There is always a tension between isolation and performance for OS kernel designs. In this paper, we present a new design named UnderBridge, which redesigns the runtime structure of microkernels to harmonize performance and isolation. The key idea is building isolated domains in supervisor mode while providing efficient cross-domain interactions, and enabling user-space system servers[1] of a microkernel OS to run in those domains. A traditional microkernel OS usually consists of a core kernel in supervisor mode and several system servers in different user processes. With UnderBridge, a system server can also run in an isolated kernel space domain besides a user process. The system servers that run in kernel can interact with each other as well as the core kernel efficiently without traditional expensive IPCs, and applications can invoke them with only two privilege switches, similar to a monolithic OS. Although the number of isolated domains is limited and may be smaller than the number of system servers, UnderBridge supports server migration. The microkernel can dynamically decide to run a server either in a user process or a kernel domain based on how performance-critical it is. However, it is challenging to efficiently provide mutually-isolated domains together with fast cross-domain interactions in kernel space.

Protection Keys for Userspace (PKU [7], Section-2.7, Volume-3), also named as Intel memory protection keys (MPK), has been introduced in recent Intel processors and investigated by researchers to achieve intra-process isolation in user space [29, 39, 64, 77]. As the name "Userspace" indicates, PKU is a mechanism that appears to be only effec-

[1] We name the microkernel OS components implementing system functionalities as system servers. File system and drivers are typical examples.

tive in user space. After a detailed investigation, we observed that *no matter in kernel space (Ring-0) or user space (Ring-3), PKU-capable CPUs transparently enforce permission checks on memory accesses only if the User/Kernel (U/K) bit of the corresponding page table entry is User (means user-accessible)*. Hence, PKU, as a lightweight hardware feature, also offers an opportunity to achieve efficient intra-kernel isolation if all the page table entries for kernel memory are marked with U bit instead of K bit. However, marking kernel memory as user-accessible is dangerous since unprivileged applications may directly access kernel memory. Fortunately, today's OS kernels are usually equipped with kernel-page-table-isolation (KPTI) when preferring stronger security guarantees, including defending against Meltdown-like attacks [20, 55] and protecting kernel-address-space-layout-randomization [8, 42]. User processes and the kernel use different page tables with KPTI, so marking kernel memory as user-accessible in a separate page table does not risk allowing applications to access kernel space.

Hence, UnderBridge allocates an individual page table for the kernel and builds isolated *execution domains* atop MPK memory domains in kernel space. Unlike software fault isolation (SFI), guaranteeing memory isolation with MPK hardware incurs nearly *zero* runtime overhead. Meanwhile, a new instruction, *wrpkru*, can help switching domains by writing a specific register, PKRU (protection key rights register for user pages), which only takes 28 cycles. Thus, domain switches can be quick. With UnderBridge, we design and implement a prototype microkernel named ChCore, which comprises a core kernel and different system servers similar to existing microkernels. ChCore still preserves the IPC interfaces with fast domain switch for the servers but embraces better performance by significantly reducing the IPC costs.

However, we find merely using MPK in kernel fails to achieve the same isolation guarantee as traditional microkernels. On the one hand, since MPK only checks read/write permissions when accessing memory but applies no restrictions on instruction fetching, any server can execute all the code in the same virtual address space. Thus, an IPC gate (a code piece), which is used in UnderBridge to establish the connection between two specific servers, can be abused by any server to issue an illegal IPC. To address the problem, UnderBridge authenticates the caller of an IPC gate through checking its (unique) memory-access permission and ensures the authentication is non-bypassable by validating a secret token at both sides of the IPC gate.

On the other hand, system servers running in kernel space can execute privileged instructions. Although the servers (initially running in user space) should not contain any privileged instruction, such instructions may arise inadvertently on x86, e.g., being composed of the bytes of adjacent instructions. Thus, a compromised server may use return-oriented programming (ROP) [21, 69] to execute them. Traditional microkernels confine system servers in user processes, which, inherently, prevent them from executing privileged instructions and exclude them from the system's trusted computing base (TCB). To do not bloat the TCB, we also prevent the in-kernel system servers from executing any privileged instruction. We leverage hardware virtualization and run ChCore in non-root mode and deploy a tiny secure monitor in root mode. For most privileged instructions that are *not* in the critical path, we configure them to trigger *VMExit* and enforce permission checks in the monitor. For others, we carefully handle them using binary scanning and rewriting.

We have implemented ChCore on a real server with Intel Xeon Gold 6138 CPUs and conducted evaluations to show the efficiency of UnderBridge. To demonstrate the generality of UnderBridge, we have also ported it to three popular microkernels, i.e., seL4 [14], Google Zircon [4], and Fiasco.OC [2]. In the micro-benchmark, UnderBridge achieves 3.0× speedup compared with SkyBridge. In IPC-intensive application benchmarks, UnderBridge also shows better performance than SkyBridge (up to 65%) and improves the performance of the above three microkernels by 2.5×∼13.1×.

In summary, this paper makes the following contributions:

- A new IPC design called UnderBridge that retrofits Intel MPK/PKU in kernel to achieve ultra-low overhead interactions across system servers.
- A microkernel prototype ChCore which uses UnderBridge to move system servers back to kernel space while keeping the same isolation properties as traditional microkernels.
- A detailed evaluation of UnderBridge in ChCore and three widely-used microkernels, which demonstrates the efficiency of the design.

2 Motivation

2.1 Invoking Servers with IPCs is Costly

To obviate the severe consequences incurred by crashes or security breaches [9, 22, 24], the microkernel architecture places most kernel functionalities into different user-space system servers and only keeps crucial functionalities in the privileged kernel, as depicted in Figure-1. Therefore, a fault in a single system server can be caught before it propagates to the whole system.

However, compared with a monolithic OS like Linux, a system service invocation usually becomes more expensive

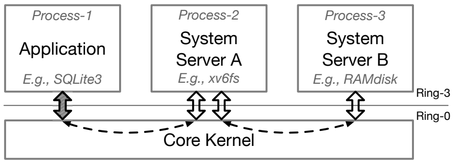

Figure 1: A simplified microkernel architecture. Even without KPTI, calling a server with IPC requires two user-kernel roundtrips with two process switches. A vertical arrow represents one roundtrip, and a dotted line means two process switches.

