and system configuration with the highest likelihood of meeting the constraints optimally.

We evaluate ALERT using various DNNs and application domains on different (CPU and GPU) machines under various constraints. Our evaluation shows that ALERT overcomes dynamic variability efficiently. Across various experimental

[1] ALERT provides probabilistic, not hard guarantees, as the latter requires much more conservative configurations, often hurting both energy and accuracy. Section 3.6 discusses this issue further.

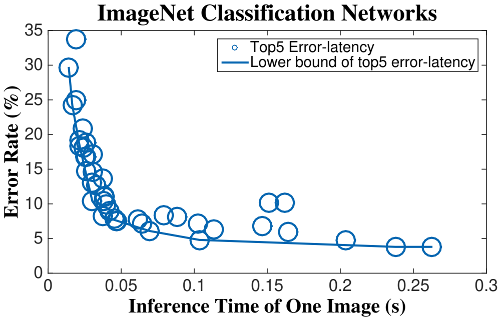

Figure 2: Tradeoffs for 42 DNNs (CPU2).

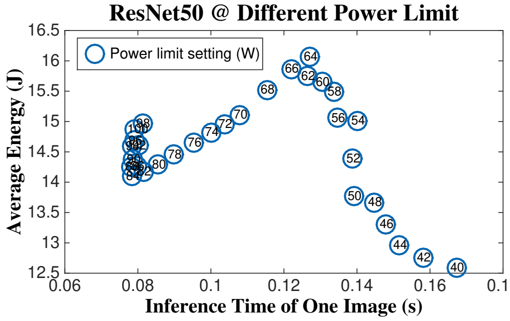

Figure 3: Tradeoffs for ResNet50 at different power settings (CPU2). (Numbers inside circles are power limit settings.)

settings, ALERT meets constraints while achieving within 93–99% of optimal energy saving or accuracy optimization. Compared to approaches that adapt at application-level or system-level only ALERT achieves more than 13% energy reduction, and 27% error reduction (Section 5).

2 Understanding Deployment Challenges

We conduct an empirical study to examine the large trade-off space offered by different DNN designs and system settings (Sec. 2.1), and the timing variability of inference (Sec. 2.2).

Table 2: ML tasks and benchmark datasets in our experiments

We use two canonical machine learning tasks, with state-of-the-art networks and common data-sets (see Table 2) on a diverse set of hardware platforms, representing embedded systems, laptops (CPU1), CPU servers (CPU2), and GPU platforms (see Table 1). The two tasks, image classification and natural language processing (NLP), are often deployed with deadlines—e.g., for motion tracking [40] and simultaneous interpretation [56]—and both have received wide attention leading to a diverse set of DNN models.

2.1 Understanding the Tradeoffs

Tradeoffs from DNNs We run **all** 42 image classification models provided by the Tensorflow website [76] on the 50000 images from ImageNet [16], and measure their average latency, accuracy (error rate), and energy consumption. The results from CPU2 are shown in Figure 2. We can clearly see two trends from the figure, which hold on other machines.

First, different DNN models offer a *wide* spectrum of accuracy (error rate in figure), latency, and energy. As shown in the figure, the fastest model runs almost 18× faster than the slowest one and the most accurate model has about 7.8× lower error rate than the least accurate. These models also consume a wide range—more than 20×—of energy usage.

Second, there is no magic DNN that offers both the best accuracy and the lowest latency, confirming the intuition that there exists a tradeoff between DNN accuracy and resource usage. Of course, some DNNs offer better tradeoffs than others. In Figure 2, all the networks sitting above the lower-convex-hull curve represent sub-optimal tradeoffs.

Tradeoffs from system settings We run ResNet50 under 31 power settings from 40–100W on CPU2. We consider a sensor processing scenario with periodic inputs, setting the period to the latency under 40W cap. We then plot the average energy consumed for the whole period (run-time plus idle energy) and the average inference latency in Figure 3.

The results reflect two trends, which hold on other machines. First, a large latency/energy space is available by changing system settings. The fastest setting (100W) is more than 2× faster than the slowest setting (40W). The most energy-hungry setting (64W) uses 1.3× more energy than the least (40W). Second, there is no easy way to choose the best setting. For example, 40W offers the lowest energy, but highest latency. Furthermore, most of these points are sub-optimal in terms of energy and latency tradeoffs. For example, 84W should be chosen for extremely low latency deadlines, but all other nearby points (from 52–100) will harm latency, energy or both. Additionally, when deadlines change or when there is resource contention, the energy-latency curve also changes and different points become optimal.

Summary: DNN models and system-resource settings offer a huge trade-off space. The energy/latency tradeoff space is not smooth (when accounting for deadlines and idle power) and optimal operating points cannot be found with simple gradient-based heuristics. Thus, there is a great

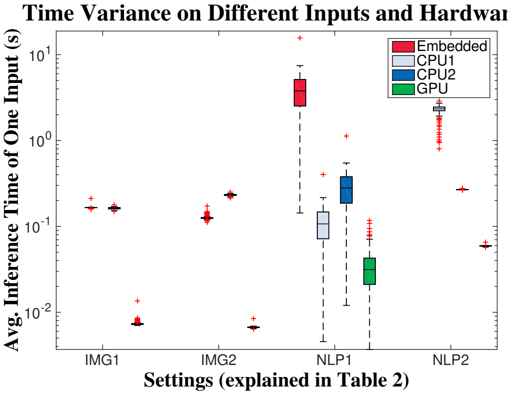

Figure 4: Latency variance across inputs for different tasks and hardware (Most tasks have 3 boxplots for 3 hardware platforms, CPU1-2, GPU from left to right; NLP1 has an extra boxplot for Embedded; other tasks run out of memory on Embedded; every box shows the 25th–75th percentile; points beyond the whiskers are >90th or <10th).

opportunity and also a great challenge in picking different DNN models and system-resource settings to satisfy inference latency, accuracy, and energy requirements.

2.2 Understanding Variability

To understand how DNN-inference varies across inputs, platforms, and run-time environment and hence how (not) helpful is off-line profiling, we run a set of experiments below, where we feed the network one input at a time and use 1/10 of the total data for warm up, to emulate real-world scenarios. We plot the inference latency without and with co-located jobs in Figure 4 and 5, and we see several trends.

First, deadline violation is a realistic concern. Image classification on video has deadlines ranging from 1 second to the camera latency (e.g., 1/60 seconds) [40]; the two NLP tasks, have deadlines around 1 second [64]. There is clearly no single inference task that meets all deadlines on all hardware.

Second, the inference variation among inputs is relatively small particularly when there are no co-located jobs (Fig. 4), except for that in NLP1, where this large variance is mainly caused by different input lengths. For other tasks, outlier inputs exist but are rare.

Third, the latency and its variation across inputs are both greatly affected by resource contention. Comparing Figure 5 with Figure 4, we can see that the co-located job has increased both the median latency, the tail inference, and the difference between these two for all tasks on all platforms. This trend also applies to other contention cases.

While the discussion above is about latency, similar conclusions apply to inference accuracy and energy: the accuracy typically drops to close to 0 when the inference time exceeds the latency requirement, and the energy consumption naturally changes with inference time.

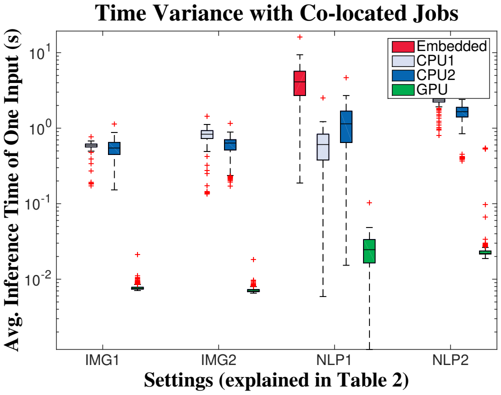

Figure 5: Latency variance with co-located jobs (the memory-intensive STREAM benchmark [60] co-located on Embedded, CPU1-2; GPU-intensive Backprop [8] co-located on GPU)

Summary: Deadline violations are realistic concerns and inference latency varies greatly across platforms, under contention, and sometimes across inputs. Clearly, sticking to one static DNN design across platforms and workloads leads to an unpleasant trade-off: always meeting the deadline by sacrificing accuracy or energy in most settings, or achieving a high accuracy some times but exceeding the deadline in others. Furthermore, it is also sub-optimal to make run-time decisions based solely on off-line profiling, considering the variation caused by run-time contention.

2.3 Understanding Potential Solutions

We now show how confining adaptation to a single layer (just application or system) is insufficient. We run the ImageNet classification on *CPU1*. We examine a range of latency (0.1s-0.7s) and accuracy constraints (85%-95%), and try meeting those constraints while minimizing energy by either (1) configuring just the DNN (selecting a DNN from a family, like that in Figure 2) or (2) configuring just the system (by selecting resources to control energy–latency tradeoffs as in Figure 3). We compare these single-layer approaches to one that simultaneously picks the DNN and system configuration. As we are concerned with the ideal case, we create oracles by running 90 inputs in all possible DNN and system configurations, from which we find the best configuration for each input. The App-level oracle uses the default system setting. The Sys-level oracle uses the default (highest accuracy) DNN.

Figure 6 shows the results. As we have a three dimensional problem—meeting accuracy and latency constraints with minimal energy—we linearize the constraints and show them on the x-axis (accuracy is faster changing, with latency slower, so each latency bin contains all accuracy goals). There are several important conclusions here. First, the App-only approach meets all possible accuracy and latency constraints, while the Sys-only approach cannot meet any constraints below 0.3s. Second, across the entire constraint range, App-

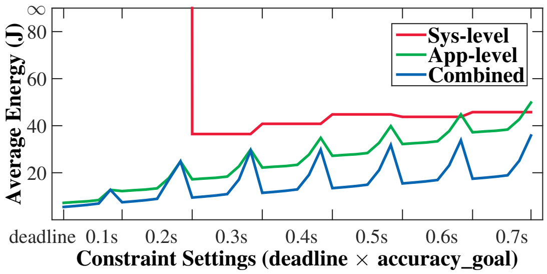

Figure 6: Minimize energy task with latency and accuracy constraint @ CPU1. (∞ means unable to meet the constraints)

only consumes significantly more energy than Combined (60% more on average). The intuition behind Combined's superiority is that there are discrete choices for DNNs; so when one is selected, there are almost always energy saving opportunities by tailoring resource usage to that DNN's needs.

Summary: Combining DNN and system level approaches achieves better outcomes. If left solely to the application, energy will be wasted. If left solely to the system, many achievable constraints will not be met.

3 ALERT Run-time Inference Management

ALERT's runtime system navigates the large tradeoff space created by *combining* DNN-level and system-level adaptation. ALERT meets user-specified latency, accuracy, and energy constraints and optimization goals while accounting for runtime variations in environment or the goals themselves.

3.1 Inputs & Outputs of ALERT

ALERT's inputs are specifications about (1) the adaption options, including a set of DNN models $\mathbb{D} = \{d_i \mid i = 1 \cdots K\}$ and a set of system-resource settings, expressed as different power-caps $\mathbb{P} = \{P_j \mid j = 1 \cdots L\}$; and (2) the user-specified requirements on latency, accuracy, and energy usage, which can take the form of meeting constraints in any two of these three dimensions while optimizing the third. ALERT's output is the DNN model $d_i \in \mathbb{D}$ and the system-resource setting $p_j \in \mathbb{P}$ for the next inference-task input.

Formally, ALERT selects a DNN d_i and a system-resource setting p_j to fulfill *either* of these user-specified goals.

Maximizing inference accuracy q (minimizing error) for an energy budget $\mathbf{E}_{\text{goal}}$ and inference deadline $\mathbf{T}_{\text{goal}}$:

$$\arg\max_{i,j} q_{i,j} \quad \text{s.t. } e_{i,j} \leq \mathbf{E}_{\text{goal}} \wedge t_{i,j} \leq \mathbf{T}_{\text{goal}} \tag{1}$$

Minimizing the energy use e for an accuracy goal $\mathbf{Q}_{\text{goal}}$ and inference deadline $\mathbf{T}_{\text{goal}}$:

$$\arg\min_{i,j} e_{i,j} \quad \text{s.t. } q_{i,j} \geq \mathbf{Q}_{\text{goal}} \wedge t_{i,j} \leq \mathbf{T}_{goal} \tag{2}$$

We omit the discussion of meeting energy and accuracy constraints while minimizing latency as it is a trivial extension of the discussed techniques and we believe it to be the least practically useful. We also omit the problem of optimizing all three dimensions, as it creates a feasibility problem, leaving nothing for optimization—lowest latency and highest accuracy are impractical to achieve simultaneously.

Generality Along the DNN-adaptation side, the input DNN set can consist of any DNNs that offer different accuracy, latency, and energy tradeoffs; e.g., those in Figure 3. In particular, ALERT can work with either or both of the broad classes of DNN adaptation approaches that have arisen recently, including: (1) traditional DNNs where the adaptation option should be selected prior to starting an inference task [20,22,61,84,89] and (2) anytime DNNs that produce a series of outputs as they execute [34,35,49,52,82,86,88]. These two classes are similar in that they both vary things like the network depth or width to create latency/accuracy tradeoffs.

On the system-resource side, ALERT uses a *power cap* as the proxy to system resource usage. Since both hardware [13] and software resource managers [33,72,90] can convert power budgets into optimal performance resource allocations, ALERT is compatible with many different schemes from both commercial products and the research literature.

3.2 ALERT Workflow

ALERT works as a feedback controller. It follows four steps to pick the DNN and resource settings for each input n:

1) Measurement. ALERT records the processing time, energy usage, and computes inference accuracy for $n-1$.

2) Goal adjustment. ALERT updates the time goal T_{goal} if necessary, considering the potential latency-requirement variation across inputs. In some inference tasks, a set of inputs share one combined requirement (e.g., in the NLP1 task in Table 2, all the words in a sentence are processed by a DNN one by one and share one sentence-wise deadline) and hence delays in previous input processing could greatly shorten the available time for the next input [1,47]. Additionally, ALERT sets the goal latency to compensate for its own, worst-case overhead so that ALERT itself will not cause violations.

3) Feedback-based estimation. ALERT computes the expected latency, accuracy, and energy consumption for every combination of DNN model and power setting.

4) Picking a configuration. ALERT feeds all the updated estimations of latency, accuracy, and energy into Eqs. 1 and 2, and gets the desired DNN model and power-cap setting for n.

The key task is step 3: the estimation needs to be accurate and fast. In the remainder of this section, we discuss key ideas and the exact algorithm of our feedback-based estimation.

3.3 Key Ideas of ALERT Estimation

Strawman Solving Eqs. 1 and 2 would be trivially easy if the deployment environment is guaranteed to match the training and profiling environment: we could estimate $t_{i,j}$ to be the average (or worst case, etc) inference time $t_{i,j}^{\text{prof}}$ over a set of profiling inputs under model d_i and power setting p_j. However, this approach does not work given the dynamic input, contention, and requirement variation.

Next, we present the key ideas behind how ALERT estimates the inference latency, accuracy, and energy consumption under model d_i and power setting p_j.

How to estimate the inference latency $t_{i,j}$? To handle the run-time variation, a potential solution is to apply an estimator, like a Kalman filter [55], to make dynamic predictions based on recent history about inferences under model d_i and power p_j. The problem is that most models and power settings will not have been picked recently and hence would have no recent history to feed into the estimator. This problem is a direct example of the challenge imposed by the large space of combined application and system options.

Idea 1: Handle the large selection space with a single scalar value. To make effective online estimation for *all* combinations of models and power settings, ALERT introduces a *global slow-down factor* ξ to capture how the current environment differs from the profiled environment (e.g., due to co-running processes, input variation, or other changes). Such an environmental slow-down factor is independent from individual model or power selection. It can fully leverage execution history, no matter which models and power settings were recently used; it can then be used to estimate $t_{i,j}$ based on $t_{i,j}^{\text{prof}}$ for all d_i and p_j combinations.

Applying a *global* slowdown factor for *all* combinations of application and system-level settings is crucial for ALERT to make quick decisions for every inference task. Although it is possible that some perturbations may lead to different slowdowns for different configurations, the slight loss of accuracy here is out-weighed by the benefit of having a simple mechanism that allows prediction even for configurations that have not been used recently.

This idea is also novel for ALERT, as previous cross-stack management systems all use much more complicated models to estimate and select different setting combinations (e.g., using model predictive control to estimate combinations of settings [57]). ALERT's global slowdown factor is based on several unique features of DNN families that accomplish the same task with different accurarcy/latency tradeoffs. We categorize these features as: (1) similarity of code paths and (2) proportionality of structure. The first is based on the observation that DNNs do not have complex conditional code dependences, so we do not need to worry about the case where different inputs would exercise very different code paths. Thus, what ALERT learns about latency, accuracy, and energy for one input will always inform it about future inputs. The second feature refers to the fact that as DNNs in a family scale in latency, the proportion of different operations tend to be similar, so what ALERT learns about one DNN in the family generally applies to other DNNs in the same family. These properties of DNNs do not hold for many other types of software, where different inputs or additional functionality can invoke entirely different code paths, with different resource requirements or responses.

How to estimate the accuracy under a deadline? Given a deadline $\mathbf{T}_{\text{goal}}$, the inference accuracy delivered by model d_i and power setting p_j is determined by three factors, as shown in Eq. 3: (1) whether the inference result, which takes time $t_{i,j}$, can be generated before the deadline $\mathbf{T}_{\text{goal}}$; (2) if yes, the accuracy is determined by the model d_i;[2] (3) if not, the accuracy drops to that offered by a backup result q_{fail}. For traditional DNN models, without any output at the deadline, a random guess will be used and q_{fail} will be much worse than q_i. For anytime DNN models that output multiple results as they are ready, the backup result is the latest output [34, 35, 49, 52, 82, 86, 88], which we discuss more in Section 3.5.

$$q_{i,j}[\mathbf{T}_{\text{goal}}] = \begin{cases} q_i & \text{, if } t_{i,j} \leq \mathbf{T}_{\text{goal}} \\ q_{\text{fail}} & \text{, otherwise} \end{cases} \tag{3}$$

A potential solution to estimate accuracy $q_{i,j}$ at the deadline $\mathbf{T}_{\text{goal}}$ is to simply feed the estimated $t_{i,j}$ into Eq. 3. However, this simple approach fails to account for two issues. First, while DNNs are generally well-behaved, significant tail effects are possible (see Figure 4). Second, Eq. 3 is not linear, and is best understood as a step function, where a failure to complete inference by the deadline results in a worthless inference output (q_{fail}). Combined, these two issues mean that for tail inputs, inference will produce a worthless result; i.e., accuracy is not proportional to latency, but can easily fall to zero for tail inputs. The tail will, of course, be increased if there is any unexpected resource contention. Therefore, the simple approach of using the mean latency prediction fails to account for the non-linear affects of latency on accuracy.

Idea 2: handle the runtime variation and account for tail behavior To handle the run-time variability mentioned in Section 1, ALERT treats the execution time $t_{i,j}$ and the global slow-down factor ξ as *random variables* drawn from a normal distribution. ALERT uses a recently proposed extension to the Kalman filter to adaptively update the noise covariance [2]. While this extension was originally proposed to produce better estimates of the mean, a novel approach in ALERT is using this covariance estimate as a measure of system volatility. ALERT uses this Kalman filter extension to predict not just the mean accuracy, but also the likelihood of meeting the accuracy requirements in the current operating environment. Section 5.3 shows the advantages of our extensions.

[2] Since it could be infeasible to calculate the exact inference accuracy at run time, ALERT uses the average training accuracy of the selected DNN model d_i, denoted as q_i, as the inference accuracy, as long as the inference computation finishes before the specified deadline.