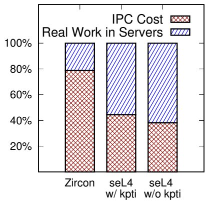
in such an OS architecture. Figure-1 shows a service invocation procedure that involves two system servers and thus leads to two IPCs. In this case, a microkernel requires *four* roundtrips between user and kernel in total, while Linux only requires *one* (i.e., the leftmost arrow between the application and the OS). It is because Linux invokes different kernel components (like system servers in microkernel) directly through function calls.



(a)

Parts (cycles)	**w/o KPTI**	**w/ KPTI**
Privilege Switch	158	690
Process Switch	295	Included above
Others	277	320
Total	**730** *	**1010**

*The result conforms to the officially reported data (722∼736) [13].

(b)

Figure 2: (a) Invoking servers with IPCs is expensive. (b) A breakdown of seL4 fast-path IPC.

To measure the performance cost of server invocations with IPC, we run SQLite3 [15] on Zircon and seL4 (§ 6 gives the detailed setup). We measure (i) the total time spent on invoking system servers (i.e., an FS server and a RAMdisk server) and (ii) the effective time used in system servers for handling the requests. The difference between the two time durations is considered as the IPC cost. As presented in Figure 2(a), the IPC cost is as high as 79% in Zircon. Even in seL4, which uses highly-optimized IPCs, 44% of the time is spent on IPC when KPTI enabled (38% without KPTI).

Moreover, a system functionality may involve even more IPCs to invoke multiple system servers. For instance, launching an application requires 8 IPC roundtrips (among *Shell, Loader, FS, and Driver*) on Zircon. In contrast, it only needs one or two system calls on Linux (e.g., fork + exec). Therefore, invoking system servers with IPCs is time-consuming in microkernels, which motivates our work in this paper.

2.2 IPC Overhead Analysis

To further understand the overhead of IPC, we break down and measure the cost of each step in the IPC procedure in seL4, which is known to be an efficient implementation of microkernel IPC. Here we use the ideal configuration by referring to [13] and measure a one-way IPC (not a roundtrip) without transferring data.

We find that the direct cost of the IPC consists of three main parts as shown in Figure-2(b). The first part is the privilege switch. A user-space caller starts an IPC by using a *syscall* instruction to trap into the kernel. The kernel needs to save the caller's context, which will be restored when resuming the caller. To invoke the target user-space callee, the kernel transfers the control flow with a *sysret* instruction after restoring the callee's context. The second part is the process switch. The major cost in this part is the *CR3* modification instruction (270 cycles). Since the caller and callee are isolated in different user-space processes (different address spaces), the kernel has to change the address space from the caller to the callee. With KPTI enabled, the kernel further needs to change the address spaces twice during the privilege switch, which inflates the overhead. The third part is other logics in IPC, such as permissions and fast-path conditions checks.

Besides its inherent cost, an IPC will inevitably cause pollution to the CPU internal structures such as the pipeline, instruction, data caches, and translation look-aside buffers (TLB), which has been evaluated in prior work [18, 32, 62, 71]. According to [71], the pollution caused by frequent privilege switches can degrade the performance by up to 65% for SPEC CPU programs.

In summary, the switches of privilege and address space in IPC bring considerable overhead, which motivates our lightweight IPC design to remove these switches.

2.3 Using Intel MPK in Kernel

Background: Intel memory protection keys (MPK) [7] is a new hardware feature to restrict memory accesses. MPK assigns a four-bit domain ID (aka, protection key) to each page in a virtual address space by filling the ID in previously unused bits of page table entries. Thus, MPK can partition user pages within a virtual address space into at most 16 memory domains. To determine the access permissions (read-only, read-write, none) on each memory domain, it introduces a per-core register, *PKRU*, and a new instruction, *wrpkru*, to modify the *PKRU* register in only 28 cycles. It is worth mentioning that MPK checks on memory accesses incur nearly *zero* runtime overhead [39, 77]. Nevertheless, MPK does not enforce permission checks on execution permission. One executable memory page is always executable to any domain, even if *PKRU* forbids the domain from reading the page.

Observation: After a detailed investigation, we observe that no matter in Ring-0 or Ring-3, MPK enforces permission checks on any user-accessible memory page. To enable MPK checks in Ring-0, the *User/Kernel (U/K)* bits of all the corresponding page table entries in a four-level page table have to be set as *User* (i.e., 1). If there exists one entry that contains the *Kernel* bit at any level, MPK will not check the access on the corresponding memory pages. Furthermore, the Supervisor Mode Access Prevention (SMAP) and Supervisor Mode Execution Prevention (SMEP) should also be disabled for accessing or executing these pages (tagged with *User*) in Ring-0.

2.4 Building Isolated Domains

There are many approaches to build lightweight and isolated domains. SFI (Software Fault Isolation), which has been actively studied over 20 years [34, 46, 60, 68, 80, 87], is one of the most mature candidates. However, although being a general solution to achieve memory/fault isolation, SFI incurs non-negligible runtime overhead due to excessive code instrumentations. For example, two representative studies show that SFI introduces around 15% overhead for SPEC CPU programs on average (Table-2 in [68]), even with the help of the latest boundary-checking hardware MPX (Figure-3 in [46]). Some other approaches [48, 88] uses x86 segmentation for memory isolation, which avoids software checks on memory accesses and is suitable for sandbox execution, but it is not widely used anymore [68].

Instruction	Cost (cycles)
Indirect Call + Return	24
syscall + *sysret*	150
Write *CR3* (no TLB flush)	226
vmfunc (switch EPT)	146
wrpkru	28

Table 1: Cost comparison of selected instructions.

Leveraging advanced hardware features to build isolated domains can achieve better runtime performance. For example, prior work [39, 46, 56, 57, 62, 65, 77] utilizes (extended) page tables to provide isolated domains in user space and exploits instructions like *vmfunc* and *wrpkru* for fast domain switches. We list the costs of these frequently-used instructions in Table-1. The cost of *wrpkru* is the closest to *indirect call*, which is used to invoke kernel components (with function pointers) in monolithic kernels. Therefore, considering that MPK is applicable to the kernel and has good performance property, we propose that MPK can be leveraged to implement an efficient fine-grained isolation mechanism in the kernel.