How to minimize energy or satisfy energy constraints? Minimizing energy or satisfying energy constraints is complicated, as the energy is related to, but cannot be easily calculated by, the complexity of the selected model d_i and the power cap p_j. As discussed in Section 2.2, the energy consumption includes both that used during the inference under a given model d_i and that used during the inference-idle period, waiting for the next input. Consequently, it is not straightforward to decide which power setting to use.

Idea 3. ALERT leverages insights from previous research, which shows that energy for latency-constrained systems can be efficiently expressed as a mathematical optimization problem [7, 48, 50, 62]. These frameworks optimize energy by scheduling available configurations in time. Time is assigned to configurations so that the average performance hits the desired latency target and the overall energy (including idle energy) is minimal. The key is that while the configuration space is large, the number of constraints is small (typically just two). Thus, the number of configurations assigned a non-zero time is also small (equal to the number of constraints) [48]. Given this structure, the optimization problem can be solved using a binary search over available configurations, or even more efficiently with a hash table [62].

The only difficulty applying prior work to ALERT is that prior work assumed there was only a single job running at a time, while ALERT assumes that other applications might contend for resources. Thus, ALERT cannot assume that there is a single system-idle state that will be used whenever the DNN is not executing. To address this challenge, ALERT continually estimates the system power when DNN inference is idle (but other non-inference tasks might be active), $p_{DNNidle}$, transforming Eq. 1 is transformed into:

$$\arg\max_{i,j} q_{i,j}[\mathbf{T}_{\text{goal}}] \quad \text{s.t. } p_{i,j}\cdot t_{i,j} + p_{DNNidle}\cdot t_{DNNidle} \leq \mathbf{E}_{\text{goal}} \tag{4}$$

3.4 ALERT Estimation Algorithm

Global Slow-down Factor ξ. As discussed in Idea-1, ALERT uses ξ to reflect how the run-time environment differs from the profiling environment. Conceptually, if the inference task under model d_i and power-cap p_j took time $t_{i,j}$ at run time and took $t_{i,j}^{\text{prof}}$ on average to finish during profiling, the corresponding ξ would be $t_{i,j}/t_{i,j}^{prof}$. ALERT estimates ξ using recent execution history under any model or power setting.

Specifically, after an input $n-1$, ALERT computes $\xi^{(n-1)}$ as the ratio of the observed time $t_{i,j}^{(n-1)}$ to the profiled time $t_{i,j}^{\text{prof}}$, and then uses a Kalman Filter[3] to estimate the mean $\mu^{(n)}$ and variance $(\sigma^{(n)})^2$ of $\xi^{(n)}$ at input n. ALERT's formulation is defined in Eq. 5, where $K^{(n)}$ is the Kalman gain variable; R is a constant reflecting the measurement noise; $Q^{(n)}$ is the process noise capped with $Q^{(0)}$. We set a forgetting factor of process variance $\alpha = 0.3$ [2]. ALERT initially sets $K^{(0)} = 0.5$, $R = 0.001$, $Q^{(0)} = 0.1$, $\mu^{(0)} = 1$, $(\sigma^{(0)})^2 = 0.1$, following the standard convention [55].

$$\begin{cases} Q^{(n)} = \max\{Q^{(0)}, \alpha Q^{(n-1)} + (1\text{-}\alpha)(K^{(n-1)}y^{(n-1)})^2\} \\ K^{(n)} = \dfrac{(1-K^{(n-1)})(\sigma^{(n-1)})^2 + Q^{(n)}}{(1-K^{(n-1)})(\sigma^{(n-1)})^2 + Q^{(n)} + R} \\ y^{(n)} = t_{i,j}^{(n-1)}/t_{i,j}^{\text{prof}} - \mu^{(n-1)} \\ \mu^{(n)} = \mu^{(n-1)} + K^{(n)}y^{(n)} \\ (\sigma^{(n)})^2 = (1-K^{(n-1)})(\sigma^{(n-1)})^2 + Q^{(n)} \end{cases} \tag{5}$$

Then, using $\xi^{(n)}$, ALERT estimates the inference time of input n under any model d_i and power cap p_j: $t_{i,j}^{(n)} = \xi^{(n)} * t_{i,j}^{\text{prof}}$.

Probability of meeting the deadline. Given the Kalman Filter estimation for the global slowdown factor, we can calculate $Pr_{i,j}$, the probability that the inference completes before the deadline T_{goal}. ALERT computes this value using a cumulative distribution function (CDF) based on the normal distribution of $\xi^{(n)}$ estimated by the Kalman Filter:

$$\begin{aligned} Pr_{i,j} &= Pr[\xi^{(n)}\cdot t_{i,j}^{\text{prof}} \leq T_{goal}] = CDF(\xi^{(n)}\cdot t_{i,j}^{\text{prof}}, T_{goal}) \\ &= CDF(\mu^{(n)}\cdot t_{i,j}^{\text{prof}}, \sigma^{(n)}, T_{goal}) \end{aligned} \tag{6}$$

Accuracy. As discussed in Idea-2, ALERT computes the estimated inference accuracy $\hat{q}_{i,j}[\mathbf{T}_{\text{goal}}]$ by considering $t_{i,j}$ as a random variable that follows normal distribution with its mean and variance computed based on that of ξ. Here $q_{i,j}$ represents the inference accuracy when the DNN inference finishes before the deadline, and q_{fail} is the accuracy of a random guess:

$$\begin{aligned} \hat{q}_{i,j}[\mathbf{T}_{goal}] &= E(q_{i,j}[\mathbf{T}_{goal}] \mid t_{i,j}^{(n)}) \\ &= E(q_{i,j}[\mathbf{T}_{goal}] \mid \xi^{(n)}\cdot t_{i,j}^{\text{prof}}) \\ &= Pr_{i,j}\cdot q_{i,j} + (1-Pr_{i,j})\cdot q_{fail} \\ \xi^{(n)} &\sim \mathcal{N}(\mu^{(n)}, (\sigma^{(n)})^2) \end{aligned} \tag{7}$$

Energy. As discussed in Idea-3, ALERT predicts energy consumption by separately estimating energy during (1) DNN execution: estimated by multiplying the power limit by the estimated latency and (2) between inference inputs: estimated based on the recent history of inference idle power using the Kalman Filter in Eq. 8. $\phi^{(n)}$ is the predicted DNN-idle power ratio, $M^{(n)}$ is process variance, S is process noise, V is measurement noise, and $W^{(n)}$ is the Kalman Filter gain. ALERT initially sets $M^{(0)} = 0.01$, $S = 0.0001$, $V = 0.001$.

$$\begin{cases} W^{(n)} = \dfrac{M^{(n-1)} + S}{M^{(n-1)} + S + V} \\ M^{(n)} = (1-W^{(n)})(M^{(n-1)} + S) \\ \phi^{(n)} = \phi^{(n-1)} + W^{(n)}(p_{\text{idle}}/p_{i,j}^{(n-1)} - \phi^{(n-1)}) \end{cases} \tag{8}$$

[3] A Kalman Filter is an optimal estimator that assumes a normal distribution and estimates a varying quantity based on multiple potentially noisy observations [55].

ALERT then predicts the energy by Eq. 9. Unlike Eq. 7 that uses probabilistic estimates, energy estimation is calculated without the notion of probability. The inference power is the same no matter the inference misses or meets the deadline, as ALERT sets power limits. Therefore it is safe to estimate the energy by its mean without considering the distribution of its possible latency. See our extended report [87] on estimating energy by its worst case latency percentile.

$$e_{i,j}^{(n)} = p_{i,j} \cdot \xi^{(n)} \cdot t_{i,j}^{\text{prof}} + \phi^{(n)} \cdot p_{i,j} \cdot (\mathbf{T}_{goal} - (\xi^{(n)} \cdot t_{i,j}^{\text{prof}})) \quad (9)$$

3.5 Integrating ALERT with Anytime DNNs

An anytime DNN is an inference model that outputs a series of increasingly accurate inference results—o_1, o_2, ... o_k, with o_t more reliable than o_{t-1}. A variety of recent works [35,49,52,82,86,88] have proposed DNNs supporting anytime inference, covering a variety of problem domains. ALERT easily works with not only traditional DNNs but also Anytime DNNs. The only change is that q_{fail} in Eq. 3 no longer corresponds to a random guess. That is, when the inference could not generate its final result o_k by the deadline $\mathbf{T}_{\text{goal}}$, an earlier result o_x can be used with a much better accuracy than that of a random guess. The updated accuracy equation is below:

$$q_{.,j} = \begin{cases} q_k & \text{, if } t_{k,j} \leq \mathbf{t}_{\text{goal}} \\ q_{k-1} & \text{, if } t_{k-1,j} \leq \mathbf{t}_{\text{goal}} < t_{k,j} \\ & \dots \\ q_{\text{fail}} & \text{, otherwise} \end{cases} \quad (10)$$

Existing anytime DNNs consider latency but not energy constraints—an anytime DNN will keep running until the latency deadline arrives and the last output will be delivered to the user. ALERT naturally improves Anytime DNN energy efficiency, stopping the inference sometimes before the deadline based on its estimation to meet not only latency and accuracy, but also energy requirements.

Furthermore, ALERT can work with a set of traditional DNNs and an Anytime DNN together to achieve the best combined result. The reason is that Anytime DNNs generally sacrifice accuracy for flexibility. When we feed a group of traditional DNNs and one Anytime DNN to construct the candidacy set $\mathbb{D}$, with Eq. 7, ALERT naturally selects the Anytime DNN when the environment is changing rapidly (because the expected accuracy of an anytime DNN will be higher given that variance), and the regular DNN, which has slightly higher accuracy with similar computation, when it is stable, getting the best of both worlds.

In our evaluation, we will use the nested design from [86], which provides a generic coverage of anytime DNNs.

3.6 Limitations and Discussions

Assumptions of the Kalman Filter. ALERT's prediction, particularly the Kalman Filter, relies on the feedback from recent input processing. Consequently, it requires at least one input to react to sudden changes. Additionally, the Kalman filter formulations assume that the underlying distributions are normal, which may not hold in practice. If the behavior is not Gaussian, the Kalman filter will produce bad estimations for the mean of ξ for some amount of time.

ALERT is specifically designed to handle data that is not drawn from a normal distribution, using the Kalman Filter's covariance estimation to measure system volatility and accounting for that in the accuracy/energy estimations. Consequently, after just 2–3 such bad predictions of means, the estimated variance will increase, which will then trigger ALERT to pick anytime DNN over traditional DNNs or pick a low-latency traditional DNN over high-latency ones, because the former has a higher expected accuracy under high variance. So—worst case—ALERT will choose a DNN with slightly less accuracy than what could have been used with the right model. Users can also compensate for extremely aberrant latency distributions by increasing the value of $Q^{(0)}$ in Eq. 5. Section 5.3 shows ALERT performs well even when the distribution is not normal.

Probabilistic guarantees. ALERT provides probabilistic, not hard, guarantees. As ALERT estimates not just average timing, but the distributions of possible timings, it can provide arbitrarily many nines of assurance that it will meet latency or accuracy goals but cannot provide 100% guarantee (see our extended report [87] on how to configure ALERT to provide guarantees with a specific probability). Providing 100% guarantees requires the worst case execution time (WCET), an upper bound on the highest possible latency. ALERT does not assume the availability of such information and hence cannot provide hard guarantees [6].

Safety guarantees. While ALERT does not explicitly model safety requirements, it can be configured to prioritize accuracy over other dimensions. When users particularly value safety (e.g., auto-driving), they could set a high accuracy requirement or even remove the energy constraints.

Concurrent inference jobs. ALERT is currently designed to support one inference job at a time. To support multiple concurrent inference jobs, future work needs to extend ALERT to coordinate across these concurrent jobs. We expect the main idea of ALERT, such as using a global slowdown factor to estimate system variation, to still apply.

Finally, how the inference behaves ultimately depends not only on ALERT, but also on the DNN models and system-resource setting options. As shown in Section 5, ALERT helps make the best use of supplied DNN models, but does not eliminate the difference between different DNN models.

4 Implementation

We implement ALERT for both CPUs and GPUs. On CPUs, ALERT adjusts power through Intel's RAPL interface [13], which allows software to set a hardware power limit. On

	Run-time environment setting		
Default	Inference task has no co-running process		
Memory	Co-locate with memory-hungry STREAM [60] (@CPU) Co-locate with Backprop from Rodinia-3.1 [8] (@GPU)		
Compute	Co-locate with Bodytrack from PARSEC-3.0 [5] (@CPU) Co-locate with the forward pass of Backprop [8] (@GPU)		
	Ranges of constraint setting		
Latency	0.4x–2x mean latency* of the largest Anytime DNN		
Accuracy	Whole range achievable by trad. and Anytime DNN		
Energy	Whole feasible power-cap ranges on the machine		
Task	Trad. DNN	Anytime [86]	Fixed deadline?
Image Classifi.	Sparse ResNet	Depth-Nest	Yes
Sentence Pred.	RNN	Width-Nest	No
Scheme ID	DNN selection		Power selection
Oracle	Dynamic optimal		Dynamic optimal
$\text{Oracle}_{\text{Static}}$	Static optimal		Static optimal
App-only	One Anytime DNN		System Default
Sys-only	Fastest traditional DNN		State-of-Art [37]
No-coord	Anytime DNN w/o coord. with Power		State-of-Art [37]
ALERT	ALERT default		ALERT default
$\text{ALERT}_{\text{Any}}$	ALERT w/o traditional DNNs		ALERT default
$\text{ALERT}_{\text{Trad}}$	ALERT w/o Anytime DNNs		ALERT default

Table 3: Settings and schemes under evaluation (* measured under default setting without resource contention)

GPUs, ALERT uses PyNVML to control frequency and builds a power-frequency lookup table. ALERT can also be applied to other approaches that translate power limits into settings for combinations of resources [33, 36, 72, 90].

In our experiments, ALERT considers a series of power settings within the feasible range with 2.5W interval on our test laptop and a 5W interval on our test CPU server and GPU platform, as the latter has a wider power range than the former. The number of power buckets is configurable.

ALERT incurs small overhead in both scheduler computation and switching from one DNN/power-setting to another, just 0.6–1.7% of an input inference time. We explicitly account for overhead by subtracting it from the user-specified goal (see step 2 in Section 3.2).

Users may set goals that are not achievable. If ALERT cannot meet all constraints, it prioritizes latency highest, then accuracy, then power. This hierarchy is configurable.

5 Experimental Evaluation

We apply ALERT to different inference tasks on both CPU and GPU with and without resource contention from co-located jobs. We set ALERT to (1) reduce energy while satisfying latency and accuracy requirements and (2) reduce error rates while satisfying latency and energy requirements. We compare ALERT with both oracle and state-of-the-art schemes and evaluate detailed design decisions.

5.1 Methodology

Experimental setup. We use the three platforms listed in Table 1: *CPU1*, *CPU2*, and *GPU*. On each, we run inference tasks[4], image classification and sentence prediction, under three different resource-contention scenarios:

- No contention: the inference task is the only job running, referred to as "Default";
- Memory dynamic: the inference task runs together with a memory-intensive job that repeatedly stops and restarts, representing dynamic memory resource contention, referred to as "Memory";
- Computation dynamic: the inference task runs together with a computation-intensive job that repeatedly stops and restarts, representing dynamic computation resource contention, referred to as "Compute".

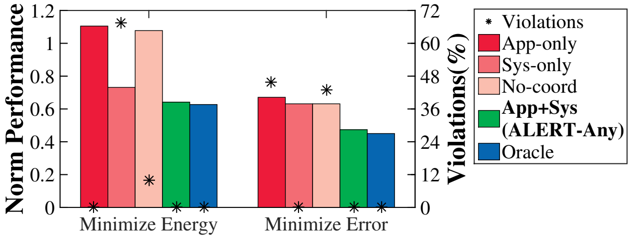

Figure 7: Average performance normalized to $\text{Oracle}_{\text{Static}}$. Violations% is %-of-constraint-settings under which a scheme incurs >10% violation of all inputs. (Smaller is better)

Schemes in evaluation. We give ALERT three different DNN sets, traditional DNN models ($\text{ALERT}_{\text{Trad}}$), an Anytime DNN ($\text{ALERT}_{\text{Any}}$), and both (ALERT), and compare it with two oracle and three state-of-the-art schemes (Table 3).

The two *Oracle*$_*$ schemes have perfect predictions for every input under every DNN/power setting (i.e., impractical). Specifically, the "Oracle" allows DNN/power settings to change across inputs, representing the best possible results; the "$\text{Oracle}_{\text{Static}}$" has one fixed setting across inputs, representing the best results without dynamic adaptation.

The three state-of-the-art approaches include the following:

- "App-only" conducts adaptation only at the application level through an Anytime DNN [86];
- "Sys-only"adapts only at the system level following an existing resource-management system that minimizes energy under soft real-time constraints [62][5] and uses the fastest candidate DNN to avoid latency violations;
- "No-coord" uses *both* the Anytime DNN for application adaptation *and* the power-management scheme [62] to adapt power, but with these two working independently.

5.2 Overall Results

Table 4 shows the results for all schemes for different tasks on different platforms and environments. Each cell shows

[4] For GPU, we only run image classification task there, as the RNN-based sentence prediction task is better suited for CPU [91].

[5] Specifically, this adaptation uses a feedback scheduler that predicts inference latency based on Kalman Filter.

Table 4: Average energy consumption and error rate normalized to *Oracle*$_{\text{Static}}$, smaller is better. (Each cell is averaged over 35–40 constraint settings; superscript: # of constraint settings violated for >10% inputs and hence excluded from energy average.)

the average energy or accuracy under 35–40 combinations of latency, accuracy, and energy constraints (the settings are detailed in Table 3), normalized to the Oracle$_{\text{Static}}$ result. Figure 7 compares these results, where lower bars represent better results and lower *s represent fewer constraint violations. ALERT and ALERT $_{\text{Any}}$ both work very well for all settings. They outperform state-of-the-art approaches, which have a significant number of constraint violations, as visualized by the many superscripts in Table 4 and the high * positions in Figure 7. ALERT outperforms Oracle$_{\text{Static}}$ because it adapts to dynamic variations. ALERT also comes very close to the theoretically optimal Oracle.

Comparing with Oracles. As shown in Table 4, ALERT achieves 93-99% of Oracle's energy and accuracy optimization while satisfying constraints. Oracle$_{\text{static}}$, the baseline in Table 4, represents the best one can achieve by selecting 1 DNN model and 1 power setting for all inputs. ALERT greatly out-performs Oracle$_{\text{static}}$, reducing its energy consumption by 3–48% while satisfying accuracy constraints (36% in harmonic mean) and reducing its error rate by 9-66% while satisfying energy constraints (54% in harmonic mean).

Figure 8 shows a detailed comparison for the energy minimization task. The figure shows the range of performance under all requirement settings (i.e., the whiskers). ALERT not only achieves similar mean energy reduction, its whole range of optimization behavior is also similar to Oracle. In comparison, Oracle$_{\text{Static}}$ not only has the worst mean but also the worst tail performance. Due to space constraints, we omit the figures for other settings, where similar trends hold.

ALERT has more advantage over Oracle$_{\text{static}}$ on CPUs than on GPUs. The CPUs have more empirical variance than the GPU, so they benefit more from dynamic adaptation. The GPU experiences significantly lower dynamic fluctuation so the static oracle makes good predictions.

ALERT satisfies the constraint in 99.9% of tests for image classification and 98.5% of those for sentence prediction. For the latter, due to the large input variability (NLP1 in Figure 4), some input sentences simply cannot complete by the deadline even with the fastest DNN. There the Oracle fails, too.

Note that, these Oracle schemes not only have perfect—and hence, impractical—prediction capability, but they also have no overhead. In contrast, ALERT is running on the same machines as the DNN workloads. *All results include ALERT's run-time latency and power overhead.*

Comparing with State-of-the-Art. For a fair comparison, we focus on ALERT$_{\text{Any}}$, as it uses exactly the same DNN candidate set as "Sys-only", "App-only", and "No-coord". Across all settings, ALERT$_{\text{Any}}$ outperforms the others.

The System-only solution suffers from not being able to choose different DNNs under different runtime scenarios. As a result, it performs much worse than ALERT$_{\text{Any}}$ in satisfying accuracy requirements or optimizing accuracy. For the former (left side of Table 4 and Figure 7), it creates accuracy violations in 68% of the settings as shown in Figure 7; for the latter (right side of Table 4 and Figure 7), although capable of satisfying energy constraints, it introduces 34% more error than ALERT$_{\text{Any}}$.

The Application-only solution that uses an Anytime DNN suffers from not being able to adjust to the energy requirements: it consumes 73% more energy in energy-minimizing tasks (left side of Table 4 and Figure 7) and introduces many energy-budget violations particularly under resource contention settings (right side of Table 4 and Fig. 7).

The no-coordination scheme is worse than both System- and Application-only. It violates constraints in both tasks with 69% more energy and 34% more error than ALERT$_{\text{Any}}$. Without coordination, the two levels can work at cross purposes; e.g., the application switches to a faster DNN to save energy while the system makes more power available.

5.3 Detailed Results and Sensitivity

Different DNN candidate sets. Table 5 compares the performance of ALERT working with an Anytime DNN (Any), a set of traditional DNN models (Trad), and both. At a high level, ALERT works well with all three DNN sets. Under close comparison, ALERT$_{\text{Trad}}$ violates more accuracy constraints than the others, particularly under resource contention on CPUs, because a traditional DNN has a much larger accuracy drop than an anytime DNN when missing a latency deadline. Consequently, when the system variation is large, ALERT$_{\text{Trad}}$ selects a faster DNN to meet latency and thus may not meet accuracy goals. Of course, ALERT$_{\text{Any}}$ is not always the best. As discussed in Section 3.5, Anytime DNNs sometimes have lower accuracy then a traditional DNN with similar execution time. This difference leads to the slightly better results for ALERT over ALERT$_{\text{Any}}$.

Figure 9 visualizes the different dynamic behavior of ALERT (blue curve) and ALERT$_{\text{Trad}}$ (orange curve) when the environment changes from Default to Memory-intensive and back. At the beginning, due to a loose latency constraint, ALERT and ALERT$_{\text{Trad}}$ both select the biggest traditional DNN, which provides the highest accuracy within the energy budget. When the memory contention suddenly starts, this DNN choice leads to a deadline miss and an energy-budget violation (as the idle period disappeared), which causes an accuracy dip. Fortunately, both quickly detect this problem and sense the high variability in the expected latency. ALERT switches to use an anytime DNN and a lower power cap. This switch is effective: although the environment is still unstable, the inference accuracy remains high, with slight ups and downs depending on which anytime output finished before the deadline. Only able to choose from traditional DNNs, ALERT$_{\text{Trad}}$ conservatively switches to much simpler and hence lower-accuracy DNNs to avoid deadline misses. This switch does eliminate deadline misses under the highly dynamic environment, but many of the conservatively chosen DNNs finish before the deadline (see the Latency panel), wasting the opportunity to produce more accurate results and causing ALERT$_{\text{Trad}}$ to have a lower accuracy than ALERT. When the system quiesces, both schemes quickly shift back to the highest-accuracy, traditional DNN.

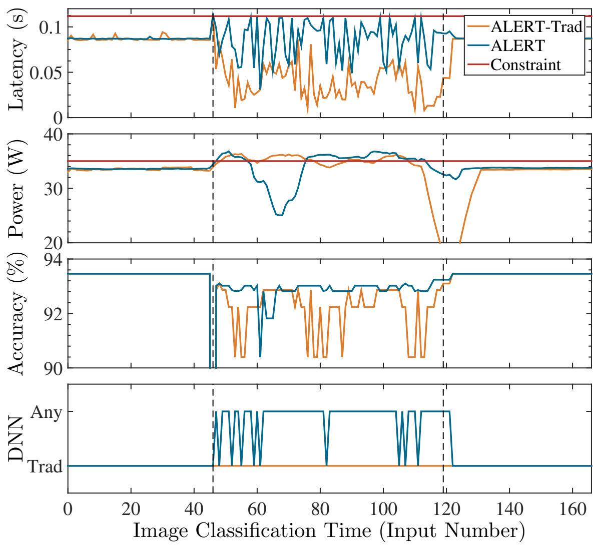

Figure 9: Minimize error rates w/ latency, energy constraints on CPU1. (Memory contention occurs from about input 46 to 119; Deadline: 1.25× mean latency of largest Anytime DNN in Default; power limit: 35W.)

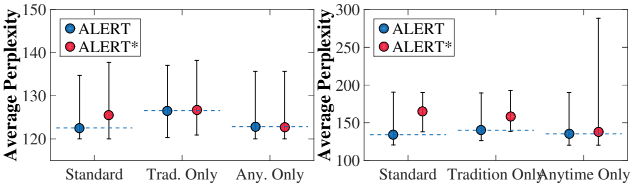
Overall, these results demonstrate how ALERT always makes use of the full potential of the DNN candidate set to optimize performance and satisfy constraints.

ALERT probabilistic design. A key feature of ALERT is its use of not just mean estimations, but also their variance. To evaluate the impact of this design, we compare ALERT to an alternative design ALERT*, which only uses the estimated mean to select configurations.

Figure 10 shows the performance of ALERT and ALERT* in the minimize error task for sentence prediction. Here, ALERT (blue circles) always performs better than ALERT*. Its advantage is the biggest when the DNN candidates include both traditional and Anytime DNNs (i.e., the "Standard"



(a) Default Contention (b) Memory Contention

Figure 10: Minimize error for sentence prediction@ CPU1 (Lower is better). (whisker: whole range; circle: mean)

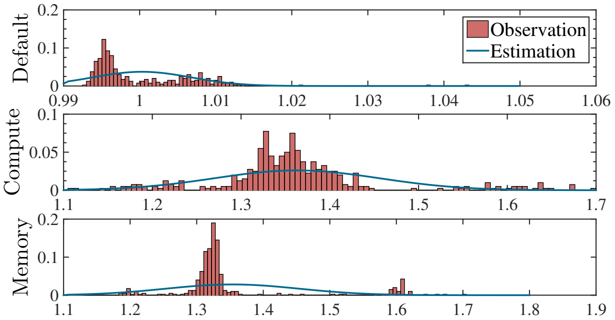


Figure 11: Distribution of ξ for image class. on CPU1.

in Figure 10). The reason is that traditional DNNs and Anytime DNN have different accuracy/latency curves, Eq. 3 for the former and Eq. 10 for the latter. ALERT* is much worse in distinguishing these two by simply using the mean of estimated latency to predict accuracy. ALERT also clearly outperforms ALERT* under memory contention with traditional DNN candidates, as ALERT's estimation better captures dynamic system variation. Overall, these results show ALERT's probabilistic design is effective.

Sensitivity to latency distribution. ALERT assumes a Gaussian distribution, but is designed to work for other distributions (see Section 3.6). As shown in Figure 11, the observed ξs (red bars) are indeed not a perfect fit for Gaussian distribution (blue lines), which confirms ALERT's robustness.

6 Related work

Past resource management systems have used machine learning [4, 51, 68, 69, 79] or control theory [32, 37, 44, 45, 62, 74, 93] to make dynamic decisions and adapt to changing environments or application needs. Some also use Kalman filter because it has optimal error properties [37, 44, 45, 62]. There are two major differences between them and ALERT: 1) prior approaches use the Kalman filter to estimate physical quantities such as CPU utilization [45] or job latency [37], while ALERT estimates a *virtual* quantity that is then used to update a large number of latency estimates. 2) while variance is naturally computed as part of the filter, ALERT actually uses it, in addition to the mean, to help produce estimates that better account for environment variability.

Past work designed resource managers explicitly to coordinate approximate applications with system resource usage [21, 31, 32, 46]. Although related, they manage applications *separately* from system resources, which is fundamentally different from ALERT's holistic design. When an environmental change occurs, prior approaches first adjust the application and then the system serially (or vice versa) so that the change's effects on each can be established independently [31, 32]. That is, coordination is established by forcing one level to lag behind the other. In practice this design forces each level to keep its own independent model and delays response to environmental changes. In contrast, ALERT's global slowdown factor allows it to easily model and update prediction about all application and system configurations simultaneously, leading to very fast response times, like the single input delay demonstrated in Figure 9.

Much work accelerates DNNs through hardware [3, 10–12, 19, 23, 24, 27, 30, 38, 43, 54, 58, 66, 73, 75, 83], compiler [9, 65], system [28, 53], or design support [25, 25, 26, 39, 42, 77, 81, 85]. They essentially shift and extend the tradeoff space, but do not provide policies for meeting user needs or for navigating tradeoffs dynamically, and hence are orthogonal to ALERT.

Some research supports hard real-time guarantees for DNNs [92], providing 100% timing guarantees while assuming that the DNN model gives the desired accuracy, the environment is completely predictable, and energy consumption is not a concern. ALERT provides slightly weaker timing guarantees, but manages accuracy and power goals. ALERT also provides more flexibility to adapt to unpredictable environments. Hard real-time systems would fail in the co-located scenario unless they explicitly account for all possible co-located applications at design time.

7 Conclusion

This paper demonstrates the challenges behind the important problem of ensuring timely, accurate, and energy efficient neural network inference with dynamic input, contention, and requirement variation. ALERT achieves these goals through dynamic and coordinated DNN model selection and power management based on feedback control. We evaluate ALERT with a variety of workloads and DNN models and achieve high performance and energy efficiency.

NeuOS: A Latency-Predictable Multi-Dimensional Optimization Framework for DNN-driven Autonomous Systems

Soroush Bateni and Cong Liu
The University of Texas at Dallas

Abstract

Deep neural networks (DNNs) used in computer vision have become widespread techniques commonly used in autonomous embedded systems for applications such as image/object recognition and tracking. The stringent space, weight, and power constraints seen in such systems impose a major impediment for practical and safe implementation of DNNs, because they have to be latency predictable while ensuring minimum energy consumption and maximum accuracy. Unfortunately, exploring this optimization space is very challenging because (1) smart coordination has to be performed among system- and application-level solutions, (2) layer characteristics should be taken into account, and more importantly, (3) when multiple DNNs exist, a consensus on system configurations should be calculated, which is a problem that is an order of magnitude harder than any previously considered scenario. In this paper, we present NeuOS, a comprehensive latency predictable system solution for running multi-DNN workloads in autonomous systems. NeuOS can guarantee latency predictability, while managing energy optimization and dynamic accuracy adjustment based on specific system constraints via smart coordinated system- and application-level decision-making among multiple DNN instances. We implement and extensively evaluate NeuOS on two state-of-the-art autonomous system platforms for a set of popular DNN models. Experiments show that NeuOS rarely misses deadlines, and can improve energy and accuracy considerably compared to state of the art.

1 Introduction

The recent explosion of computer vision research has led to interesting applications of learning-driven techniques in autonomous embedded systems (AES) domain such as object detection in self-driving vehicles and image recognition in robotics. In particular, deep neural networks (DNNs) with generally the same building blocks have been dominantly applied as effective and accurate implementation of image recognition, object detection, tracking, and localization towards enabling full autonomy in the future [60, 50]. For example, using such DNNs alone, Tesla has recently demonstrated that a great deal of autonomy in self-driving cars can be achieved [33]. Another catalyzer for the feasibility of DNN-driven autonomous systems in practice has been the advancement of fast, energy-efficient embedded platforms, particularly accelerator-enabled multicore systems such as the NVIDIA Drive AGX and the Tesla AI platforms [44, 22].

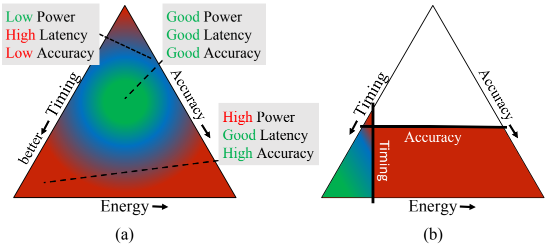

Figure 1: Ternary depiction of the 3D optimization space.

Autonomous systems based on embedded hardware platforms are bounded by stringent Space, Weight, and Power (SWaP) constraints. The SWaP constraints require system designers to carefully take into account energy efficiency. However, DNN-driven autonomous embedded systems are considered mission-critical real-time applications and thus, require predictable latency[1] and sufficient accuracy[2] (of the DNN output) in order to pass rigorous certifications and be safe for end users [46]. This causes a challenging conflict with energy efficiency since accurate DNNs require a tremendous amount of resources to be feasible and to be timing-predictable, and are by far the biggest source of resource consumption in such systems [5]. This usually results in less complicated (and less resource-demanding) DNN models to be designed and used in these systems, reducing accuracy considerably.

Fig. 1(a) shows a hypothetical three-dimensional space between latency, power, and accuracy mapped to a ternary plot [55] (where (Energy + Timing + Accuracy) has been normalized to 3). Each dot in Fig. 1(a) represents a configuration with a unique set of latency, power, and accuracy characteristics. The power consumption is usually

[1] Latency from each system component (including the DNNs) in AES will add up to the reaction latency between when a sensor observes an event and when the system externally reacts to that event, such as by applying the breaks in a self-driving vehicle. The faster a system reacts, the more likely it is for the system to avoid a disaster, such as an accident. However, policymakers might adopt a reasonable reaction time, such as 33ms or even 300ms [48, 27, 12, 14, 9, 4] as ”safe enough".

[2] We should mention here that there is currently no established standard to connect DNN accuracy to the safety of a particular system, such as DNNs in self-driving vehicles. In this paper, we assume the more accurate the DNN, the safer the system is.

adjusted at system-level via dynamic voltage/frequency scaling (DVFS) [5, 21]. The accuracy adjustment is done at application-level via DNN approximation configuration switching (see Sec. 4 for details). Note that both DVFS and DNN configuration adjustments would impact runtime latency. This figure highlights three configurations with various levels of latency, power consumption, and accuracy tradeoff that might or might not be acceptable given the current performance constraints. Choosing the best three-dimensional trade-off optimization point is a significant challenge given the vast and complex DVFS and accuracy configuration space.

Although all autonomous systems are required to be latency predictable in nature, the constraints on power and accuracy may vary based on the type of autonomous system (e.g., highly constrained power for drones and maximum accuracy requirement for autonomous driving). To illustrate one such variation, note Fig. 1(b), which shows a constraint on latency, and a constraint on accuracy imposed in the configuration space limiting the possible configurations considerably.

Challenges specific to DNN-driven AES. In addition to the aforementioned optimization problem, DNNs are constructed from layers, where each layer responds differently to DVFS changes and has unique approximation characteristics (as we shall showcase in Sec. 3.1). In order to meet a latency target with optimized energy consumption and accuracy, each layer requires a unique DVFS and approximation configuration, whereas existing approaches such as Poet [23] and JouleGuard [21] deal with DNNs as a black-box. Moreover, system-level DVFS adjustments and application-level accuracy adjustments happen at two separate stages. Without smart coordination, the system might fall in a negative feedback loop, as we shall demonstrate in Sec. 3.2. This coordination needs to happen at layer boundaries, making the problem at least an order of magnitude harder than previous work.

Furthermore, existing techniques mostly focus on single-tasking scenarios [5, 3, 20] whereas AES generally require multiple instances of different DNNs. As we shall motivate in Sec. 3.3 using a real-world example, these DNNs need to communicate and build a cohort on a layer-by-layer basis to avoid greedy and inefficient decision-making. Moreover, system-level and application-level coordination in this multi-DNN scenario is much harder than isolated processes considered in previous work.

Finally, existing approaches [13, 5] optimize latency performance on a best-effort basis (e.g., by using control theory) that can overshoot a latency target (as demonstrated in Sec. 3.2). A better solution should include proven real-time runtime strategies such as LAG analysis [51].

Contribution. In this paper, we present NeuOS[3], a comprehensive timing-predictable system solution for multi-DNN workloads in autonomous embedded systems. NeuOS can manage energy optimization and dynamic accuracy adjustment for DNNs based on specific system constraints via smart coordinated system- and application-level decision-making.

NeuOS is designed fundamentally based on the idea of multi-DNN execution by introducing the concept of cohort, a collective set of DNN instances that can communicate through a shared channel. To track this cohort, we address how latency, energy, and accuracy can be measured and propagated efficiently in the multi-DNN cohort.

Besides the fundamental goal of providing latency predictability (i.e., meeting deadlines for processing each DNN instance), NeuOS addresses the challenge of balancing energy at system level and accuracy at application level for DNNs, which has never been addressed in literature to the best of our knowledge. Balancing three constraints at various execution levels in the multi-DNN scenario requires smart coordination 1) between system level and application level decision making, and 2) among multiple DNN instances.

Towards these coordination goals, we introduce two algorithms in Sec. 4.2 that are executed at the layer completion boundary of each DNN instance: one algorithm that can predict the best system-level DVFS configuration for each DNN member of the cohort to meet deadline and minimize power for that specific member in the upcoming layer, and one algorithm that decides what application level approximation configuration is required for others if any one of these system-level DVFS decisions were chosen. These two algorithms effectively propagate all courses of action for the next layer in order to meet the deadline. Based on these two algorithms, we propose an optimization problem in Sec. 4.3 that can decide the best course of action depending on the system constraint, and minimize system overhead. This method is effective because 1) it introduces an identical decision-making among all DNN instances in the cohort and solves the coordination problem between system-level and application-level decision making, and 2) provides adaptability to three typical scenarios imposing different constraints on energy and accuracy.

Implementation and Evaluation. We implement a system prototype of NeuOS and extensively evaluate NeuOS using popular image detection DNNs as a representative of convolutional deep neural networks used in AES. The evaluation is done under the following conditions:

- **Extensible in terms of architecture.** We fully implement NeuOS using a set of popular DNN models on two different platforms: an NVIDIA Jetson TX2 SoC (with architecture designed for low overhead embedded systems), and an NVIDIA AGX Xavier SoC (with architecture designed for complex autonomous systems such as self-driving cars).
- **Multi-DNN scenarios.** We ensure that our system can trade-off and balance multiple DNNs in all conditions by testing NeuOS under three cohort sizes: a small 1-process, a medium 2-4 process, and a large 6-8 process.

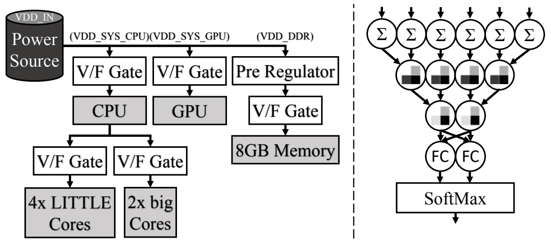
[3] The latest version of NeuOS can be found at https://github.com/Soroosh129/NeuOS.

- **Latency predictability.** We extensively compare NeuOS to six state-of-the-art solutions in literature, and find that NeuOS rarely misses deadlines under all evaluated scenarios, and can improve runtime latency on average by 68% (between 8% and 96% depending on DNN complexity) on TX2, by 40% on average (between 12% and 89%) on AGX, and by 54% overall.
- **Versatility.** NeuOS can be easily adapted to the following three constraint scenarios:
  - **Balanced energy and accuracy.** Without any system constraints given, NeuOS is proved to be energy efficient while sacrificing an affordable degree of accuracy, improving energy consumption on average by 68% on TX2, by 40% on average on AGX, while incurring an accuracy loss of 21% on average (between 19% and 42%).
  - ***Min energy.*** When energy is constrained to be minimal, NeuOS is able to sacrifice accuracy a small amount (at most 23%) but further improve energy consumption by 11% over the general unrestricted case, while meeting the latency requirement.
  - ***Max accuracy.*** When accuracy is given as a constraint, NeuOS is able to improve accuracy by 10% on average compared to balanced case, but also sacrifices energy by only a small amount, increasing by 23% on average.