3 UnderBridge

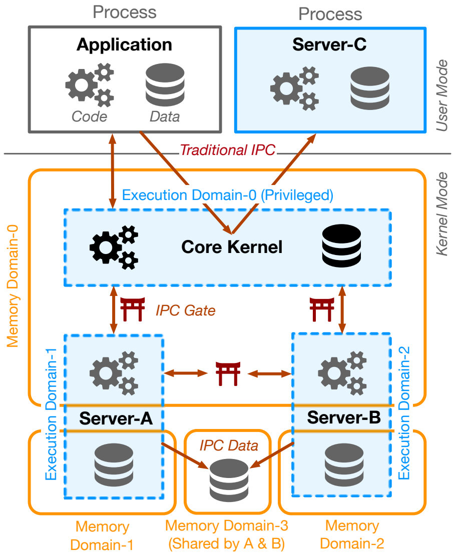


Figure 3: The overview of ChCore based on UnderBridge.

The goal of UnderBridge is to optimize the synchronous IPC[2] while simultaneously maintaining strong isolation. An intuitive design is adopting the MPK-based intra-process isolation [39, 77] to run system servers within an application address space. However, this design has three major problems. First, it requires to map a server into multiple applications' page tables, which makes updating the server's memory mappings especially expensive (i.e., update all the page tables). Second, its cost to setting up the IPC is non-negligible due to intensive page table modifications. Third, it restricts the applications' ability to use the whole address space and the MPK hardware freely.

Instead, UnderBridge boosts IPC performance by putting the system servers, which are user-space processes in traditional microkernels, back into kernel space. Figure-3 shows the system overview. The core kernel resembles the traditional microkernel, which provides crucial functionalities such as managing memory protection, capability enforcement, scheduling, and establishing IPC connections. With UnderBridge, system servers can run in kernel space (e.g., Server-A/B) but are confined in isolated environments (called *execution domain*). UnderBridge makes the core kernel and in-kernel system servers share the same (kernel) address space while leveraging Intel MPK to guarantee memory isolation.

To use MPK in kernel space, UnderBridge tags all the kernel memory pages with "User" bits in the kernel page table, as introduced in § 2.3. However, marking kernel memory as user-accessible enables unprivileged user-space applications to access kernel memory directly. UnderBridge prevents this by allocating a separate page table to each application. An application's page table does not contain the kernel space memory except for a small trampoline region (tagged with "Kernel"), which is used for privilege switch (e.g., *syscall*).

Building IPC connections with in-kernel system servers takes the following steps. First, a system server proactively registers a function address (IPC function) in the core kernel before serving requests. The core kernel will check whether the address is legal, i.e., both executable and belonging to the server. Second, another server can ask the core kernel to establish an IPC connection with the registered server. Third, the core kernel generates an *IPC Gate*, which helps to accomplish the IPC function invocation.

If an application needs to invoke the in-kernel server, it also needs to establish the connection first. Later, it invokes the system call for IPC and traps into the core kernel. Then, the kernel will help to invoke the requested server via the corresponding IPC gate (between the kernel and the server).

3.1 Execution Domains

As shown in Figure-3, UnderBridge constructs isolated *execution domains* over MPK *memory domains* and confines each in-kernel system server in an individual execution domain. Specifically, UnderBridge builds 16 execution domains in kernel space and assigns a unique domain ID (0∼15) to each of them. Execution domain 0 is specialized

[2] Synchronous IPC is commonly used in microkernels, especially when calling system servers. After issuing a synchronous IPC, the caller blocks until the callee returns.

for running the (trustworthy) core kernel and can access all the memory. Every other execution domain (1∼15) has a private memory domain with a specific ID and can only access its private memory domain by default. A system server, exclusively running in one execution domain, stores its data, stack, and heap regions in its private memory domain, which cannot be accessed by other servers. Nevertheless, its code region resides in memory domain 0 that can only be read/written by the core kernel. In this way, the server cannot read-/write its own code but can still execute it (i.e., execute-only memory) as MPK memory domains do not affect instruction fetching. UnderBridge ensures an execution domain can only access allowed memory domains by configuring its *PKRU* register. It also forbids an execution domain (a server) from modifying this register by itself (details in § 4.2).

Shared memory between two servers is allocated by allowing them to access a free memory domain together (e.g., Memory Domain-3). Shared memory between a server and the core kernel is achieved by letting the core kernel directly access the server's private memory domain. Shared memory between an application and a server is achieved by mapping some private memory of the server in the application's page table, which does not require a free memory domain.

3.2 IPC Gates

Even though system servers reside in the same kernel address space, UnderBridge still preserves the well-defined IPC interfaces for them. When connecting two system servers (in two execution domains), the core kernel generates an IPC gate for them, which resides in memory domain 0. Specifically, it first allocates a piece of memory for the gate and loads the gate code, which is small, as shown in Figure-4, into the memory. Then, it fills specific values (e.g., per-gate *SECRET_TOKEN*) into the gate. After that, it gives the gate address to the two system servers connected by this gate.

Later, during an IPC invocation, the gate transfers the control flow from a caller to a callee. To be more specific, it saves the caller's execution state, switches to the callee's domain by setting the *PRKU* register, and restores the callee's execution state. UnderBridge allows the caller and callee to define their calling conventions (the gates only save/restore necessary state by default), which is flexible and efficient. Transferring messages by registers and shared memory are both supported.

Since the system server in UnderBridge only executes when being called through an IPC gate, we adopt the mechanism of decoupling the execution context, which contains the execution state (e.g., register values), with the scheduling context, which contains the scheduling information (e.g., time slice used in the scheduler) [47, 58, 72] and mark those servers as passive. When an application (T1) invokes the system server (T2) through an IPC, T2 inherits T1's scheduling context and then starts executing. When T2 invokes another server (T3), T3 also inherits the scheduling context, which is originally from T1. Thus, the scheduling overhead is avoided in the IPC gates.

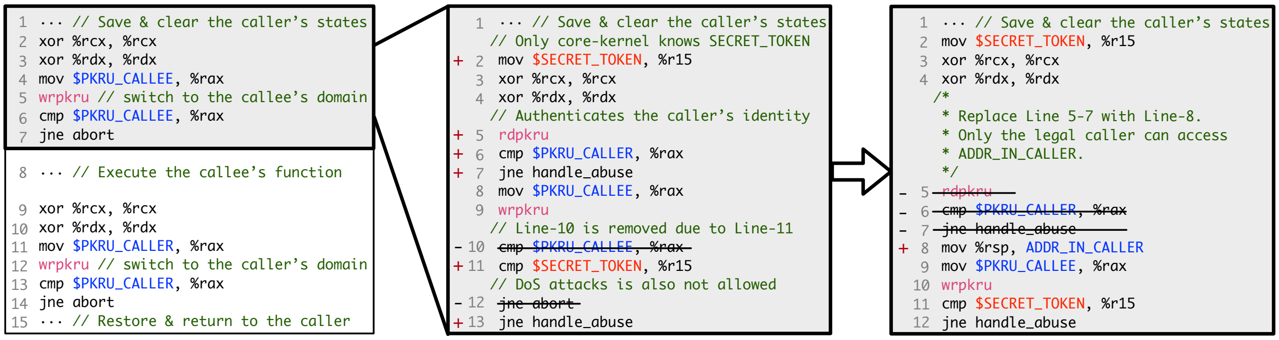
Besides intra-server, IPC gates also exist between the core kernel and the servers, which enables the core kernel to interact with the servers. Specifically, those in-kernel system servers invoke the core kernel's service through dedicated IPC gates connected with the core kernel instead of using *syscall* instructions. To handle exceptions/interrupts during the execution of in-kernel servers, UnderBridge provides similar gates at the beginning of each handler to switch the execution domain to the core kernel (execution domain 0).

3.3 Server Migration

As MPK provides 16 memory domains in total, UnderBridge can only support at most 16 execution domains concurrently, including the reserved one for the core kernel. Nevertheless, more system servers can be required, considering the number of different device drivers. When the number of concurrent system servers exceeds 15, one solution is time-multiplexing [64] but will bring non-negligible overhead if frequently stopping and restarting servers.

Instead, UnderBridge enables *server migration*, which dynamically moves servers between user and kernel space. Each server is compiled as a position-independent executable, and the core kernel assigns disjoint virtual memory regions for different system servers. Whenever runs in an execution domain in the kernel or a user process, a server always uses the same virtual addresses. So, when migrating a server between user and kernel, UnderBridge does not need to do relocations because all the memory references in the server are always valid (no changes), which significantly simplifies the migration procedure. Moreover, the system call layer of the LibC used by servers is also modified, and thus all the *syscall* instructions are organized in one memory page, namely the *syscall page*. When migrating a server from user space to kernel space, the core kernel overrides this page with another prepared page which contains IPC gates connected to the core kernel. Therefore, a server can seamlessly perform system calls no matter in user or kernel space.

Specifically, there are four steps to migrate a server from kernel space to user space. First, the core kernel will wait for the server to enter a quiescent state by blocking new IPC requests to the server temporarily and waiting for the finishes of on-going ones. Second, it will modify the *syscall page* of the server and making the server perform system calls through *syscall* instruction instead of IPC gates later. Third, it will free the execution domain (ID) of the server by setting the domain ID of the server's page table entries to 0 and flush TLBs. If the server installs shared memory with another in-kernel server (S), the domain ID of the shared memory will also be freed because the shared memory can use the domain ID of S in the kernel page table. Last, the core kernel will activate the in-user server and allow clients to issue IPCs to it. Migrating a server from user space to kernel space



```
 1 ··· // Save & clear the caller's states
 2 xor %rcx, %rcx
 3 xor %rdx, %rdx
 4 mov $PKRU_CALLEE, %rax
 5 wrpkru // switch to the callee's domain
 6 cmp $PKRU_CALLEE, %rax
 7 jne abort

 8 ··· // Execute the callee's function

 9 xor %rcx, %rcx
10 xor %rdx, %rdx
11 mov $PKRU_CALLEE, %rax
12 wrpkru // switch to the caller's domain
13 cmp $PKRU_CALLEE, %rax
14 jne abort
15 ··· // Restore & return to the caller
```

(a)

```
   1 ··· // Save & clear the caller's states
    // Only core-kernel knows SECRET_TOKEN
+  2 mov $SECRET_TOKEN, %r15
   3 xor %rcx, %rcx
   4 xor %rdx, %rdx
    // Authenticates the caller's identity
+  5 rdpkru
+  6 cmp $PKRU_CALLER, %rax
+  7 jne handle_abuse
   8 mov $PKRU_CALLEE, %rax
   9 wrpkru
    // Line-10 is removed due to Line-11
- 10 ~~cmp $PKRU_CALLEE, %rax~~
+ 11 cmp $SECRET_TOKEN, %r15
    // DoS attacks is also not allowed
- 12 ~~jne abort~~
+ 13 jne handle_abuse
```

(b)

```
   1 ··· // Save & clear the caller's states
   2 mov $SECRET_TOKEN, %r15
   3 xor %rcx, %rcx
   4 xor %rdx, %rdx
    /*
     * Replace Line 5-7 with Line-8.
     * Only the legal caller can access
     * ADDR_IN_CALLER.
     */
-  5 ~~rdpkru~~
-  6 ~~cmp $PKRU_CALLER, %rax~~
-  7 ~~jne handle_abuse~~
+  8 mov %rsp, ADDR_IN_CALLER
   9 mov $PKRU_CALLEE, %rax
  10 wrpkru
  11 cmp $SECRET_TOKEN, %r15
  12 jne handle_abuse
```

(c)

Figure 4: (a) A basic IPC gate for switching execution domains: Line 1-7 is from the caller to the callee and Line 9-15 is just a reverse process. (b) A security-enhanced IPC gate (from the caller to the callee only) that solves the arbitrary IPC problem. (c) An optimized IPC gate based on the secure one.

works similarly. The mappings of a system server in the kernel page table (used when running in the kernel) will not be removed, and the system server's page table (used when running in user) always exists. And the core kernel will keep corresponding mappings in the two page tables the same.

With server migration, UnderBridge can run frequently-used servers (according to either online or offline profiling) in kernel space while accommodating other servers in user processes. Besides that, we think the number of frequently-used servers may usually be small according to a preliminary survey on some popular applications including Memcached, MySQL, GCC, and a ROS-based (robot) application. We run those applications on Linux and find the most required system calls are only related to the File System, Network, Synchronization, and Memory-Management. For a microkernel, these system calls are usually implemented in only several system servers or directly in the core kernel, which indicates the server migration may rarely happen.

4 Enforcing Isolation in UnderBridge

Threat Model and Assumptions. UnderBridge aims to achieve the same security guarantee as existing microkernels and inherits the same trust model. Specifically, the (trusted) core kernel is assumed to be bug-free and correctly implemented because it has relatively small codebase (e.g., 8,500 LoC in our implementation) and is amenable to formal verification [44]. We do not trust applications or the operating system servers, which may have vulnerabilities or even be maliciously crafted and can be fully compromised by attackers. Physical attacks and hardware bugs are out of the scope of this paper.