2 Background

DVFS space in autonomous systems. The trade-off between latency and power consumption is usually achieved via adjustments to frequency and/or voltages of hardware components. A software and hardware technique typical of modern systems is DVFS. Through DVFS, system software such as the operating system or hardware solutions can dynamically adjust voltage and frequency. To understand this technique better, consider Fig. 2(a), showing the components of a Jetson TX2, which contains a Parker SoC with a big.LITTLE architecture with 2 NVIDIA Denver big cores and 4 ARM Cortex A53 LITTLE cores. The Parker SoC also contains a 256-core Pascal-architecture GPU. The TX2 module also contains 8 GB of shared memory (the Jetson AGX Xavier also used in Sec. 5 has a more advanced Xavier SoC with 8 NVIDIA "Carmel" cores, a 512 Volta-architecture GPU, and 16GB of shared memory). Each component includes a voltage/frequency (V/F) gate that can be adjusted via software. The value for frequency and voltage for each component forms a unique topple, called a DVFS configuration throughout this paper.

DNN and its approximation techniques. Fig. 2(b) depicts a simplified version of a Deep Neural Network (DNN). Neurons are the basic building blocks of DNNs. Depending on the layer neurons belong to, they perform various different operations. A DNN may contain multiple layers of different types, such as the convolutional and the normalization layers, which are connected via their inputs and outputs.



(a) Jetson TX2 V/F Structure (b) An example DNN

Figure 2: DVFS configuration space and DNN structure.

DNNs by nature are approximation functions [36]. DNNs are trained on a specific training set. After training, accuracy is measured by using a test data set, set aside from the training set and measuring the accuracy (e.g., top-5 error rate–comparing the top 5 guesses against the ground truth). The accuracy of the overall DNN can be adjusted by manipulating the layer parameters.

A rich set of DNN approximation techniques have been proposed in the literature and adopted in the industry [17, 58, 24, 29, 43, 56, 7, 18]. Such techniques aim at reducing the computation and storage overhead for executing DNN workloads. An example technique to provide approximation for convolutional layers is Lowrank [45], which performs a lowrank decomposition of the convolution filters. In our implementation, dynamic accuracy adjustment or "hot swapping" layers will refer to applying the lowrank decomposition to the upcoming layers before their execution. Note that applying such approximation adjustments on the fly is possible because the generated pair of layers have the exact combined input and output dimensions. Moreover, this adjustment is only possible for future layers at each layer boundary.

Measuring Accuracy. The approximation on the fly will affect the final accuracy. Due to the dynamic nature of this adjustment, the exact value of accuracy measurement using traditional methodology is impractical. Most related work thus incorporate an alternative scoring method [3], where the system will deduce the accuracy score accordingly if certain approximation techniques are to be applied to the next layer. In our method, we assume a perfect score for the original DNN, and switching to the lowrank approximation of any layer will reduce the score by a set amount. For example, running AlexNet in its entirety will result in a score of 100. If we swap a convolutional layer with a lowrank version of that layer, the overall accuracy will be affected by some amount (e.g., 1 in our method), thus yielding a lower score (e.g., 99 under the scoring method). Therefore, the score is always relative to the original DNN configuration and not related to the absolute value of accuracy on a particular dataset. This method of keeping relative accuracy is still invaluable to maximizing accuracy in a dynamic runtime environment but cannot be used to calculate the exact accuracy loss.

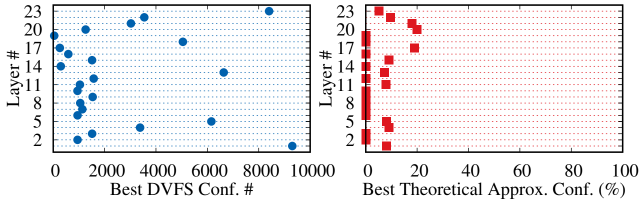


Figure 3: Calculated best system level DVFS configuration and best application level theoretical approximation configuration for AlexNet on Jetson TX2 in order to meet a 12ms deadline (0 means no approximation).

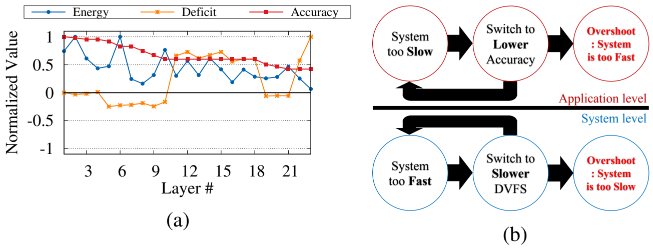
3 Motivation

In this section, we lay out several motivational case studies to understand the challenges that exist for DNNs, and gain insights on why existing approaches (or naively extended ones) may fail under our problem context.

3.1 Balancing in two-dimensional Space

The trade-off to meet a specified latency target while maximizing accuracy is done in a 2-dimensional space by choosing an approximation configuration for the application. Similarly, the 2-dimensional trade-off between energy and latency is done by changing an optimal DVFS configuration. Traditional control-theory based solutions treat the entire application as a black-box, and decide on what DVFS or approximation configuration should be chosen every few iterations of that specific application [21, 20]. However, treating DNNs as a blackbox does not yield the most efficient results. Fig. 3 left hand shows the best DVFS configuration for each layer of AlexNet among all possible DVFS configurations for a Jetson TX2 in terms of energy consumption. The y-axis is the layer number for AlexNet, and the x-axis is the DVFS configuration index, partially sorted based on frequency and activated core counts. The dots show the configuration that has the absolute minimum energy consumption. As is evident, each layer has a different optimal DVFS configuration. More interestingly, we observe a non-linearity where sometimes faster DVFS configurations have lower energy consumption. This is due to the massive parallelism of GPUs, where increasing the frequency by 2x for example can yield a 10-fold improvement in performance, which outweighs the momentary increase in energy consumption. Fig. 3 right hand shows the best theoretical approximation configurations required for each layer of AlexNet in order to meet a 12ms deadline[4]. As is evident in the figure, each layer requires a different approximation configuration for optimal results.

Thus, the DNN must somehow become transparent to the system, conveying layer-by-layer information in order to make the correct decisions. This can make the decision space in the 2-dimensional space at least an order of magnitude harder (e.g., AlexNet has 23 layers) since every layer must be considered for each execution of the DNN application.



(a)

(b)

Figure 4: Negative feedback loop between an application-level solution and a system-level solution.

Observation 1: Layer-level trade-off makes the problem an order of magnitude harder than ordinary blackbox techniques.

3.2 Balancing in three-dimensional Space

Balancing energy/latency and accuracy/latency in isolation can be naive, and lead to unnecessary consumption of energy or reduced accuracy. Fig. 4a shows a similar experiment to Sec. 3.1, but both the system and application (Alexnet) are employed at the same time without any coordination. The goal of both solutions is to reach a 20ms deadline (by using latency deficit, LAG, as a guide (Sec. 4.2)). In the case of AlexNet, the system-level DVFS adjustment can be enough to meet the desired deadline. In an ideal scenario, only energy is adjusted slightly until AlexNet is not behind schedule. However, as is evident in the figure, normalized energy consumption and accuracy for each layer are both decreased continuously and dramatically. This is due to an unwanted negative loop, where a negative deficit (indicating that the system is behind schedule) has resulted in the application-level solution switching to a lower approximation configuration. Because these configurations are discrete, as we shall discuss in Sec. 4.2, the deficit will overshoot (at around layer 10) and becomes positive (meaning the system is ahead of schedule). The system-level solution would see this deficit as a headroom to reduce energy consumption, and in the case of Fig. 4a, has turned the positive deficit into a small negative at around layer 18. This cycle (as depicted in Fig. 4b) is repeated until the minimum approximation configuration is reached. This result is extremely undesirable in accuracy-sensitive applications such as autonomous driving (but can be okay for energy sensitive applications such as remote sensing). Thus, a feasible solution would be for the system and application to communicate, and make decisions based on given constraints for an application based on given constraints. This communication should be done at the granularity of layers, which makes the problem extra hard.

Observation 2: Trade-off in a 3-dimensional latency, energy, and accuracy optimization space is a significant challenge due to both system constraints as well as lacking harmony between application-level and system-level solutions.

3.3 Balancing for Multi-DNN Scenarios

To the best of our knowledge, no existing approach deals with multiple DNN instances in a coordinated manner.

[4] Please see Sec. 4.2 for more details on how this is calculated.

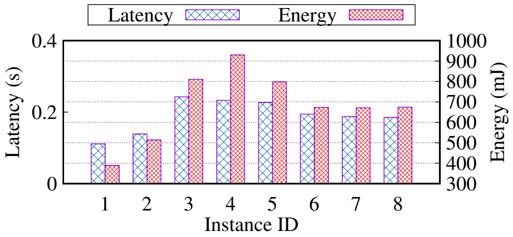


Figure 5: Energy consumption and execution time of running 8 instances of Resnet-50 on a Jetson TX2 under PredJoule.

Straightforwardly extending single-tasking latency/energy trade-off approaches, such as PredJoule [5], to multi-tasking scenarios would only result in decision-making that is local and greedy, based on locally measured variables. To showcase why coordination in this additional dimension is a key issue, examine Fig. 5, which shows the latency and energy consumption for running 8 DNN instances together averaged over 20 iterations under PredJoule on a Jetson TX2. We chose PredJoule because in our experiments, it outperformed all other existing solutions on exploring the 2D tradeoff between latency and energy for DNNs. The left (right) y-axis in Fig. 5 depicts the latency (energy consumption) in seconds (miliJoules) for each instance. As is evident in the figure, the DVFS management is greedy, resulting in instances 1 and 2 having relatively good latency and energy consumption. This greediness has pushed the rest of the DNN instances into unacceptable latency range (which is above 150ms for ResNet-50) because the chosen DVFS configuration at each layer boundary has been mostly beneficial only to the current layers of DNN instance 1 and 2. Moreover, the distribution of timing and energy consumption is not even across all instances because of the same reason. This disparity is the result of an uncoordinated system solution that chooses DVFS configurations greedily based on local variables.

Observation 3: In addition to the 2D and 3D complexities of solving the latency/accuracy/energy trade-off, a complete system solution must also accommodate for Multi-DNN scenarios, which are inherently more complicated to model and predict than single-DNN scenarios. The case studies also imply that naive extensions on existing single-DNN 2D solutions may fail in multi-DNN cases because they make greedy decisions based on local variables without coordination towards being globally optimal.

4 System Design

4.1 NeuOS Overview

To optimize the three-dimensional tradeoff space at the layer granularity, two basic research questions need to be answered first: 1) *how* to define and track the values of the three performance constraints in the system, and 2) *what* target should be imposed for optimizing each constraint.

For the first research question, we define a value of LAG (defined in Sec. 4.2, as a measurement of how far behind the DNN is compared to an ideal schedule that meets the relative deadline D), which tracks the progress of DNN execution at layer boundaries, P for energy consumption (in mJ) for each layer, and a variable X to reflect accuracy. We choose to track LAG at runtime instead of using an end-to-end optimization because it is more practical due to two reasons: 1) in a multi-DNN scenario, predicting the overlap between different DNN instances (and thus coordinating an optimal solution) cannot be done offline without making unrealistic assumptions, such as synchronized release times, and, 2) LAG is especially useful in a real system since it can account for outside interference, such as interference by other processes in the system, whereas an end-to-end optimization framework could miss the latency target. Moreover, as we shall discuss in Sec. 4.2, the value of P can be inferred by LAG in our design as these two variables fundamentally depend on the runtime DVFS configuration. Thus, the essential variables to track the status of a DNN execution can be simplified to $\{LAG, X\}$. Since we are dealing with a multi-DNN scenario, each DNN instance will have its own set of these variables. To know the collective status of the system, each DNN instance will put its variables in a shared queue.

In order to answer the second question regarding what optimization targets should be imposed on the system, we focus on the following three typical scenarios (expanded on in Sec. 4.3) that entail different performance constraints:

- **Min Energy** (M_P) is when NeuOS is deployed on an embedded system with a critically small energy envelope. Thus, the system should minimize energy without sacrificing too much accuracy. This scenario is motivated by applications seen in extremely power-limited systems such as drones, robotics, and a massive set of internet-of-thing devices.
- **Max Accuracy** (M_A) is when NeuOS is deployed on a system that has limited energy but accuracy is of utmost importance. Thus, the system should try to maximize accuracy without losing too much energy. This scenario is motivated by CPS-related applications such as autonomous driving.
- **Balanced Energy and Accuracy** (S) describes a more general, flexible scenario when the system is limited by both energy consumption and accuracy requirements, but no priority is given to either. Thus, the system should try to balance energy consumption and accuracy.

With the given scenarios and the values of $\{LAG, X\}$ at hand, we can answer the two key research questions presented in our motivation: 1) how to coordinate in a multi-DNN scenario such that the overall system is balanced and can meet the performance constraints, and, 2) how to efficiently tradeoff between latency, energy, and accuracy given the complexity of the problem space and how to prevent the negative feedback loop discussed in Sec. 3.2?

Design overview. Fig. 6 shows the overall design of NeuOS

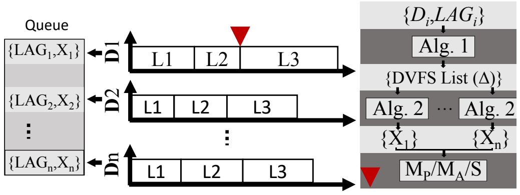

Figure 6: Design Overview

around $\{LAG, X\}$. The left side depicts the shared queue among multiple DNN instances. In the middle, a simple example of n concurrently running DNN instances each with three layers is shown. NeuOS makes runtime decisions on DVFS and DNN approximation configuration adjustments at layer boundaries, i.e., whenever a layer of a DNN instance completes. This is beneficial not only because applying approximation on-the-fly is possible only at layer boundaries, but in terms of overhead as well (as proved by our evaluation).

As illustrated in the figure, at the boundary between layers L2 and L3 of the first DNN instance, NeuOS is going through the process of decision-making which contains several steps. The first step is Alg.1, which senses the last known value of LAG for each DNN instance. Alg. 1 decides what DVFS configuration (at system level) is best for each instance in order to meet their deadlines D, outputting a list of potential DVFS configurations (Δ), where each member of the list corresponds to a DNN instance. In the next step, the list of potential DVFS configurations are fed into Alg.2, which predicts what approximation $\{X_i\}$ (at application level) would be required for other DNN instances to meet the deadline if the DVFS configuration for any one of the DNN instances is applied. Thus, Alg. 1 and Alg. 2 in tandem discover all possible courses of action the system can take to meet the deadline. However, at this point, no decision has been made on what DVFS configuration or accuracy configuration should be chosen for the system, because that depends on the given system constraint. This problem is inherently an optimization problem of finding the best possible choice in the propagated configuration space. We present this optimization problem formally in Sec. 4.3, where depending on broad scenarios, a particular setting is chosen for the next period of execution. In the last step of NeuOS, the system chooses one of these possibilities based on the scenario involved.

4.2 Coordinated System- and Application-level Adjustments

In this section, we expand on how runtime LAG is measured, how it relates to energy consumption, how accuracy X is calculated, and how the two developed algorithms take advantage of these two measurements to discover all possible choices the system can make efficiently in order to reduce the LAG to zero and meet the deadline.

LAG. We quantify the relationship between the partial execution time at time t of DNN instance i (e_i) and its relative deadline D_i as a form of LAG [51], denoted by LAG_i. LAG_i is a local variable (that can be updated at layer boundaries) for each DNN instance that keeps track of how far ahead or how far behind the DNN instance is compared to the deadline at time t. LAG_i is calculated as:

$$LAG_i(t, L_i(t)) = \sum_{l \in L_i(t)} (d_l - e_l), \tag{1}$$

in which $L_i(t)$ is the list of the layers of instance i that have completed by time t. For layer $l \in L_i(t)$, d_l and e_l depict the sub-deadline for layer l and the recorded execution time for layer l, respectively. NeuOS keeps track of e_l by measuring the elapsed time between each layer. Moreover, we use the proportional deadline method [38] to devise sub-deadlines for each layer based on D_i, the relative (end-to-end) deadline of DNN instance i, in which the subdeadline d_l for layer l is calculated as:

$$d_l = (e_l / \sum_{x \in L_i} (e_x)) \cdot D_i, \tag{2}$$

where $\sum_{x \in L_i} (e_x)$ denotes the execution time of DNN i. The proportional nature of sub-deadlines means that they only need to be calculated once for the lifetime of a given DNN instance on a platform.

Each DNN instance i would broadcast LAG_i among all instances via the shared queue. Thus, LAG_i would reflect the last known status of DNN instance i up to the last executed layer. We call the collection of LAG from all instances the LAG cohort, and we denote it by Φ. At completion of a DNN instance, a special message is sent to the cohort so that every DNN instance in the system is aware of their exit.

Based on the LAG cohort, the DNN instances can make decisions on accuracy and DVFS. A cohort will be perfect if every LAG within it is 0, or $\forall LAG_i \in \Phi, LAG_i = 0$. This means that all layers have exactly finished by their sub-deadline so far. Thus, the system has reasons to believe that the DNN instances will exactly finish by the deadline and do not require a faster DVFS or an approximation configuration, saving energy and accuracy in the process.

Since LAG indicates how far behind ($LAG < 0$) or ahead ($LAG > 0$) each DNN is, the DVFS and the approximation configuration need to be adjusted to run faster or slower accordingly. However, energy consumption and accuracy constraints must also be considered. We discuss each next.

System-level DVFS adjustment. At system-level, the question is which DVFS configuration is the best given the state of Φ to minimize energy consumption while reducing LAG to zero? The answer would vary between different DNN instances in the cohort, as they exhibit different LAGs. Moreover, different layers react differently to DVFS adjustments.

Alg. 1 is responsible for finding the best DVFS configuration for each DNN instance in the cohort. Alg. 1 takes as input the LAG cohort Φ and a SpeedUp/PowerUp table for the current layer of each DNN instance i. The structure of

Algorithm 1 Δ Calculator.

```
Input: $\Phi$        ▷ Progress Cohort
Input: SpeedUp/PowerUp[]        ▷ The SpeedUp/PowerUp table of DNNs.
Output: $\Delta$

1: function RETURN$\Delta(\Phi)$
2:     for $LAG_i$ in $\Phi$ do
3:         $S_{P_i} \leftarrow \frac{D_i + LAG_i}{D_i}$.
4:         $\delta_i \leftarrow$ LookUp(SpeedUp/PowerUp[$S_{P_i}$])
```

Table 1: SpeedUp/PowerUp and SpeedUp/Accuracy tables.

(a) SpeedUp/PowerUp for a layer of DNN instance i.

DVFS Configuration(δ)	SpeedUp	PowerUp
1	1x	1x
2	2.1x	2x
3	2.8x	1.5x

(b) SpeedUp/Accuracy.

X	SpeedUp
81%	1x
71%	1.8x
59%	2.5x

the SpeedUp/PowerUp table is depicted in Table 1a. The first column of Table 1a is the index for all the possible DVFS configurations in the system. The second column indicates how fast each DVFS configuration is in the worst case scenario compared to the baseline DVFS configuration (baseline is usually chosen to be the slowest configuration). The third column indicates how much power that DVFS configuration will consume relative to baseline.