Two Security Challenges. Although UnderBridge achieves memory isolation by utilizing MPK hardware, there are still two security threats.

The first threat is the arbitrary IPC problem. The core kernel generates IPC gates in memory domain 0 to ensure any server cannot modify the gates. However, an IPC gate can still be invoked by any (in-kernel) system server as the MPK does not enforce permission check on *execution permission*. Although recent work on MPK-based intra-process isolation [39, 77] does not consider such gate abusing problem, we cannot neglect it because it violates the enforcement of the IPC capability in microkernels. Therefore, UnderBridge ensures only a legal caller (allowed by the core kernel) can successfully use an IPC gate by adding mandatory authentications in the gate. § 4.1 explains the secure design of IPC gates.

The second threat is that untrusted in-kernel system servers run in supervisor mode (Ring-0). Thus, a compromised server can execute any privileged instructions theoretically, which threatens the whole system. For example, it could install a new page table and freely access all memory. One possible defense solution is to enforce control-flow integrity (CFI), which ensures that servers cannot execute any illegal control flow leading to executing privileged instructions. However, CFI instrumentations inevitably bring obvious runtime overhead. Instead, we choose hardware virtualization technology and run ChCore in non-root mode. A tiny secure monitor in root mode audits the execution of most privileged instructions, as summarized in Table 2, by simply trapping them through *VMExits*. In the meanwhile, we use the binary rewriting technique to avoid the expensive *VMExits* on the critical paths. § 4.2 gives more details.

4.1 Unauthorized IPCs Prevention

As shown in Figure-4(a), the responsibility of an IPC gate is saving/restoring the (necessary) execution context of the caller/callee and switching the execution domain from the caller to the callee. Line 2-4 prepares the argument registers for *wrpkru*, which requires *eax* to store the target permission, and both *ecx* and *edx* to be zero. The *wrpkru* instruction in Line 5 sets *PKRU_CALLEE* (the callee's permission) to the *PKRU* register, which specifies the memory-access permission, so the execution domain changes to the callee's domain after this instruction finishes. Line 6-7 prevents a compromised thread from directly jumping (e.g., ROP) to Line 5 with some carefully chosen value in *eax*. Existing work [39, 77] on MPK also designs similar gates for intra-process isolation.

However, such a design faces the gate abusing problem. Since MPK has no restriction on execution permission, a domain can use the gates belonging to other domains to issue IPCs. UnderBridge solves this problem by authenticating the caller's identity in the IPC gates. As the core kernel is responsible for generating IPC gates when two execution domains establish the IPC connection, it knows which domain is the legal caller of the gate. Besides, since each domain has unique memory-access permission, UnderBridge regards the permission as the domain's identity and checks the identity with *rdpkru* in Line 5-7 of Figure-4(b). Moreover, UnderBridge must ensure that the identity check cannot be bypassed. Otherwise, a compromised thread can jump to Line 8/9 without going through the check. To this end, each gate adds two cheap instructions (Line 2 and Line 11 in Figure-4(b)) to guarantee that a successful IPC invocation must go through the check. When setting up an IPC gate, the core kernel randomly produces a 64-bit secret token with *rdrand* instruction and inserts it to the gate. Note that any server cannot read the token value since the IPC gates belong to domain 0 (core kernel). Thus, any caller who wants to pass the check at Line 11 must execute Line 2 first, which ensures the identity check at Line 5-7 is non-bypassable for successful invocations. Similarly, Line 8 is also non-bypassable for successful IPCs; thus, Line 10 is no more required.

Figure-4(c) further gives a more efficient design, which eliminates the overhead of identity check. Although *rdpkru* only takes about 9 cycles, it as well as the extra comparison (Line 6-7) are still on the critical path of IPC. To remove the overhead, UnderBridge authenticates IPC callers by *reusing* the stack-pointer saving instruction (Line 8), which is initially located in the procedure of state saving (Line 1). In this way, any illegal caller will trigger a fault when accessing *ADDR_IN_CALLER* (Line 8) and get caught.

4.2 Privilege Deprivation

In traditional microkernels, system servers only have Ring-3 privilege. To achieve the same security/isolation guarantee, UnderBridge should restrict the servers' behavior when running them in execution domains (Ring-0). However, a compromised server may find and execute privileged instructions at unaligned instruction boundaries with ROP to attack the whole system. Based on an in-depth analysis of privileged instructions (briefly summarized in Table-2), UnderBridge combines virtualization hardware support, binary rewriting technique, and some specific solutions to de-privilege the execution domains for servers with negligible overhead.

According to our survey on four microkernels, system registers such as *IDTR* are only configured at boot time; debug/profile registers are only accessed at debugging/profiling time; most model-specific registers (*MSRs*) are also not accessed in the critical paths. Thus, UnderBridge runs the microkernel in non-root mode and configures the privileged instructions operating on those registers to trigger *VMExits*. And, the secure monitor in root mode checks whether they are executed by the core kernel according to the memory-access permission in *PKRU*. Nevertheless, *rdmsr/wrmsr* may also be used to operate *FS/GS* in the critical path. UnderBridge can configure these two specific registers not to trap or replace them with some newer non-privileged instructions (e.g., *wrfsbase*).

Similarly, since control registers *CR0* and *CR4* are set at boot time only, UnderBridge also traps the setting instructions. Nevertheless, accessing *CR2* and reading *CR0*/*CR4* cannot trigger VMExits. UnderBridge clears *CR2*, where CPU saves the page fault address in the fault handler to prevent information leakage, and hides the real *CR0*/*CR4* value with a shadow value by leveraging virtualization hardware functionality. As for *CR3*, it points to page tables and needs modifications when switching address spaces, which frequently appears in the critical path. So, triggering *VMExits* on *CR3* modifications is expensive. Instead, we use the following lightweight solution (*a special method*). When loading system servers, UnderBridge leverages binary scanning and rewriting to guarantee the servers contain no *CR3* modification instructions, including at unaligned instruction boundaries. While in the core kernel, this privileged instruction must exist to switch address spaces. UnderBridge prevents a compromised system server from executing this instruction in the core kernel through defenses in depth. First (a simple defense), the instruction location is unknown to the servers. Second, to achieve higher security, the core kernel can write this instruction right before executing it and immediately remove it after the execution. Thus, a system server cannot execute it even if knowing its location. Furthermore, on different cores, UnderBridge makes the page table mapping for this instruction (page) different. So, when one core writes this instruction, other cores still cannot execute it.

Instructions that invalidate cache/TLB may be used by compromised servers for conducting performance attacks. While trapping cache invalidation instructions via *VMExits* does not affect overall performance since they are rarely executed, flushing TLB frequently appears on the critical path. So, we use binary rewriting to ensure there are no TLB flush instructions in system servers instead of trapping these instructions. The core kernel must contain these instructions, but they cannot be abused by faulting servers because we make sure they are followed by instructions that access the core kernel memory. Cacheline flush instructions (non-privileged instructions, e.g., *clflush* and *clflushopt*) are also considered because the system servers share the same address space with the core kernel. Nevertheless, these instructions obey MPK memory (read) checks and thus, cannot be utilized by a server to flush others' memory areas.

For other privileged instructions and I/O related operations, we take similar solutions as listed in Table-2. One thing to notice is that a compromised server may disable interrupts

Categories	Related Instructions or Registers	Usages in Zircon/Fiasco.OC/seL4/ChCore or Brief Explanations	Solutions
Load/Store System Registers	IDTR, GDTR, LDTR TR, XCR0 ...	Although seL4 uses "LTR" instruction when switching processes, it can be removed by setting different TSSs at boot time as do in other microkernels. Others are required at boot time only.	VMExit
Debug/Profile Registers	Debug registers RDPMC	Required for debugging and profiling, which are not performance-oriented.	VMExit
Model Specific Registers	RDMSR/WRMSR	Usually, they are mostly used at boot time or debug time and can trigger VMExits for selected registers according to configuration bitmaps.	Selected VMExit
Read/Write Control Registers	mov CRn, reg mov reg, CRn CLTS (modify CR0)	- In the four microkernels, CR0/CR4 is written at boot time only and CR8 is not used. - No VMExits: accessing CR2, reading CR0 and CR4. - CR3 is used for switching address space. So, we handle it with a special method.	- VMExit - Clear/hide - Special method
Cache/TLB States	- INVD/WBINVD - INVLPG/INVPCID - clflush instructions	- Whole cache eviction. WBINVD is rarely used, and INVD is even not used. - TLB clear is needed after updating page tables. So, triggering VMExits is costly here. - (executable in Ring-3) Evicting a single cache line. MPK checks take effects.	- VMExit - Binary rewritng - None
I/O Related Operations	- Port I/O - MMIO - DMA	- Port I/O is not performance-oriented and can trigger VMExits with I/O bitmaps. - MMIO operations go through MPK checks. - The core kernel initializes DMA devices at boot time and takes the control plane.	- VMExit - None - None
Other Privilege Instructions	- SMSW, RSM, HLT ... - SWAPGS, SYSRET... - CLI, POPFQ...	- Either related to other modes like legacy and SMM mode or rarely used. - Cannot break the system states, otherwise leading to the execution of fault handlers. - Can be used by compromised servers to disable interrupts.	- VMExit - None - Check in VMM
PKRU Register (Ring-0/3)	- xsave set instructions - WRPKRU	- For restoring extended processor states, which may include PKRU state. - For changing the value of PRKU register as used in IPC gates.	- No restoring - Binary rewriting

Table 2: Deprive the execution domains for system servers of the ability to execute privileged instructions.

through instructions like *cli* to monopolize the CPU. Fortunately, it cannot disable the host timer interrupts, which unconditionally trigger *VMExits*. Thus, the secure monitor can easily detect such malicious behaviors by checking *PKRU* and *interrupt state*.

Last but not least, we must forbid system servers from changing the *PKRU* register, i.e., changing the memory-access permission, by themselves. There are two kinds of instructions that can modify *PKRU*. For the first kind (*xrstor/xrstors*), the core kernel configures them not to manage *PKRU* by setting a control bit (bit-9) in *XRC0*. For the second kind (*wrpkru*), the core kernel ensures it does not exist outside the IPC gates by rewriting the binary code (similar to [77]). The *wrpkru* in the IPC gates cannot be abused as specified in § 4.1.

We omit the detailed policies of the binary rewriting in this paper as it is a mature technique [17, 25, 77]. Nevertheless, it is worth noting that using binary rewriting to directly eliminating all privilege instructions is undecidable because some privilege instructions only take one byte (e.g., hlt). Our hybrid approach is both effective and efficient.

4.3 Security Analysis

By introducing in-kernel servers, our system has one major difference from existing microkernels, which may lead to a larger attack surface. The in-kernel servers run in the kernel mode, which means a compromised server is able to execute any privileged instruction. We will analyze the attacks caused by the difference and illustrate how to defend against them.

Restricting privileged in-kernel servers: System servers are not trusted in our threat model. Although they can run in the kernel mode, they are highly restricted when trying to attack the core kernel, other servers, or the applications.

We assume that an attacker has fully compromised an in-kernel server and can execute arbitrary instructions. Since the server runs in another execution domain (no access to the memory domain 0), it cannot directly access the memory of the core kernel. As long as it tries to read or write any disallowed memory, a CPU exception will immediately be triggered and handled by the core kernel.

There are four ways to bypass the memory isolation mechanism enforced by MPK: the first one is to run the disabling instructions, e.g., by setting *CR4.PKE* to 0 or setting *CR0.WP* to 0; the second is to change the *PKRU* register to gain access permission of other memory domains illegally; the third is to change the page table base address by setting the *CR3* register; the fourth is to modify the page table directly.

ChCore can defend against all these attacks. Before loading a server, ChCore uses binary scanning/rewriting to eliminate the undesired privileged instructions. At runtime, the secure monitor will prevent a server from executing other privileged instructions. Compared with running on traditional microkernels, servers, including maliciously crafted ones, have no more attack means on microkernels with UnderBridge. First, when the malicious server executes the disabling instructions, it will trigger *VMExits*, and the monitor will locate the compromised server. Second, as described in the last paragraph of § 4.2, the two ways of modifying the *PKRU* register are prevented. Third, the malicious server has no way to modify *CR3* since the binary rewriting guarantees no *CR3* modification instructions exist in any server's address space. Fourth, the malicious server cannot modify the page table because the kernel page table resides in memory domain 0. Meanwhile, it cannot modify or add instructions which require to change the page table first. The isolation between in-kernel servers is the same as the isolation between an in-kernel server and the core kernel. Since an in-kernel server does not share address space with user applications, it cannot access applications' memory either.