Storing relative speedup and powerup values (instead of absolute measurements) is useful for looking up the table. In Alg. 1, given a LAG_i (line 2) and a relative deadline D_i for DNN instance i, the required speedup (denoted as S_i) could be directly calculated as (line 3):

$$S_P = \frac{D_i + LAG_i}{D_i}, \tag{3}$$

in which S_P is the speedup (or slowdown) value calculated as the relationship between the current projected execution time ($D_i + LAG_i$) and the ideal execution time (D_i). Since LAG can be negative or positive, the value of S_P can indicate a slowdown or speedup, where the slowdown is a way to conserve energy, which is the goal of NeuOS. The LookUp procedure (line 4) would then find the closest DVFS configuration that matches the speedup (or slowdown) in relation to the current configuration.

For our Alg. 1 to operate, we prepare a structure such as Table 1a for all DNN instances in a hashed format[5]. The LookUp procedure would then directly find a bucket by using the SpeedUp as an index. The output of Alg. 1 is a set $\Delta = \{\delta_1, \delta_2, ..., \delta_n\}$, in which δ_i is the ideal DVFS configuration for DNN instance i in order to meet the deadline. Imagine we ultimately decide that $\delta_c \in \Delta$ is the best DVFS configuration for the next scheduling period. A very interesting question would be that, what is the effect of applying δ_c on other DNN instances $i \neq c$? The speedup of δ_c for other DNN instances can be calculated by using δ_c as the lookup key in their corresponding SpeedUp/PowerUp table. But what if this speedup does not reduce LAG_i to zero? To solve this problem, we next present the algorithm that calculates the application-level approximation required to reduce LAG_i to zero given a DVFS configuration $\delta_c \in \Delta$.

Algorithm 2 X_i Calculator.

```
Input: $\Delta$        ▷ Potential DVFS list.
Input: SpeedUp/Accuracy[]        ▷ The SpeedUp/Accuracy table of DNNs.
Input: SpeedUp/PowerUp[]        ▷ The SpeedUp/PowerUp table of DNNs.
Output: $X[][]$        ▷ The accuracy list for each DNN instance for each $\delta$

1: function RETURN$X_i(\Delta)$
2:     for $\delta_c$ in $\Delta$ do
3:         for $i = 0$ to $i < |\Delta|$ do
4:             $S_{A_i} \leftarrow \frac{S_{P_i}(\delta_c) \cdot (D_i + LAG_i)}{D_i}$
5:             $X[c][i] \leftarrow$ LookUp(SpeedUp/Accuracy[$S_{A_i}$])
```

Application-level accuracy adjustment. Alg. 2 portrays the procedures to calculate the required approximation for the upcoming layers of all DNN instances based on a DVFS configuration. If the instance i is behind the ideal schedule by LAG_i, with a relative deadline of D_i, and if the chosen DVFS configuration is δ_c, the remaining required speedup can be calculated as follows (line 4):

$$S_{A_i}(\delta_c) = \frac{S_{P_i}(\delta_c) \cdot (D_i + LAG_i)}{D_i}, \tag{4}$$

in which $S_{A_i}(\delta_c)$ is the required speedup (or slowdown) via approximation for DNN instance i when DVFS configuration δ_c is chosen, and $S_{P_i}(\delta_c) \cdot (D_i + LAG_i)$ is the new projected execution time of DNN instance i. The value of S_{A_c}, the speedup from accuracy for the chosen DVFS configuration, should always be zero or less than zero since by definition, δ_c is the ideal DVFS configuration for c and requires no additional speedup from approximation.

The value of S_{A_i} is then used as a lookup key to a new table, called the SpeedUp/Accuracy table, depicted in Table 1b. Table 1b stores the relative worst case execution times for each layer's approximation configuration. We index each row by X, which is the value of the total accuracy of that configuration[6]. Note that the exact value of X has no effect in the algorithm and what matters is the relative order in Table 1b (i.e., the lower we go down the table, the lower the relative accuracy). The output of Alg.2 is the row index in the SpeedUp/Accuracy table sufficient to meet the deadline for all DNN instances except c. We denote this index for layer k of DVFS configuration i as X_i^k. This value is then broadcasted in the accuracy cohort and indicates the application-level

[5] Our hashing is custom, and hashes the relationship between SpeedUp and PowerUp. This method relies on partially sorting the DVFS configuration space. You can find the latest hashing code at https://git.io/Jfogq

[6] Each row could be indexed by any measure. However, indexing with X has benefits in overhead reduction for the LookUp procedure in Alg. 2 because it can be more easily hashed.

configuration chosen for the next immediate layer of the corresponding DNN instance.

The remaining question is that which δ_c should be chosen. We answer this question next.

4.3 Constraints and Coordination

The combination of Alg. 1 and Alg. 2 produces a list of potential DVFS configurations Δ, and for each DVFS configuration in Δ, a corresponding list of required approximations for all DNN instances in the cohort if that DVFS configuration were to be applied. Such a scenario can be visualized as a decision tree. The remaining question of our design would be which path to go down to in order to have a perfect *LAG* cohort. As discussed in Sec. 3.2, the requirements on energy and accuracy can vary depending on specific scenarios. We present the following three approaches based on the three scenarios defined in Sec. 4.1, i.e., minimum energy (M_P), maximum accuracy (M_A), and balanced energy and accuracy (S).

Min Energy. This approach aims at minimizing power usage at the cost of accuracy. To choose the best DVFS configuration in the DVFS candidate set Δ, we should look at the corresponding $S_{P_i}(\delta_c), \delta_c \in \Delta$ values in the SpeedUp/PowerUp table and choose the δ_c that has the smallest PowerUp value for that corresponding DNN instance, namely:

$$\delta_c = \{\delta_i \in \Delta \mid PowerUp_i(\delta_i) \leq PowerUp_i(\delta_x), \forall \delta_x \in \Delta\}, \quad (5)$$

in which $PowerUp_i(\delta_i)$ is extracted from the SpeedUp/PowerUp table of DNN instance i. Note that in our experience, the values of PowerUp can be non-linear in relation to SpeedUp, and hence, a comprehensive search as noted above is required. Then, using Alg. 2, the accuracy cohort can be calculated and broadcasted based on the projected new execution times. Even though this approach has the best power consumption, it will not have the best accuracy since many processes will most likely not meet the deadline without significant loss of accuracy, since the speedup from DVFS alone will likely not make up for the vast majority of the progress values in the cohort.

Max Accuracy. In this method, our system chooses the DVFS configuration δ_c in such a way that:

$$\delta_c = \{\delta_i \in \Delta \mid \sum(S_{Aj}(\delta_i)) \leq \forall \sum(S_{Aj}(\delta_x \in \Delta)), \; \forall \text{ DNN instance j in cohort}\}, \quad (6)$$

in which $\sum S_{Aj}(\delta_i)$ is the sum of all the required speedups from approximation (S_{Ai}) for configuration δ_i, and $\leq \forall \sum(S_{Aj}(\delta_x \in \Delta))$ is indicating that the sum of approximation-induced speedup for the chosen δ_c should be less than or equal any other sum of approximation values for other $\delta_x \in \Delta$ (this indirectly ensures minimized accuracy loss).

Statistical Approach for Balanced Energy and Accuracy. To achieve balanced energy and accuracy, we propose a statistical approach that checks the state of Δ and the projected accuracy cohort in statistical terms to make a decision. The calculation of S_{P_i} and S_{A_i} (which depends on S_{P_i}) resemble the form of Bivariate Regression Analysis (BRA) [57], in which:

$$S_{A_i} = S_{P_i} \cdot \frac{D_i + LAG_i}{D_i} + 0, \quad (7)$$

in which, $\frac{D_i + LAG_i}{D_i}$ is called the influence of S_{P_i} on the required approximation. To measure this influence, we first calculate

$$I = \sum_{i=0}^{i=n-1} \frac{D_i + LAG_i}{D_i}, \quad (8)$$

in which I is the collective influence of LAG on approximation. If the value of I is high, it means that the accuracy can be more adversely affected by a low value of DVFS-induced speedup(S_{P_i}). Similarly, a low value of I means that the accuracy can remain minimal even with a low value for DVFS-induced speedup. We simplify our decision making by dividing the *LAG* cohort Φ into three groups based on how big or small the value of *LAG* is. The boundary for the intervals is calculated using:

$$Boundary = \frac{\max\{\Phi\} - \min\{\Phi\}}{3}. \quad (9)$$

The three groups $G1[0...Boundary]$, $G2[Boundary...2 \cdot Boundary]$, and $G3[2 \cdot Boundary...3 \cdot Boundary]$ are then formed, and the ultimate DVFS configuration is chosen as:

$$\delta_c = \begin{cases} median(G1) & if(I < t) \\ median(G2) & if(t < I < 1+t) \\ median(G3) & if(I > 1+t) \end{cases}, \quad (10)$$

in which, t is a threshold for I, set to the standard deviation σ of the set I. However, t can be chosen by the system designer to indicate a requirement on power consumption and accuracy. A small value for t will push the system towards faster DVFS configurations and vice versa.

Discussion on choosing modes and safety. We would like to conclude our design by a discussion on which modes to choose and the safety concern it might entail. Our stand from a system perspective is to design a flexible system architecture that can adapt to various external needs. Where absolute mission-critical applications are concerned, we offer Max Accuracy. Nonetheless, depending on the safety requirement, our Balanced approach might be good enough with the proper threshold t even for applications such as self-driving vehicles. However, choosing a mode dynamically at runtime or statically for a particular system offline has more to do with the certification standards (which are in their preliminary stages for self-driving vehicles) as well as the requirement on maximum reaction time and accuracy. Thus, we believe the decision should be relegated to an external policy controller [54, 31, 6, 34, 52]

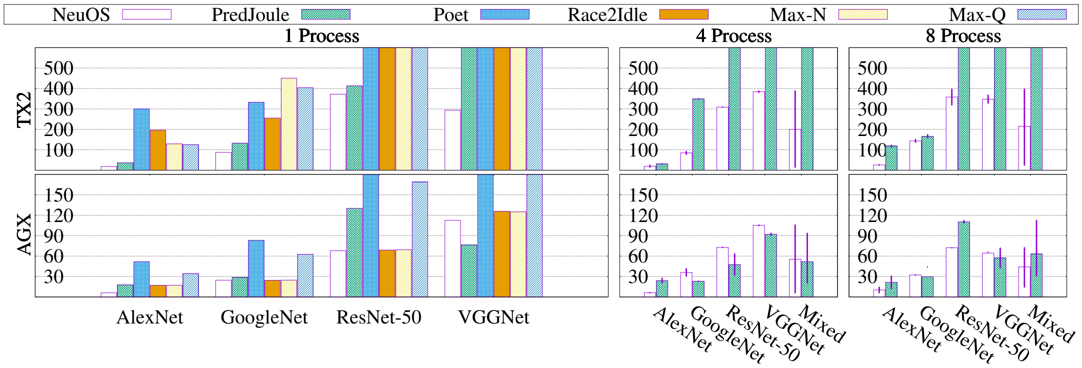

Figure 7: Energy under various methods (in mJ) for 1, 4, and 8 instances of 4 DNN models.

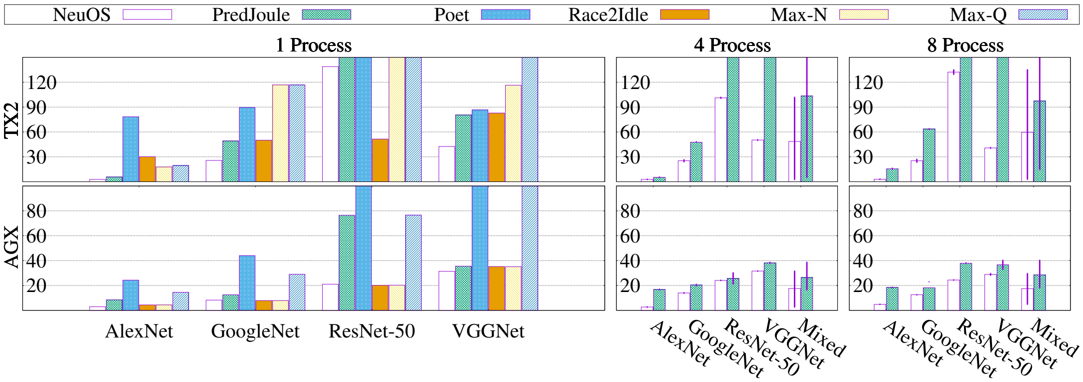

Figure 8: Latency under various methods (in ms) for 1, 4, and 8 instances of 4 DNN models.

5 Evaluation

In this section, we test our full implementation on top of Caffe [25] with an extensive set of evaluations.

5.1 Experimental Setup

In this section we lay out our experimental setup, which includes two embedded platforms and four popular DNN models. We compare NeuOS to 6 existing approaches.

Testbeds. We have chosen two different NVIDIA platforms imposing different architectural features (since deployed autonomous systems solutions, particularly for autonomous driving and robotics, seem to gravitate towards NVIDIA hardware as of writing this paper [26, 30]) to showcase the cross-platform nature of our design when it comes to hardware. We use NVIDIA Jetson TX2, with 6 big.LITTLE ARM-based cores and a 256-core Pascal based GPU with 11759 unique DVFS configurations, and the NVIDIA Jetson AGX Xavier, the latest powerful platform for robotics and autonomous vehicles with an 8-core NVIDIA Carmel CPU and a 512-core Volta-based GPU with 51967 unique DVFS configurations.

DNN models. Having a diversified portfolio of DNN models can showcase that NeuOS is future proof in the fast-moving field of neural networks. To that end, we use AlexNet [32], ResNet [19], GoogleNet [2], and VGGNet [49] in our experiments. Our method dynamically applies a lowrank version of a convolutional layer whenever approximation is necessary by keeping both version of the layer in memory for fast switching. The deadline for each DNN instance is based on their worst-case execution time (WCET) on each platform, and is set to 10ms, 30ms, 150ms, and 40ms respectively for Jetson TX2 and 5ms, 10ms, 25ms, 30ms respectively for AGX Xavier. Note that ResNet is much slower on Jetson TX2 due to the older JetPack software.

Small Cohort, Medium Cohort, Large Cohort sizes. We test NeuOS under three different cohort size classes to test for adaptability and balance: 1 process for small, 2 to 4 processes for medium, and 6 to 8 processes for large. Each of these cohort sizes have their own unique challenges. We measure average timing, energy consumption, and accuracy for these scenarios and provide a measure of balancing where applicable. For medium and large cohorts, we include a mixed scenario, where different DNN models are executed, which represents systems that use different DNNs (for example for voice and image recognition). For the medium cohort, one instance of each DNN model and for the large cohort, two instances of each model are initiated.

Adaptability to different system scenarios. As discussed in Sec. 4.1, we consider three different scenarios with different limits on latency, energy and accuracy: minimum energy, maximum accuracy, and balanced energy and accuracy.

Compared Solutions. We implement and compare six state-

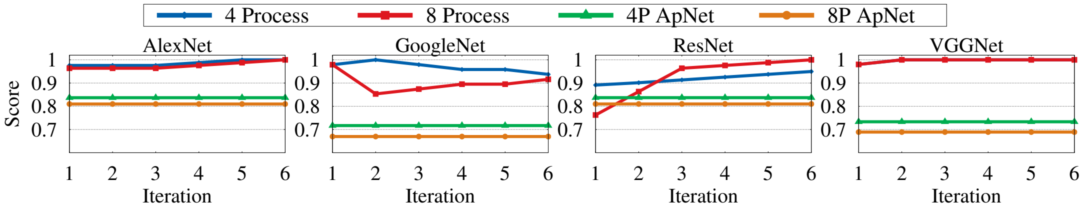

Figure 9: Average accuracy (y-axis as a fraction of 1) of the cohort over iteration of execution for 4 different DNN models with 4 and 8 instances compared to ApNet (x-axis is the iteration number).

of-the art solutions from the literature, including DNN-specific and DNN-agnostic ones, software-based DVFS and hardware-based DVFS, and application-level and system-level solutions. We present a short detail for each as follows.

PredJoule [5] is a system-level solution tailored towards DNN by employing a layer-based DVFS adjustment solution for optimization latency and energy. *Poet* [23] is a system-level control-theory based software solution that balances energy and timing in a best-effort manner via adjusting DVFS. We choose to compare against Poet instead of its extended approaches including JouleGuard [21] and CoAdapt [20], as they employ essentially the same set of control theory-based techniques as Poet. *ApNet* [3] is an application-level solution based on DNNs that can theoretically provide a per-layer approximation requirement offline to meet deadlines. *Race2Idle* [28] is the classic “run it as fast as you can” philosophy, which is always interesting to compare to. *Max-N* [10, 11] is a reactive hardware DVFS that maximizes frequency and sacrifices energy in the name of speed, in NVIDIA embedded hardware. *Max-Q* [10] is a hardware DVFS on Jetson TX2 that dynamically adjusts DVFS on the fly to conserve energy. However, this feature has been removed from the Xavier platform [11], and is replaced by low level power caps, such as 10W, 15W, and 30W. We use the 15w cap instead of Max-Q on Xavier.

5.2 Overall Effectiveness

In this section, we measure the efficacy of NeuOS on the two evaluated platforms under the balanced scenario. Since our design is concerned with timing predictability, energy consumption, and DNN accuracy, we measure all three constraints and compare against state-of-the-art literature under each platform and each scenario.

5.2.1 Small Cohort

Energy. The left column of Fig. 7 depicts our measurements in terms of average energy consumption compared to a GPU-enabled Poet, Max-Q, Max-N, PredJoule, and Race2Idle using AlexNet, GoogleNet, ResNet-50 and VGGNet as the base DNN model and using lowrank as the approximation method. As is evident in the figure, NeuOS is able to save energy considerably compared to all other methods on Jetson TX2 on all DNN models, with improvements of 68% on average for Jetson TX2 and 46% on average for AGX Xavier. This saving is due to the fact that in some cases accuracy is minimally traded off for the benefit of energy and timing.

On the Jetson AGX Xavier, NeuOS has better energy consumption compared to all other approaches on every DNN model except compared to PredJoule for VGGNet. As we shall see for timing, PredJoule misses the deadline of 30 for VGGNet, and NeuOS has decided to sacrifice energy to meet timing.

Latency. Fig. 8 shows the average execution time for NeuOS compared to the 5 methods and using 4 DNN models. NeuOS outperforms all other approaches, improving on average execution time by 68% on Jetson TX2 and by 40% on AGX Xavier. It is also interesting to note that AGX Xavier is much faster than Jetson TX2, by 70% on average.

Tail Latency. Through response time measurements, we find that NeuOS rarely misses the deadline (3.25% of the time). Moreover, the variance is low with the 99th percentile execution time for AlexNet, GoogleNet, ResNet-50, and VGGNet as 9.2 ms, 48 ms, 130.3 ms and 39.1 ms for TX2 and 5.0 ms, 12.0 ms, 26.1 ms and 36.2 ms for AGX respectively.

Accuracy. We also measure the accuracy loss of NeuOS compared to ground truth and compared to ApNet (Fig. 9 omits small cohort for clarity). ApNet is the only DNN-specific application level solution we are aware of. NeuOS has an approximation score of 0.94% on average (out of 1), which is better than ApNet by 21%.

5.2.2 Medium and Large Cohorts

In order to save space, we only compare PredJoule for the 4-process medium and 8-process large cohort sizes. In our testings, PredJoule already vastly outperforms other methodologies, and thus is a good comparison to NeuOS.