Defending side-channel attacks: Since all the in-kernel servers share one address space, it is easier for a malicious one to issue Spectre [45] and Meltdown [54] attacks compared with the case where all servers have their own address spaces. Although these attacks are caused by CPU bugs (out-of-scope), ChCore can mitigate them with existing software defenses like using address randomization makes a compromised server hard to locate the sensitive memory area. Considering the secret tokens leakage on buggy CPUs, extra checks can be added in the IPC gates, e.g., Line-10 in Figure-4(b), to prevent malicious PKRU modification and ensure the memory isolation. Besides that, most known hardware vulnerabilities have been fixed by major CPU vendors in their latest products [5, 6], which is orthogonal to ChCore.

5 Implementation

Based on our UnderBridge design, we have implemented a prototype microkernel ChCore, which contains about 8500 lines of C code (LOC). ChCore runs in guest-mode, i.e., non-root mode on x86_64, and a small secure monitor (around 300 LOC) runs in hypervisor-mode, i.e., root mode on x86_64. We have implemented the tiny secure monitor in a minimal virtualization-layer, RootKernel (1,500 LOC) of SkyBridge [62]. Note that RootKernel is not a hypervisor and works only for running one OS in the guest-mode and thus avoids most overhead caused by virtualization. Therefore, although our system requires hardware virtualization, it still can be deployed in bare-metal machines with RootKernel and achieve close-to-native performance. Considering the above, our system increases the trusted computing base (TCB) by 1,800 LOC in total when running on bare-metal machines, which is acceptable. Besides, we also integrate the tiny secure monitor in a commercial hypervisor, KVM, which makes deploying our system in cloud feasible. Even if nested virtualization is required, our secure monitor can still work because it simply utilizes the hardware-provided capability to trap sensitive instructions. Because the instructions to trap are deliberately selected and do not exist on critical paths, they will not degrade the overall performance. Nevertheless, our current implementation requires cloud providers to patch their hypervisors. In such a case, our system increases TCB by 300 LOC. Alternatively, we may leverage eBPF [61, 81] to deploy our secure monitor without modifications to the commercial hypervisor (left as future work).

We also apply UnderBridge to three state-of-the-art microkernels, i.e., seL4 [3], Zircon, and Fiasco.OC, to demonstrate the generality of the design. The porting effort is about 1000∼1500 LOC for each of them. Since UnderBridge uses different page tables for applications and kernel, it also enables and leverages the PCID hardware feature for avoiding unnecessary TLB flushing. As native Fiasco.OC does not support to use this feature, we also add a simple extension to assign different PCIDs to an application and the kernel.

6 Performance Evaluation

Basic Setup. We conduct all the experiments on a Dell PowerEdge R640 server, which is equipped with a 20-core Intel Xeon Gold 6138 2.0GHz CPU and 128GB memory. Both Turbo Boost and Hyper-threading are disabled. ChCore runs on Linux/KVM-4.19 and QEMU-4.1.

Systems for Comparison. We evaluate the native IPC performance of three popular microkernels (Zircon, seL4, and Fiasco.OC) on bare metal. Also, we evaluate SkyBridge [62], which is the state-of-the-art optimization for IPC in microkernels by using *vmfunc*. SkyBridge deploys a small hypervisor called RootKernel and runs microkernels in non-root mode. When evaluating UnderBridge, we deploy the secure monitor of UnderBridge in RootKernel and run microkernels with UnderBridge on it. As Zircon has no kernel-page-table-isolation (KPTI) support, we simulate the overhead of page table switching by writing *CR3* twice when evaluating UnderBridge on it, this is because UnderBridge requires to make the kernel and applications use different page tables.

6.1 IPC Performance Analysis

Cross-server IPC. Firstly, we analyze the IPC performance between two servers (we abbreviate "system server" as "server" in this section) in a micro-benchmark, which uses *rdtsc* instruction to measure the *round-trip* latency of invoking an empty function in server B from server A.

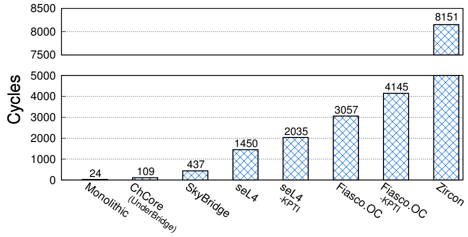


Figure 5: Round-trip latency of cross-server IPC.

Figure-5 gives the absolute cost of cross-server IPCs in different designs. Since invocations between servers (components) in monolithic kernels are usually achieved by using (indirect) *call*/*ret* instructions, the round-trip latency is only 24 cycles. The latency of an IPC round-trip in ChCore is 109 cycles, which is dominated by two *wrpkru* instructions (56 cycles in total). Note that the IPC is achieved by UnderBridge and thus only involves the lightweight *wrpkru* and the procedure of saving necessary registers. SkyBridge requires two much heavier *vmfunc* instruction (292 cycles in total) and therefore has larger latency.

The round-trip latency of a native IPC in the other three microkernels are much more noticeable. Among them, seL4

[3] We do not retain formal correctness guarantees of seL4.

shows the best performance as it will directly switch the caller thread to callee thread when executing fast-path IPCs. Although Fiasco.OC applies a similar strategy, it has a more complex IPC capability handling procedure. Zircon does not support direct-switch and thus has the worst performance due to the high scheduling cost.

Compared with the native IPC in the three microkernels, our UnderBridge design is more than 12.3× faster. The performance improvement mainly comes from two parts. First, UnderBridge avoids the time-consuming privilege switches in traditional IPC designs, as measured in § 2.2. Second, UnderBridge avoids the complex validation and invocation of the IPC capability on the critical path. An IPC gate is only generated after the corresponding capabilities having been checked, so UnderBridge needs not to check the capability at runtime. Also, the gate only requires several lightweight instructions for the domain switching (details in § 4.1).

Another benefit of UnderBridge is that the in-kernel servers can invoke system calls faster via the IPC gates instead of using *syscall* instructions.

Application-to-Server IPC. We further analyze the IPC (round-trip) performance between a user application and a server in this part. Commonly, a system call involves multiple servers in microkernels (or multiple kernel components in monolithic kernels), which means an application-to-server IPC may involve several cross-server IPCs. To simulate such cases, we design a micro-benchmark that includes one application and several servers. Each server will do nothing but routing IPCs to another server. We vary the number of cross-server IPCs in the benchmark.