Energy. As is evident in the second and third columns of Fig. 7, NeuOS can almost always outperform PredJoule in terms of energy consumption on Jetson TX2 improving 70% on average. However, rather interestingly, NeuOS performs worse in terms of energy compared to PredJoule for GoogleNet, ResNet, and VGGNet on AGX Xavier. This is due to the fact that PredJoule again misses the deadlines on AGX Xavier, and NeuOS has sacrificed a negligible amount of energy (1.5% on average) in order to meet the deadline.

Latency. NeuOS always outperforms state-of the art, improving by 53% on average for Jetson TX2, and by 32% on average for AGX. This is due to the fact that NeuOS is able to leverage a small amount of accuracy and energy loss (in the case of AGX Xavier) for better timing and energy characteristics.

Tail Latency. We find that deadline miss ratio is about the

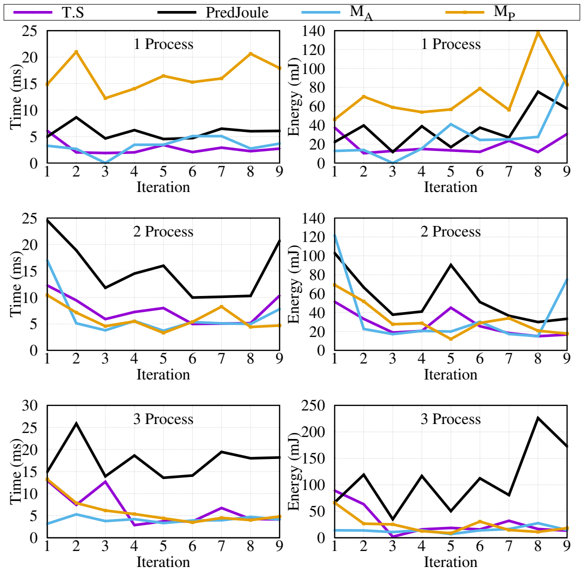

Figure 10: Performance of NeuOS under three scenarios compared to PredJoule on Jetson TX2.

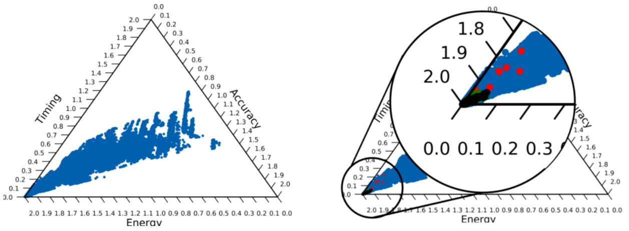
same as the small cohort. Moreover, the variance is similarly low with the 99th percentile execution time for AlexNet, GoogleNet, ResNet-50, and VGGNet as 10.4 ms, 39.2 ms, 101.7 ms and 69 ms for TX2 and 11 ms, 12.5, 26.3 and 35.9 ms for AGX respectively for the medium cohort and 13.6 ms, 40.8 ms, 190 ms and 72 ms for TX2 and 10.7 ms , 54 ms , 62 ms and 36.1 ms for AGX respectively for the large cohort.

Accuracy. Fig. 9 shows the average accuracy of the cohort over 6 iterations on AGX Xavier. As is evident in the figure, NeuOS generally improves upon accuracy as the system progresses because the optimization in Sec. 4.3 is able to find better DVFS configurations. When compared to the efficient approximation-aware solution APnet, NeuOS is able to achieve noticeably better accuracy in all scenarios.

Balance. A very important measure discussed in Sec. 3.3 is how balanced the system solution is when faced with multiple processes. To measure how balanced NeuOS is compared to PredJoule in the 4-process and 8-process scenarios, we include min-max bars in Fig. 7 and Fig. 8 to showcase the discrepancy between minimum and maximum timing/energy. As is evident in the figure, the discrepancy is negligible compared to the total energy consumption and execution time (up to 79 mJ and 4 ms). Thus, NeuOS maintains balance in the cohort. This is due to the coordinated cohorts and a uniform non-greedy decision making approach introduced in our design.

5.3 Detailed Examination on Tradeoff

In this section, we focus on the fact that system designers might require certain constraints that limits the ability of NeuOS in a certain dimension. To this end, we test our platform under three different scenarios: Maximum Accuracy (M_A), Minimum Power (M_P), and Balanced ($T.S$).



(a) The entire configuration space for all DVFS and accuracy combinations for Jetson TX2.

(b) Chosen configurations in the triangle space.

5.3.1 Energy and Latency.

We compare against PredJoule and measure average timing for the cohort in ms and average energy in mJ in Fig. 10 for 1-process (small), 2-process (medium), and 3-process (large) scenarios on AlexNet over 9 iterations on the Jetson TX2. PredJoule is shown as a black line. The deadline in this scenario is set to 25 to show the interesting characteristics of each method.

Balanced. As is evident in the figure, our statistical balanced approach outperforms PredJoule over all iterations. Notably in the case of medium and large cohorts, PredJoule has a particularly bad start in terms of timing and has higher fluctuation due to the greedy nature of DVFS selection.

Min Energy. Interestingly, M_P performs very bad (still meets the deadline) for the small cohort both in terms of timing and energy consumption. This is due to the algorithms discussed in Sec. 4.3. The system has switched to a very slow DVFS configuration to save energy. However, because of the non-linearity inherent in very slow DVFS configurations for GPUs [5], this has resulted in a very bad energy consumption as well. However, the coordination starts to pay off for medium and large cohorts. This is because a coordinated multi-process cohort needs faster DVFS configurations and thus, the circumstances push M_P out of the slow and power inefficient DVFS configuration subset. The greediness of PredJoule is inherent for medium and large cohorts in the form of very large fluctuations throughout the iterations.

Max Accuracy. M_A should improve accuracy while sacrificing energy and timing. We shall discuss the accuracy decisions shortly. However, the timing for M_A is worse than balanced energy by a negligible amount. The same is true for energy consumption (23% on average). This highlights a big design decision of the balanced scenario overall. Even for the balanced general approach, sacrificing accuracy is done very conservatively as was discussed earlier. Thus, the slight push toward perfect accuracy does not introduce very large overheads. However, as was discussed earlier guaranteeing a tight deadline (such as 10ms for AlexNet) requires some approximation if energy consumption is a consideration.

5.3.2 Energy-Accuracy Tradeoff.

For accuracy and to show where the variations of NeuOS jump in terms of system and application configurations, we bring back the triangle of Fig. 1, but with real DVFS and

Table 2: Average execution time overhead of NeuOS compared to other approaches on AlexNet (ms).

	1 Process	4 Process	8 Process
NeuOS	0.145	0.571	0.738
PredJoule	0.772	0.929	1.597
ApNet	0	3.27	5.85
Poet	151.03	604.12	1208.27

accuracy configurations with the selected configurations of M_P, M_A, and $T.S$ highlighted in Fig. 11b. As is evident in the triangle, the deadline limits the possible configurations to the bottom left corner. However, within that limitation, M_P (in red) has chosen configurations that are lower on energy consumption toward the upper right. On the other hand M_A (in green) has chosen configurations that are not as good in terms of energy consumption, but are better in terms of accuracy toward bottom left. Finally, $T.S$, colored black, is similar to M_A because of the high emphasis on accuracy in our design.

5.4 Overhead

Execution time: Table 2 shows the overhead of NeuOS compared to Poet, PredJoule, and ApNet using AlexNet as the baseline model on Jetson TX2 (times are in milliseconds). As is evident in Table 2, the overhead for NeuOS is negligible, especially compared to Poet and the overhead is also negligible compared to the overall execution time of AlexNet itself. The reason Poet is so slow is because it has to go through all DVFS configurations in a quadratic way ($O(n^2)$, n is the number of DVFS configurations). Even $O(n)$ would be unacceptable on embedded systems with more than 10000 unique DVFS configurations. This proves that applying our complexity reduction techniques (via hashing) is a must for a practical system solution. Moreover, NeuOS is more efficient than PredJoule and ApNet, especially in 4 Process and 8 Process scenarios.

Memory: As discussed in Sec. 5.1, our implementation keeps both the original and the lowrank approximation of the model in GPU memory for fast switching at layer boundaries. Moreover, NeuOS also holds the per-layer hash tables containing approximation and DVFS configuration information as described in Sec. 4. Table 3 depicts the added overhead in terms of both raw and percentage of the total NeuOS memory usage. As expected, the lowrank approximated version of each model has slightly less overall size compared to the original model. Nonetheless, this technique sacrifices memory overhead to improve latency and energy consumption. A viable alternative left as future work is dynamic approximation on the fly, which trades off latency for lower memory consumption. Moreover, the overhead of the hash tables is negligible compared to the total memory usage. Finally, the last two columns depict the cumulative maximum percentage of total available memory occupied by one instance of NeuOS for each platform (this memory usage also includes the temporary intermediate layer data [39]).

Table 3: Raw and percentage based memory overhead of applying NeuOS for each model.

	(a) Overhead in addition to Caffe			(b) Ratio to total memory	
	Lowrank	Hash Table	Ratio	Jetson TX2	AGX Xavier
AlexNet	226 MB	331 B	49%	10%	4%
GoogleNet	23 MB	2.1 KB	30%	2%	1%
ResNet-50	82 MB	3.2 KB	45%	7%	3%
VGGNet	509 MB	634 B	48%	25%	12.7%

6 Related Work

Trading off latency and power efficiency has been a hot topic in the related fields including real-time embedded systems and mobile computing [40, 8, 41, 53, 59, 16, 37, 42, 47, 1]. Due to the explosion of approximation techniques in different application domains, there has been several recent works [15, 35, 13] seeking to address this problem in a three dimensional space covering accuracy as well. Unfortunately, these works cannot resolve the problem as their applicability is limited in scope in various ways. JouleGuard [21], MeanTime [13], CoAdapt [20] and other similar approaches provide general system or hardware solution for non-DNN applications that claim to explore the three dimensional optimization space.

A very recent set of works including PredJoule [5], and ApNet [3] are able to provide latency predictability (meeting deadlines) for DNN-based workloads, yet they only consider two out of the three dimensions and focus on single-DNN scenarios. As we have discussed in Sec. 3.2, running ApNet and PredJoule at the same time even at different frequencies will result in a negative feedback loop. Thus, a better, more coordinated approach is required.

Such limitations would dramatically reduce the complexity of the optimization space, as the system-level and application-level tradeoffs focusing on a single task can be considered in an independent manner (e.g., pure system-level and application-level optimization under Poet [23] and CoAdapt, respectively). This results in solutions that are inapplicable to any practical autonomous real-time system featuring a multi-DNN environment.

7 Acknowledgment

We would like to thank our shepherd, Amitabha Roy, and the anonymous referees for their invaluable insight and advice into making this paper substantially better. This work is supported by NSF grant CNS CAREER 1750263.

8 Conclusion

This paper presents NeuOS, a comprehensive latency predictable system solution for running multi-DNN workloads in autonomous embedded systems. NeuOS can guarantee latency predictability, while managing energy optimization and dynamic accuracy adjustment based on specific system constraints via smart coordinated system- and application-level decision-making among multiple DNN instances. Extensive evaluation results prove the efficacy and practicality of NeuOS.

Abstract

In this paper we present PERCIVAL, a browser-embedded, lightweight, deep learning-powered ad blocker. PERCIVAL embeds itself within the browser's image rendering pipeline, which makes it possible to intercept every image obtained during page execution and to perform image classification based blocking to flag potential ads.

Our implementation inside both Chromium and Brave browsers shows only a minor rendering performance overhead of 4.55%, for Chromium, and 19.07%, for Brave browser, demonstrating the feasibility of deploying traditionally heavy models (i.e. deep neural networks) inside the critical path of the rendering engine of a browser. We show that our image-based ad blocker can replicate EasyList rules with an accuracy of 96.76%. Additionally, PERCIVAL does surprisingly well on ads in languages other than English and also performs well on blocking first-party Facebook ads, which have presented issues for rule-based ad blockers. PERCIVAL proves that image-based perceptual ad blocking is an attractive complement to today's dominant approach of block lists.

1 Introduction

Web advertising provides the financial incentives necessary to support most of the free content online, but it comes at a security and privacy cost. To make advertising effective, ad networks or publishers track user browsing behavior across multiple sites to generate elaborate user profiles for targeted advertising.

Users find that ads are intrusive [61] and cause disruptive browsing experience [6, 27]. In addition, studies have shown that advertisements impose privacy and performance costs to users, and carry the potential to be a malware delivery vector [2, 35, 37, 54, 55, 76].

Ad blocking is a software capability for filtering out unwanted advertisements to improve user experience, performance, security, and privacy. At present, ad blockers either run directly in the browser [4, 12] or as browser extensions [1].

Current ad blocking solutions filter undesired content based on "handcrafted" filter lists such as EasyList [74], which contain rules matching ad-carrying URLs and DOM elements. Most widely-used ad blockers, such as uBlock Origin [26] and Adblock Plus [1] use these block lists for content blocking. While useful, these approaches fail against adversaries who can change the ad-serving domain or obfuscate the web page code and metadata.

In an attempt to find a more flexible solution, researchers have proposed alternative approaches to ad blocking. One such approach is called Perceptual ad blocking, which relies on "visual cues" frequently associated with ads like the AdChoices logo or a sponsored content link. Storey et al. [70] built the first perceptual ad blocker that uses traditional computer vision techniques to detect ad-identifiers. Recently, Adblock Plus developers built filters into their ad blocker [15] to match images against a fixed template in order to detect ad labels. Due to the plethora of ad-disclosures, AdChoices logo and other ad-identifiers, it is unlikely that traditional computer vision techniques are sufficient and generalizable to the range of ads one is likely to see in the wild.

A natural extension to traditional vision-based blocking techniques is deep learning. Adblock Plus recently proposed SENTINEL [65] that detects ads in web pages using deep learning. SENTINEL's deep learning model takes as input the screenshot of the rendered webpage to detect ads. However, this technology is still in development.

To this end, we present PERCIVAL, a native, deep learning-powered *perceptual ad blocker*, which is built into the browser image rendering pipeline. PERCIVAL intercepts every image obtained during the execution sequence of a page and blocks images that it classifies as ads. PERCIVAL is small (half the average webpage size [25]) and fast, and we deploy it online within two commercial browsers to block and detect ads at real-time.

PERCIVAL can be run *in addition* to an existing ad blocker, as a last-step measure to block whatever slips through its

[†]Employed by Brave software when part of this work took place.

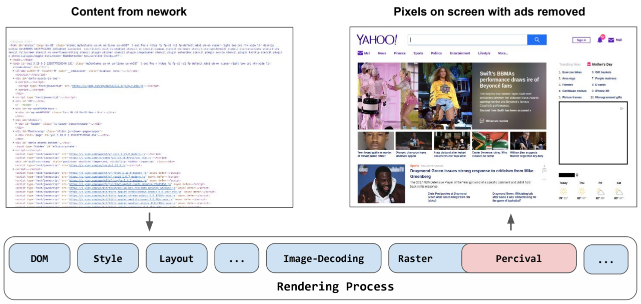

Figure 1: Overall architecture of PERCIVAL. PERCIVAL is positioned in the renderer process-which is responsible for creating rasterized pixels from HTML, CSS, Javascript. As the renderer process creates the DOM and decodes and rasterizes all image frames, these are first passed through PERCIVAL. PERCIVAL blocks the frames that are classified as ads. The corresponding output with ads removed is shown above (right).

filters. However, PERCIVAL may also be deployed *outside* the browser, for example, as part of a crawler, whose job is to construct comprehensive block lists to supplement EasyList.

1.1 Contributions

This paper makes the following contributions:

- **Perceptual ad blocking in Chromium-based browsers.** We deploy PERCIVAL in two Chromium-based browsers: Chromium and Brave. We demonstrate two deployment scenarios; first, PERCIVAL blocks ads synchronously as it renders the page, with a modest performance overhead. Second, PERCIVAL classifies images *asynchronously* and memoizes the results, thus speeding up the classification process[1].
- **Lightweight and accurate deep learning models.** We show that ad blocking can be done effectively using highly-optimized deep neural network-based models for image processing. Previous studies suggest that models over 5MB in size become hard to deploy on mobile devices [62]; because of our focus on low-latency detection, we create a compressed in-browser model that occupies 1.76MB[2] on disk, which is smaller by factor of 150 compared to other models of this kind [22], while maintaining similar accuracy results.
- **Accuracy and performance overhead measurements.** We show that our perceptual ad blocking model can replicate EasyList rules with the accuracy of 96.76%, making PERCIVAL a viable and complementary ad blocking layer. Our implementation within Chromium shows an average overhead of 178.23ms for page rendering. This overhead shows the feasibility of deploying deep neural networks inside the critical path of the rendering engine of the browser.
- **First-party ad blocking.** While the focus of traditional ad blocking is primarily on third-party ad blocking, we show that PERCIVAL blocks first-party ads as well, such as those found on Facebook. Specifically, our experiments show that PERCIVAL blocks ads on Facebook (often referred to as "sponsored content") with a 92% accuracy, with precision and recall of 78.4% and 70.0%.
- **Language-agnostic blocking.** We demonstrate that our model in PERCIVAL blocks images that are in languages we did not train our model on. We evaluate our trained model on Arabic, Chinese, Korean, French and Spanish image-based ads. Our model achieves an accuracy of 81.3% on Arabic, 95.1% on Spanish, and 93.9% on French datasets, with moderately high precision and recall. However, results from Chinese and Korean ads are less accurate.

2 Motivation

Intrusive, online, advertising has been a long standing concern for user privacy, security and overall web experience. While web advertising makes it easier and more economic for businesses to reach a wider audience, bad actors have exploited this channel to engage in malicious activities. Attackers use ad-distribution channels to hijack compromised web pages in order to trick users into downloading malware [54]. This is known as malicious advertising.

Mobile users are also becoming targets of malicious advertising [68]. Mobile applications contain code embedded from the ad networks, which provides the interface for the ad networks to serve ads. This capability has been abused by attackers where the landing page of the advertisements coming from ad networks links to malicious content. Moreover, intrusive advertisements significantly affect the user experience on mobile phones due to limited screen size [38]. Mobile ads also drain significant energy and network data [73].

Web advertising also has severe privacy implications for users. Advertisers use third party web-tracking by embedding code in the websites the users visit, to identify the same users again in a different domain, creating a more global view of the user browsing behavior [52]. Private user information is collected, stored and sold to other third party advertisers. These elaborate user profiles can be used to infer sensitive information about the users like medical history or political views [31,57]. Communication with these third party services is unencrypted, which can be exploited by attackers.

The security and privacy concerns surrounding web advertising has motivated research in ad blocking tools

[1] We make the source code, pre-trained models and data available for other researchers at https://github.com/dxaen/percival

[2] Our in-browser model is 3.2MB due to a less efficient serialization format. Still, the weights are identical to our 1.76MB model

from both academia [29, 40, 44, 69, 75] and industry notably Adblock Plus [1], Ghostery [13], Brave [4], Mozilla [47], Opera [16] and Apple [17]. Ad blocking serves to improve web security, privacy, usability, and performance. As of February 2017, 615 million devices had ad blockers installed [19] However, recently Google Chrome [14] and Safari [3] proposed changes in the API exposed to extensions, with the potential to block extension based ad-blockers. This motivates the need for native ad blockers like Brave [4], Opera [16], AdGraph [44], PageGraph [32] and even Percival.

3 Percival Overview

This paper presents Percival, a novel deep-learning based system for blocking ads. Our primary goal is to build a system that blocks ad images that could escape detection by current techniques, while remaining small and efficient enough to run in a mobile browser.

Figure 1 shows how Percival blocks rendering of ads. First, Percival runs in the browser image rendering pipeline. By running in the image rendering pipeline, Percival can inspect all images before the browser shows them to the user. Second, Percival uses a deep convolutional neural network (CNN) for detecting ad images. Using CNNs enables Percival to detect a wide range of ad images, even if they are in a language that Percival was not trained on.

This section discusses Percival's architecture overview, possible alternative implementations and detection model. Section 4 discusses the detailed design and implementation for our browser modifications and our detection model.

3.1 Percival's Architecture Overview

Percival's detection module runs in the browser's image decoding pipeline after the browser has decoded the image into pixels, but before it displays these pixels to the user. Running Percival after the browser has decoded an image takes advantage of the browser's mature, efficient, and extensive image decoding logic, while still running at a choke point before the browser displays the decoded pixels. Simply put, if a user sees an image, it goes through this pipeline first.

More concretely, as shown in Figure 1 Percival runs in the renderer process of the browser engine. The renderer process on receiving the content of the web page proceeds to create the intermediate data structures to represent the web page. These intermediate representations include the DOM-which encodes the hierarchical structure of the web page, the layout-tree, which consists of the layout information of all the elements of the web page, and the display list, which includes commands to draw the elements on the screen. If an element has an image contained within it, it needs to go through the *Image Decoding Step* before it can be rasterized. We run Percival after the *Image Decoding Step* during the *raster* phase which helps run Percival in parallel for multiple images at a time. Images that are classified as ads are blocked from rendering. The web page with ads removed is shown in Figure 1 (right). We present the detailed design and implementation in Section 4.

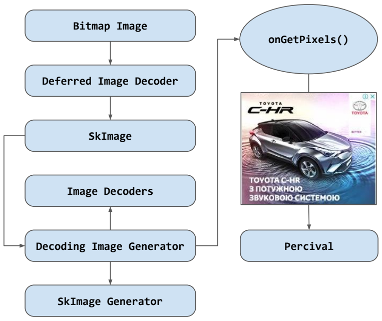

Figure 2: Percival in the image decoding pipeline. SkImage Generator allocates a bitmap and calls the `onGetPixels()` of `DecodingImageGenerator` to populate the bitmap. This bitmap is then passed to the network for classification and cleared if it contains an ad.

3.2 Alternative Possible Implementations and Advantages of Percival

One alternative to running Percival directly in the browser could have been to run Percival in the browser's JavaScript layer via an extension. However, this would require scanning the DOM to find image elements, waiting for them to finish loading, and then screenshotting the pixels to run the detection model. The advantage of a JavaScript-based system is that it works within current browser extensibility mechanisms, but recent work has shown how attackers can evade this style of detection [71].

Ad blockers that inspect web pages based on the DOM such as Ad Highlighter [70] are prone to DOM obfuscation attacks. They assume that the elements of the DOM strictly correspond to their visual representation. For instance, an ad blocker that retrieves all `img` tags and classifies the content contained in these elements does not consider the case, where a rendered image is a result of several CSS or JavaScript transformations and not the source contained in the tag. These ad blockers are also prone to resource exhaustion attacks where the publisher injects a lot of dummy elements in the DOM to overwhelm the ad blocker.

Additionally, a native implementation is much faster than a browser extension implementation with the added benefit of having access to the unmodified image buffers.

3.3 Detection Model

Percival runs a detection model on every image loaded in the document's main frame, a sub-document such as an `iframe`, as well as images loaded in JavaScript to determine if the image is an ad.

Although running directly within the browser provides Percival with more control over the image rendering process, it introduces a challenge: how to run the model efficiently in a browser? Our goal is to run PERCIVAL in browsers that run on laptops or even mobile phones. This requires that the model be small to be practical [62]. This design also requires that the model run directly in the image rendering pipeline, so overhead remains low. Any overhead adds latency to rendering for all images it inspects.

In PERCIVAL, we use the SqueezeNet [43] CNN as the starting point for our detection model. We modify the basic SqueezeNet network to be optimized for ad blocking by removing less important layers. This results in a model size that is less than 2MB and detects ad images in 11ms per image.

A second challenge in using small CNNs is how to provide enough training data. In general, smaller CNNs can have suitable performance but require more training data. What is more, the labels are highly imbalanced making the training procedure even more challenging.

Gathering ad images is non-trivial; most ads are programmatically inserted into the document through `iframe`s or JavaScript, and so simple crawling methods that work only on the initial HTML of the document will miss most of the ad images.

To crawl ad images, other researchers [22, 71] propose screenshotting iframes or JavaScript elements. This data collection method leads to problems with synchronizing the timing of the screenshot and when the element loads. Many screenshots end up with whites-space instead of the image content. Also, this method only makes sense if the input to the classifier is the rendered content of the web page.

To address these concerns and to provide ample training data, we design and implement a custom crawler in Blink[3] that handles dynamically-updated data and eliminates the race condition between the browser displaying the content and the screenshot we use to capture the image data. Our custom-crawler fetches ad and non-ad images directly from the rendering pipeline and uses the model trained during the previous phase as a labeler. This way we amplify our dataset to fine-tune our model further.

4 Design and Implementation of PERCIVAL

This section covers the design and implementation of the browser portion of PERCIVAL. We first cover the high-level design principles that guide our design, and then we discuss rendering and image handling in Blink, the rendering engine of Chromium-based browsers. Finally, we describe our end-to-end implementation within Blink.

4.1 Design Goals

We have two main goals in our design of PERCIVAL:

Run PERCIVAL at a choke point: Advertisers can serve ad images in different formats, such as JPG, PNG, or GIF. Depending on the format of the image, an encoded frame can traverse different paths in the rendering pipeline. Also, a wide range of web constructs can cause the browser to load images, including HTML image tags, JavaScript image objects, HTML Canvas elements, or CSS background attributes. Our goal is to find a single point in the browser to run PERCIVAL, such that it inspects all images, operates on pixels instead of encoded images, but does so before the user sees the pixels on the screen, enabling PERCIVAL to block ad images cleanly. **Note:** If individual pixels are drawn programmatically on canvas, PERCIVAL will not block it from rendering.

In Blink, the raster task within the rendering pipeline enables PERCIVAL to inspect, and potentially block, all images. Regardless of the image format or how the browser loads it, the raster task decodes the given image into raw pixels, which it then passes to the GPU to display the content on the screen. We run PERCIVAL at this precise point to abstract different image formats and loading techniques, while still retaining the opportunity to block an image before the user sees it.

Run multiple instances of PERCIVAL in parallel: Running PERCIVAL in parallel is a natural design choice because PERCIVAL makes all image classification decisions independently based solely on the pixels of each individual image. When designing PERCIVAL, we look for opportunities to exploit this natural parallelism to minimize the latency added due to the addition of our ad blocking model.

4.2 Rendering and PERCIVAL: Overview

We integrate PERCIVAL into Blink, the rendering engine for Google Chrome and Brave. From a high level, Blink's primary function is to turn a web page into the appropriate GPU calls [5] to show the user the rendered content.

A web page can be thought of as a collection of HTML, CSS, and JavaScript code, which the browser fetches from the network. The rendering engine parses this code to build the DOM and layout tree, and to issue OpenGL calls via `Skia`, Google's graphics library [24].

The layout tree contains the locations of the regions the DOM elements will occupy on the screen. This information together with the DOM element is encoded as a `display item`.

The browser then proceeds with rasterization, which takes the display items and turns them into bitmaps. Rasterization issues OpenGL draw calls via the Skia library to draw bitmaps. If the display list items have images in them (a common occurrence), the browser must decode these images before drawing them via Skia.

PERCIVAL intercepts the rendering process at this point, after the `Image Decode Task` and during the `Raster Task`. As the renderer process creates the DOM and decodes and rasterizes all image frames, these are first passed through

[3] Blink http://www.chromium.org/blink is the rendering engine used by Chromium.

Percival. Percival blocks the frames that are classified as ads.

4.3 End-to-End Implementation in Blink

We implement Percival inside Blink (Chromium rendering engine), where Percival uses the functionality exposed by the Skia library. Skia uses a set of image decoding operations to turn `SkImages`, which is the internal type within Skia that encapsulates images, into bitmaps. Percival reads these bitmaps and classifies their content accordingly. If Percival classifies the bitmap as an ad, it blocks it by removing its content. Otherwise, Percival lets it pass through to the next layers of the rendering process. When content is cleared, there are several ways to fill up the surrounding white-space; either collapsing it by propagating the information upwards or displaying a predefined image (user's spirit animal) in place of the ad.

Figure 2 shows an overview of our Blink integration. Blink class `BitmapImage` creates an instance of `DeferredImageDecoder` which in turn instantiates a `SkImage` object for each encoded image. SkImage creates an instance of `DecodingImageGenerator` (blink class) which will in turn decode the image using the relevant image decoder from Blink. Note that the image hasn't been decoded yet since chromium practices deferred image decoding.

Finally, `SkImageGenerator` allocates bitmaps corresponding to the encoded `SkImage`, and calls `onGetPixels()` of `DecodingImageGenerator` to decode the image data using the proper image decoder. This method populates the buffer (pixels) that contain decoded pixels, which we pass to Percival along with the image height, width, channels information (`SKImageInfo`) and other image metadata. Percival reads the image, scales it to 224 × 224 × 4 (default input size expected by SqueezeNet), creates a tensor, and passes it through the CNN. If Percival determines that the buffer contains an ad, it clears the buffer, effectively blocking the image frame.

Rasterization, image decoding, and the rest of the processing happen on a raster thread. Blink rasters on a per tile basis and each tile is like a resource that can be used by the GPU. In a typical scenario there are multiple raster threads each rasterizing different raster tasks in parallel. Percival runs in each of these worker threads after image decoding and during rasterization, which runs the model in parallel.

As opposed to Sentinel [65] and Ad Highlighter [36] the input to Percival is not the rendered version of web content; Percival takes in the Image pixels directly from the image decoding pipeline. This is important since with Percival we have access to unmodified image buffers and it helps prevent attacks where publishers modify content of the webpage (including iframes) with overlaid masks (using CSS techniques) meant to fool the ad blocker classifier.

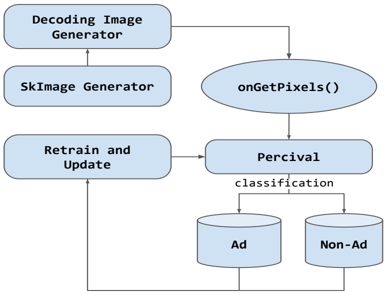

Figure 3: Crawling, labelling and re-training with Percival. Every decoded image frame is passed through Percival and Percival downloads the image frame into the appropriate bucket.

5 Deep Learning Pipeline

This section covers the design of Percival's deep neural network and the corresponding training workflow. We first describe the network employed by Percival and the training process. We then describe our data acquisition and labelling techniques.

5.1 Percival's CNN Architecture

We cast ad detection as a traditional image classification problem, where we feed images into our model and it classifies them as either being (1) an ad, or (2) not an ad. CNNs are the current standard in the computer vision community for classifying images.

Because of the prohibitive size and speed of standard CNN based image classifiers, we use a small network, SqueezeNet [43], as the starting point for our in-browser model. The SqueezeNet authors show that SqueezeNet achieves comparable accuracy to much larger CNNs, like AlexNet [48], and boasts a final model size of 4.8 MB.

SqueezeNet consists of multiple *fire modules*. A *fire module* consists of a "squeeze" layer, which is a convolution layer with 1 × 1 filters and two "expand" convolution layers with filter sizes of 1 × 1 and 3 × 3, respectively. Overall, the ”squeeze” layer reduces the number of input channels to larger convolution filters in the pipeline.

A visual summary of Percival's network structure is shown in Figure 4. As opposed to the original SqueezeNet, we down-sample the feature maps at regular intervals in the network. This helps reduce the classification time per image. We also perform max-pooling after the first convolution layer and after every two fire modules.

5.2 Data Acquisition

We use two systems to collect training image data. First, we use a traditional crawler with traditional ad-blocking rules (EasyList [7]) to identify ad images. Second, we use our browser instrumentation from Percival to collect images, improving on some of the issues we encountered with our traditional crawler.

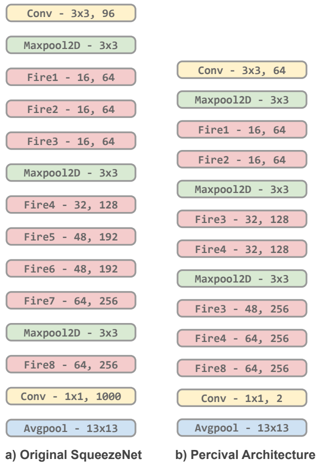

Figure 4: Original SqueezeNet (left) and PERCIVAL's fork of SqueezeNet (right). For `Conv`, `Maxpool2D`, and `Avgpool` blocks $a \times b$ represents the dimensions of the filters used. For fire blocks *a, b* represents the number of intermediate and output channels. We remove extraneous blocks as well as downsample the feature maps at regular intervals to reduce the classification time per image.

5.2.1 Crawling with EasyList

We use a traditional crawler matched with a traditional rule-based ad blocker to identify ad content for our first dataset. In particular, to identify ad elements which could be iframes or complex JavaScript constructs, we use EasyList, which is a set of rules that identify ads based on the URL of the elements, location within the page, origin, class or id tag, and other hand-crafted characteristics known to indicate the presence of ad content.

We built a crawler using Selenium [21] for browser automation. We then use the crawler to visit Alexa top-1,000 web sites, waiting for 5 seconds on each page, and then randomly selecting 3 links and visiting them, while waiting on each page for a period of 5 seconds as before. For every visit, the crawler applies every EasyList network, CSS and exception rule.

For every element that matches an EasyList rule, our crawler takes a screenshot of the component, cropped tightly to the coordinates reported by Chromium, and then stores it as an ad sample. We capture non-ad samples by taking screenshots of the elements that do *not* match any of the EasyList rules. Using this approach we, extract 22,670 images out of which 13,741 are labelled as ads, and 8,929 as non-ads. This automatic process was followed by a semi-automated post-processing step, which includes removing duplicate images, as well as manual spot-checking for misclassified images.

Eventually, we identify 2,003 ad images and 7,432 non-ad images. The drop in the number of ad images from 13,741 to 2,003 is due to a lot duplicates and content-less (single-color) images due to the asynchrony of iframe-loading and the timing of the screenshot. These shortcomings motivated our new crawler. To balance the positive and negative examples in our dataset so the classifier doesn't favor one class over another, we limited the number of non ad and ad images to 2,000.

5.2.2 Crawling with PERCIVAL

We found that traditional crawling was good enough to bootstrap the ad classification training process, but it has the fundamental disadvantage that for dynamically-updated elements, the meaningful content is often unavailable at the time of the screenshot, leading to screenshots filled with white-space.

More concretely, the *page load* event is not very reliable when it comes to loading iframes. Oftentimes when we take a screenshot of the webpage after the *page load* event, most of the iframes do not appear in the screenshots. Even if we wait a fixed amount of time before taking the screenshot, iframes constantly keep on refreshing, making it difficult to capture the rendered content within the iframe consistently.

To handle dynamically-updated data, we use PERCIVAL's browser architecture to read all image frames after the browser has decoded them, eliminating the race condition between the browser displaying the content and the screenshot we use to capture the image data. This way we are guaranteed to capture all the iframes that were rendered, independently of the time of rendering or refresh rate.

Instrumentation: Figure 3 shows how we use PERCIVAL's browser instrumentation to capture image data. Each encoded image invokes an instance of `DecodingImageGenerator` inside Blink, which in turn decodes the image using the relevant image decoder (PNG, GIFs, JPG, etc.). We use the buffer passed to the decoder to store pixels in a bitmap image file, which contains exactly what the rendering engine sees. Additionally, the browser passes this decoded image to PERCIVAL, which determines whether the image contains an ad. This way, every time the browser renders an image, we automatically store it and label it using our initially trained network, resulting in a much cleaner dataset.

Crawling: To crawl for ad and non-ad images, we run our PERCIVAL-based crawler with a browser automation tool called Puppeteer [20]. In each phase, the crawler visits the landing page of each Alexa top-1,000 websites, waits until `networkidle0` (when there are no more than 0 network connections for at least 500 ms) or 60 seconds. We do this to ensure that we give the ads enough time to load. Then our crawler finds all internal links embedded in the page. Afterwards, it visits 20 randomly selected links for each page, while waiting for `networkidle0` event or 60 seconds time out on each request.

In each phase, we crawl between 40,000 to 60,000 ad images. We then post process the images to remove duplicates, leaving around 15-20% of the collected results as useful. We

Images	Ads Identified	Accuracy	Precision	Recall
6,930	3466	96.76%	97.76%	95.72%

Figure 5: Summary of the results obtained by testing the dataset gathered using EasyList with PERCIVAL.

crawl for a total of 8 phases, retraining PERCIVAL after each stage with the data obtained from the current and all the previous crawls. As before, we cap the number of non-ad images to the amount of ad images to ensure a balanced dataset.

This process was spread-out in time over 4 months, repeated every 15 days for a total of 8 phases, where each phase took 5 days. Our final dataset contains 63,000 unique images in total with a balanced split between positive and negative samples.

6 Evaluation

6.1 Accuracy Against EasyList

To evaluate whether PERCIVAL can be a viable shield against ads, we conduct a comparison against the most popular crowd-sourced ad blocking list, EasyList [7], currently being used by extensions such as Adblock Plus [1], uBlock Origin [26] and Ghostery [13].

Methodology: For this experiment, we crawl Alexa top 500 news websites as opposed to Alexa top 1000 websites used in the crawl for training. This is because news websites are an excellent source of advertisements [18] and the crawl can be completed relatively quickly. Also, Alexa top 500 news websites serves as a test domain different from the train domain we used previously.

For our comparison we create two data sets: First, we apply EasyList rules to select DOM elements that potentially contain ads (IFRAMEs, DIVs, etc.); we then capture screenshots of the contents of these elements. Second, we use resource-blocking rules from EasyList to label all the images of each page according to their resource URL. After crawling, we manually label the images to identify the false positives resulting in a total of 6,930 images.

Performance: On our evaluation dataset, PERCIVAL is able to replicate the EasyList rules with accuracy 96.76%, precision 97.76% and recall 95.72% (Figure 5), illustrating a viable alternative to the manually-curated filter-lists.

Ads	No-ads	Accuracy	FP	FN	Precision	Recall
354	1,830	92.0%	68	106	78.4%	70.0%

Figure 7: The screenshots show one of the author' Facebook home page accessed with PERCIVAL. The black rectangles are not part of the original screenshot.

6.2 Blocking Facebook Ads

Facebook obfuscates the "signatures" of ad elements (e.g. HTML classes and identifiers) used by filter lists to block ads since its business model depends on serving first-party ads. As of now, Facebook does not obfuscate the content of sponsored posts and ads due to the regulations regarding misleading advertising [10, 11]. Even though this requirement favors perceptual ad blockers over traditional ones, a lot of the content on Facebook is user-created which complicates the ability to model ad and non-ad content.

In this section, we assess the accuracy of PERCIVAL on blocking Facebook ads and sponsored content.

Methodology: To evaluate PERCIVAL's performance on Facebook, we browse Facebook with PERCIVAL for a period of 35 days using two non-burner accounts that have been in use for over 9 years. Every visit is a typical Facebook browsing session, where we browse through the feed, visit friends' profiles, and different pages of interest. For desktop computers two most popular places to serve ads is the right-side columns and within the feed (labelled sponsored) [9].

For our purposes, we consider content served in these elements as ad content and everything else as non-ad content. A false positive (FP) is defined as the number of non-ads incorrectly blocked and false negative (FN) is the number of ads PERCIVAL missed to block. For every session, we manually compute these numbers. Figure 6 shows the aggregate numbers from all the browsing sessions undertaken. Figure 7 shows PERCIVAL blocking right-side columns correctly.

Results: Our experiments show that PERCIVAL blocks ads on Facebook with a 92% accuracy and 78.4% and 70.0% as precision and recall, respectively. Figure 6 shows the complete results from this experiment. Even though we achieve the accuracy of 92%, there is a considerable number of false positives and false negatives, and as such, precision and recall are lower. The classifier always picks out the ads in the right-columns but struggles with the ads embedded in the feed. This is the source of majority of the false negatives. False positives come from high "ad intent" user-created content, as well as content created by brand or product pages on Facebook (Figure 8).

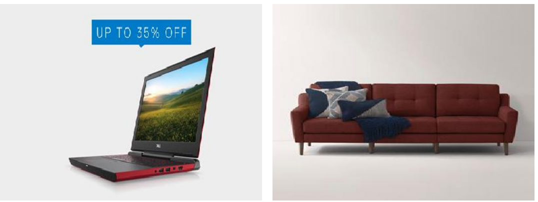

Figure 8: Examples of false positives and false negatives on Facebook (left) **False Positive:** This post was created by page owned by Dell Corp. (right) **False Negative:** This post was part of the sponsored content in the news feed.

Discussion: False Positives and False Negatives: To put Figure 6 into perspective since it might appear to have an alarming number of false positives and false negatives, it is worthwhile to consider an average scenario. If each facebook visit on average consists of browsing through 100 images, then by our experiments, a user will find roughly 16 ad images and 84 non-ad images, out of which PERCIVAL will block 11 to 12 ad images on average while also blocking 3 to 4 non-ad images. This is shown in Figure 10.

In addition to the above mentioned experiments which evaluate the out of box results of using PERCIVAL, we trained a version of PERCIVAL on a particular user's ad images. The model achieved higher precision and recall of 97.25%, 88.05% respectively.

6.3 Blocking Google Image Search Results

To improve our understanding of the misclassifications of PERCIVAL, we used Google Images as a way to fetch images from distributions that have high or low ad intent. For example, we fetched results with the query "Advertisement" and used PERCIVAL to classify and block images. As we can see in Figure 11, out of the top 23 images, 20 of them were successfully blocked. Additionally, we tested with examples of low ad intent distribution we used the query "Obama"). We also searched for other keywords, such as "Coffee", "Detergent", etc. The detailed results are presented in Figure 12. As shown, PERCIVAL can identify a significant percentage of images on a highly ad-biased content.

6.4 Language-Agnostic Detection

We test PERCIVAL against images with language content different than the one we trained on. In particular, we source a data set of images in Arabic, Chinese, French, Korean and Spanish.

Language	# crawled	# Ads	Accuracy	Precision	Recall
Arabic	5008	2747	81.3%	83.3%	82.5%
Spanish	2539	309	95.1%	76.8%	88.9%
French	2414	366	93.9%	77.6%	90.4%
Korean	4296	506	76.9%	54.0%	92.0%
Chinese	2094	527	80.4%	74.2%	71.5%

Figure 9: Accuracy of PERCIVAL on ads in non-English languages. The second column represents the number of images we crawled, while the third column is the number of images that were identified as ads by a native speaker. The remaining columns indicate how well PERCIVAL is able to reproduce these labels.

Images	Ads	No-ads	FP	FN
100	16	84	3-4	4-5

Figure 10: Average reporting of evaluation of Facebook ads and sponsored content per visit. We assume each Facebook visit consists of browsing through 100 total images.

Crawling: To crawl for ad and non-ad images, we use ExpressVPN [8] to VPN into major world cities where the above mentioned languages are spoken. For instance, to crawl Korean ads, we VPN into two locations in Seoul. We then manually visit top 10 websites as mentioned in SimilarWeb [23] list. We engage with the ad-networks by clicking on ads, as well as closing the ads (icon at the top right corner of the ad) and then choosing random responses like content not relevant or ad seen multiple times. This is done to ensure we are served ads from the language of the region.

We then run PERCIVAL-based crawler with the browser automation tool Puppeteer [20]. Our crawler visits the landing page of each top 50 SimilarWeb websites for the given region, waits until `networkidle0` (when there are no more than 0 network connections for at least 500 ms) or 60 seconds. Then our crawler finds all internal links embedded in the page. Afterwards, it visits 10 randomly selected links for each page, while waiting for `networkidle0` event or 60 seconds time out

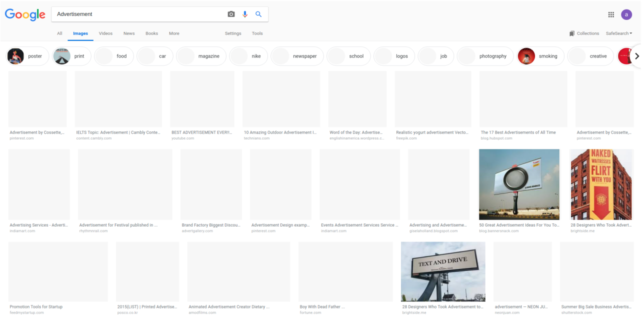

Figure 11: Search results from searching for "Advertisement" on Google images, using PERCIVAL.

Query	# blocked	# rendered	FP	FN
Obama	12	88	12	0
Advertisement	96	4	0	4
Coffee	23	77	-	-
Detergent	85	15	10	6
iPhone	76	24	23	1

Figure 12: PERCIVAL blocking image search results. For each search we only consider the first 100 images returned ("-" represents cases where we were not able to determine whether the content served is ad or non-ad).

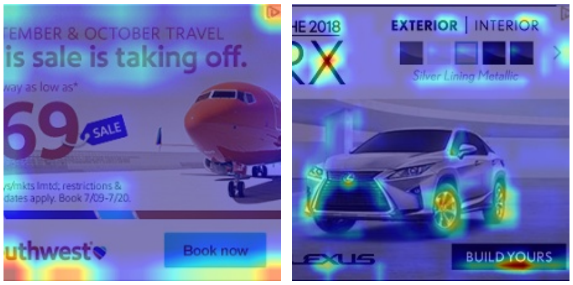
on each request. As opposed to Section 5.2.2, we download every image frame to a single bucket.

Labeling: For each language, we crawl 2,000–6,000 images. We then hire a native speaker of the language under consideration and have them label the data crawled for that language. Afterwards, we test PERCIVAL with this labeled dataset to determine how accurately can PERCIVAL reproduce these human annotated labels. Figure 9 shows the detailed results from all languages we test on. Figure 14 shows a screen shot of a Portuguese website rendered with PERCIVAL.

Results: Our experiments show that PERCIVAL can generalize to different languages with high accuracy (81.3% for Portuguese, 95.1% for Spanish, 93.9% for French) and moderately high precision and recall (83.3%, 82.5% for Arabic, 76.8%, 88.9% for Spanish, 77.6%, 90.4% for French). This illustrates the out-of-the box benefit of using PERCIVAL for languages that have much lower coverage of EasyList rules, compared to the English ones. The model does not perform as well on Korean and Chinese datasets.

6.5 Salience Map of the CNN

To visualize which segments of the image are influencing the classification decision, we used Grad-CAM [64] network salience mapping which allow us to highlight the important regions in the image that caused the prediction. As we can see in Figure 13, our network is focusing on ad visual cues (*AdChoice* logo), when this is present (case (a)), also it follows the outlines of text (signifying existence of text between white space) or identifies features of the object of interest (wheels of a car).



(a) Ad image: Layer 9

(b) Ad image: Layer 5

6.6 Runtime Performance Evaluation

We next evaluate the impact of PERCIVAL-based blocking on the browser performance. This latency is a function to the number and complexity of the images on the page and the time the classifier takes to classify each of them. We measure the rendering time impact when we classify each image *synchronously*.

To evaluate the performance of our system, we used top 5,000 URLs from Alexa to test against Chromium compiled on Ubuntu Linux 16.04, with and without PERCIVAL activated. We also tested PERCIVAL in Brave, a privacy-oriented Chromium-based browser, which blocks ads using block lists by default. For each experiment we measured `render` time which is defined as the difference between `domComplete` and `domLoading` events timestamps. We conducted the evaluations sequentially on the same Amazon m5.large EC2 instance to avoid interference with other processes and make the comparison fair. Also, all the experiments were using `xvfb` for rendering, an in-memory display server which allowed us to run the tests without a display.

In our evaluation we show an increase of 178.23ms of median render time when running PERCIVAL in the rendering critical path of Chromium and 281.85ms when running inside Brave browser with ad blocker and shields on. Figures 15 and 16 summarize the results.

To capture rendering and perceptual impact better, we create a micro-benchmark with `firstMeaningfulPaint` to illustrate overhead. In our new experiment, we construct a static html page containing 100 images. We then measure `firstMeaningfulPaint` with Percival classifying images synchronously and asynchronously. In synchronous classification, PERCIVAL adds 120ms to Chrome and 140ms

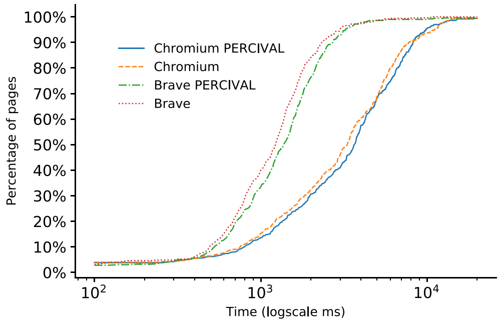

Figure 15: `Render` time evaluation in Chromium and Brave browser.

to Brave. In asynchronous classification, PERCIVAL adds 6ms to Chrome and 3ms to Brave. Although asynchronous classification nearly eliminates overhead, it opens up the possibility of showing an image to the user that we later remove after flagging it as an ad because the rasterization of the image runs in parallel with classification in this mode of operation.

To determine why PERCIVAL with Brave is slower than Chromium. We trace events inside the decoding process using `firstMeaningfulPaint` and confirm there is no significant deviation between the two browsers. The variance observed initially is due to the additional layers in place like Brave's ad blocking shields.

6.7 Comparison With Other Deep Learning Based Ad Blockers

Recently, researchers evaluated the accuracy of three deep-learning based perceptual ad blockers including PERCIVAL [71]. They used real website data from Alexa top 10 news websites to collect data which is later manually labelled. In this evaluation, PERCIVAL outperformed models 150 times bigger than PERCIVAL in terms of recall. We show their results in Figure 17.

6.8 Adversarial Attacks against PERCIVAL

In recent work by Tramèr et al. [71], they show how the implementation of some state-of-the-art perceptual ad blockers, including PERCIVAL, is vulnerable to attacks.

First, the authors in [71] claim that one adversarial sample influences PERCIVAL to block another benign non-ad image. This, however, is not true; the authors claim to use two benign images, one of which is not benign and other is contentless white-space image. PERCIVAL blocks these images. If these are replaced with stock non-ad images, PERCIVAL correctly renders both, meaning that PERCIVAL makes each decision independently and is not vulnerable to hijacking as is claimed in the paper.

Baseline	Treatment	Overhead (%)	(ms)
Chromium	Chromium + PERCIVAL	4.55	178.23
Brave	Brave + PERCIVAL	19.07	281.85

Figure 16: Performance evaluation of PERCIVAL on `Render` metric.

We found that one of the attacks where they used PERCIVAL's model to create adversarial ad images affects PERCIVAL due to our design decision to run PERCIVAL client-side thereby giving attackers white box access to the model. To address this concern, we argue that PERCIVAL is extremely light-weight and can be re-trained and updated very quickly. Our model currently takes 9 minutes (7 epochs) to fine-tune the weights of the network on an NVIDIA V 100 GPU, meaning that we can generate new models very quickly. PERCIVAL is 1.7MB which is almost half the average web page in 2018 [25] making frequent downloads easier.

To demonstrate, re-training and model update as an effective defense against the adversarial samples, we trained a MobilenetV2 [63] with our current dataset. It took 9 minutes of fine-tuning to get to our baseline accuracy. The updated model correctly classified all the adversarial samples generated for PERCIVAL by Tramer et al. [71] suggesting that none of the samples transferred to this model. It should be noted that, we did not add any more data to our dataset.

While we do accept that given sufficient time and machine learning expertise, it may be possible to create adversarial samples that generalize across different models but it in effect makes evasion more expensive. If we can update the model frequently, adversaries will have to play catch-up every time.

Additionally, to improve the robustness of the models against adversarial attacks one could employ techniques like *min-max* (robust) optimization [56] ,where the classification loss is minimized while maximizing the acceptable perturbation one can apply to the image, or *randomized smoothing* [34, 51, 53] where provable (or certified) robust accuracy can be afforded. Such techniques have shown promising results in training robust models and are currently under active research [66, 78].

Two main criticisms with such techniques is the performance degradation in accuracy but also the costly optimization involved. Although the "inherent tension" between robustness and accuracy [72] is inevitable, the l_2 perturbations drive the network to focus on more perceptual features and not on imperceptual features that can be exploitable. The training time penalty though can be mitigated by adopting fast *min-max*-based adversarial robustness training algorithms like [67, 79]. Given the fast iteration time for fine-tuning our network, any such performance degradation should be within our iteration cycle quota. We leave thorough study of such mitigation techniques for future work.

Model	Size	FP	FN
Sentinel [22] Clone	256 MB	0/20	5/29
ResNet [42]	242 MB	0/20	21/39
PERCIVAL	1.76 MB	2/7	3/33

Figure 17: Tramer et al.'s [71] evaluation of various deep learning based perceptual ad blockers. The difference in the number of images used for evaluation stem from the kind of images the ad blocker is expecting.

7 Limitations

Dangling Text: By testing PERCIVAL integrated into Chromium, we noticed the following limitations. Many ads consist of multiple elements, which contain images and text information layered together. PERCIVAL is positioned in the rendering engine, and therefore it has access to one image at a time. This leads to situations where we effectively block the image, but the text is left dangling. Although this is rare, we can mitigate this by retraining the model with ad image frames containing just the text. Alternatively, a non-machine learning solution would be to memorize the DOM element that contains the blocked image and filter it out on consecutive page visitations. Although this might provide an unsatisfying experience to the user, we argue that it is of the benefit of the user to eventually have a good ad blocking experience, even if this is happening on a second page visit.

Small Images: Currently, images that are below 100×100 size skips PERCIVAL to reduce the processing time. This is a limitation which can be alleviated by deferring the classification and blocking of small images to a different thread, effectively blocking *asynchronously*. That way we make sure that we don't regress the performance significantly, while we make sure that consecutive requests will continue blocking small ads.

8 Related Work

Filter lists: Popular ad blockers like, Adblock Plus [1], uBlock Origin [26], and Ghostery [13] are using a set of rules, called filter-list, to block resources that match a predefined crowd-sourced list of regular expressions (from lists like EasyList and EasyPrivacy). On top of that, CSS rules are applied, to prevent DOM elements that are potential containers of ads. These filter-lists are crowd-sourced and updated frequently to adjust on the non-stationary nature of the online ads [70]. For example, EasyList, the most popular filter-list, has a history of 9 years and contains more than 60,000 rules [74]. However, filter-list based solutions enable a continuous cat-and-mouse game: their maintenance cannot scale efficiently, as they depend on the human-annotator and they do not generalize to "unseen" examples.

Perceptual Ad Blocking: Perceptual ad blocking is the idea of blocking ads based solely on their appearance; an example ad, highlighting some of the typical components. Storey et al. [70] uses the rendered image content to identify ads. More specifically, they use OCR and fuzzy image search techniques to identify *visual cues* such as ad disclosure markers or sponsored content links. Unlike PERCIVAL, this work assumes that the ad provider is complying with the legislation and is using visual cues like *AdChoices*.

Sentinel [65] proposes a solution based on convolutional neural networks (CNNs) to identify Facebook ads. This work is closer to our proposal; however, their model is not deployable in mobile devices or desktop computers because of its large size (>200MB). Also, we would like to mention the work of [28, 42, 77], where they use deep neural networks to identify the represented signifiers in the Ad images. This is a promising direction in semantic and perceptual ad blocking.

Adversarial attacks: In computer-vision, researchers have demonstrated attacks that can cause prediction errors by near-imperceptible perturbations of the input image. This poses risks in a wide range of applications on which computer vision is a critical component (e.g. autonomous cars, surveillance systems) [58–60]. Similar attacks have been demonstrated in speech to text [30], malware detection [39] and reinforcement-learning [41]. To defend from adversarial attacks, a portfolio of techniques has been proposed [33, 45, 46, 49, 50, 56], whether these solve this open research problem, remains to be seen.

9 Conclusion

With PERCIVAL, we illustrate that it is possible to devise models that block ads, while rendering images inside the browser. Our implementation shows a rendering time overhead of 4.55%, for Chromium and and 19.07%, for Brave browser, demonstrating the feasibility of deploying deep neural networks inside the critical path of the rendering engine of a browser. We show that our perceptual ad blocking model can replicate EasyList rules with an accuracy of 96.76%, making PERCIVAL a viable and complementary ad blocking layer. Finally, we demonstrate off the shelf language-agnostic detection due to the fact that our models do not depend on textual information and we show that PERCIVAL is a compelling blocking mechanism for first-party Facebook sponsored content, for which traditional filter based solutions are less effective.

Harmonizing Performance and Isolation in Microkernels with Efficient Intra-kernel Isolation and Communication

Jinyu Gu, Xinyue Wu, Wentai Li, Nian Liu, Zeyu Mi, Yubin Xia, Haibo Chen
Engineering Research Center for Domain-specific Operating Systems, Ministry of Education, China
Institute of Parallel and Distributed Systems (IPADS), Shanghai Jiao Tong University

Abstract

This paper presents UnderBridge, a redesign of traditional microkernel OSes to harmonize the tension between messaging performance and isolation. UnderBridge moves the OS components of a microkernel between user space and kernel space at runtime while enforcing consistent isolation. It retrofits Intel Memory Protection Key for Userspace (PKU) in kernel space to achieve such isolation efficiently and design a fast IPC mechanism across those OS components. Thanks to PKU's extremely low overhead, the inter-process communication (IPC) roundtrip cost in UnderBridge can be as low as 109 cycles. We have designed and implemented a new microkernel called ChCore based on UnderBridge and have also ported UnderBridge to three mainstream microkernels, i.e., seL4, Google Zircon, and Fiasco.OC. Evaluations show that UnderBridge speeds up the IPC by 3.0× compared with the state-of-the-art (e.g., SkyBridge) and improves the performance of IPC-intensive applications by up to 13.1× for the above three microkernels.

1 Introduction

The microkernel OS design has been studied for decades [3, 27, 35, 44, 49, 52, 70]. Microkernels minimize code running in supervisor mode by moving OS components, such as file systems and the network stack, as well as device drivers, into isolated user processes, which achieves good extensibility, security, and fault isolation. Other than the success of microkernels in safety-critical scenarios [1, 40, 66], there is a resurgent interest in designing microkernels for more general-purpose applications, such as Google's next-generation kernel Zircon [3].

However, a cost coming with microkernel is its commonly lower performance compared with its monolithic counterparts, which forces a tradeoff between performance and isolation in many cases. One key factor of such cost is the communication (IPC) overhead between OS components, which is considered as the Achilles' Heel of microkernels [30, 33, 51, 53, 62, 76]. Hence, there has been a long line of research work to improve the IPC performance for microkernels [19, 30, 36, 44, 50, 52, 62, 79, 82]. Through a combination of various optimizations such as in-register parameter passing and scheduling avoidance, the performance of highly optimized IPC has reached less than 1500 cycles per roundtrip [13]. The state-of-the-art SkyBridge IPC design, which retrofits Intel *vmfunc* to optimize IPCs, has further reduced the IPC cost to around 400 cycles per roundtrip [62]. However, such cost is still considerable compared with the cost of invoking kernel components in monolithic kernels (e.g., calling function pointers takes around 24 cycles).