Approaches	Cross-server IPCs		
	0	1	2
SkyBridge	437	931	1390
ChCore (UnderBridge)	723	856	981
seL4	1450	2932	4266

Table 3: Round-trip latency (cycles) of one application-to-server IPC and different number of cross-server IPCs.

Table-3 compares the performance of SkyBridge (applied on Fiasco.OC) and UnderBridge (applied on ChCore) in this micro-benchmark. Results are similar when we apply them to other microkernels and thus omitted. If an application invokes a server *without* causing any cross-server IPCs, SkyBridge (437 cycles) shows better performance than UnderBridge (723 cycles). It is because UnderBridge has to switch the privilege level and the address space for transferring the control flow from user space to kernel space, while SkyBridge applies more lightweight EPT switching via *vmfunc*. Nevertheless, UnderBridge still outperforms the best native IPC (1450 cycles in seL4), because of reducing one privilege switch and minimizing the software logic of an IPC.

As the number of cross-server IPCs increases, the latency of SkyBridge increases in proportion. It is because that IPC from application to the server and between servers are symmetric and cost the same cycles. In contrast, the latency of UnderBridge grows much slower because its cross-server IPC is much more lightweight. As shown in Table-3, the performance of UnderBridge becomes better than SkyBridge when involving one cross-server IPC, and is better than that by 42% when involving two. The performance speedup is expected to grow along with the increasing number of the cross-server IPCs and finally close to 3.0× as in Figure-5.

6.2 Application Benchmarks

We further evaluate the performance of UnderBridge with two real-world applications: a database application and an HTTP server application. In the following experiments, shared memory is used to transfer data during IPCs.

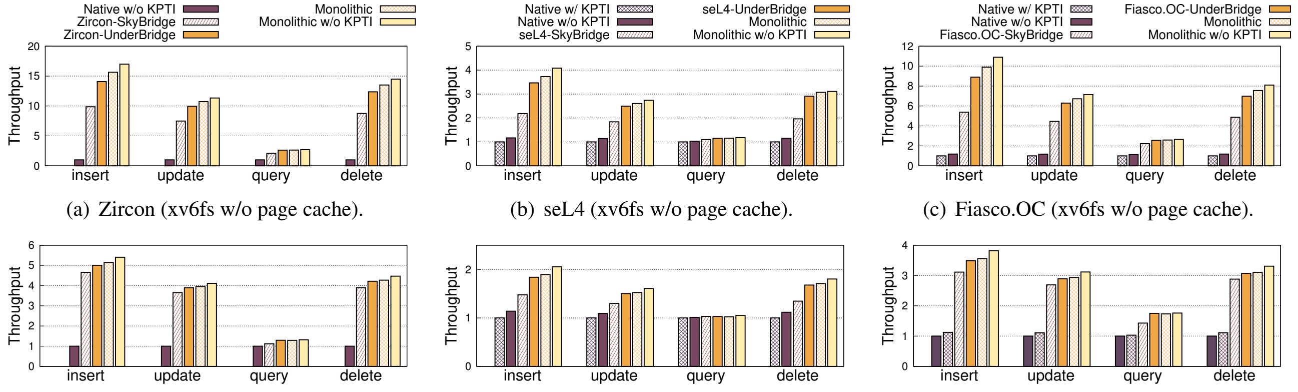
Database Evaluation. To faithfully compare with SkyBridge, we use the benchmarks in [62]. Specifically, for serving a relational database, SQLite3 [15], we run two system servers: one is a file system named xv6fs [16, 23], and the other is a RAMdisk (memory-only). When SQLite3 operates on a file, it will first invoke the xv6fs server by an application-to-server IPC, and then the xv6fs will read or write the RAMdisk by cross-server IPCs.

Basic Operations. We first evaluate the performance of basic operations, including insert, update, query, and delete operations. Our evaluation includes three IPC approaches: the native IPC, UnderBridge, and SkyBridge. Specifically, for each microkernel, we not only evaluate the performance with its native IPC designs but also test the performance after applying UnderBridge and SkyBridge to it. We also emulate the performance of a monolithic kernel by replacing all the IPC gates in UnderBridge with function calls.

Figure-6(a), 6(b) and 6(c) show the normalized throughput of basic operations in the three microkernels, separately. The baseline is set as the performance of native IPC design in each microkernel.

UnderBridge achieves up to 13.1×, 9.0×, 1.6× and 11.3× speedup for each of these operations, individually. The improvement of query operations is relatively small since SQLite3 has an internal buffer for storing recent data and may handle the queries without issuing IPCs. Compared with SkyBridge, the performance improvement of UnderBridge (up to 65%) is because a single IPC from SQLite3 to xv6fs is likely to trigger multiple cross-server IPCs between xv6fs and RAMdisk. Even compared with the emulated performance of monolithic kernels, UnderBridge only introduces about 5.0% overhead.

The above-tested xv6fs (exactly the same one used in the SkyBridge paper [62]) contains no page cache, which, thus, emulates an IPC-intensive scenario. We further enable the page cache in xv6fs to show how UnderBridge performs with fewer cross-server IPCs between xv6fs and RAMdisk. As shown in Figure-6(d), 6(e) and 6(f), the performance improvement of UnderBridge is still obvious. UnderBridge shows up to 4.0×, 2.9×, 0.7× and 3.2× speedup



(a) Zircon (xv6fs w/o page cache).

(b) seL4 (xv6fs w/o page cache).

(c) Fiasco.OC (xv6fs w/o page cache).

(d) Zircon (xv6fs w/ page cache).

(e) seL4 (xv6fs w/ page cache).

(f) Fiasco.OC (xv6fs w/ page cache).

Figure 6: Normalized throughput of basic SQLite3 operations.

compared with the native IPC and achieves comparable performance with monolithic kernels. Nevertheless, since fewer cross-server IPCs are involved, the maximum improvement of UnderBridge compared with SkyBridge drops from 65% to 25%.

Since UnderBridge runs in non-root mode, we also count the number of *VMExit*, which is known as the cost of virtualization. Thanks to the careful design of RootKernel and our secure monitor, there are *almost zero VMExits* during the experiments. For example, at most one VMExit (due to timer) happens during the query test.

YCSB Benchmark. We also evaluate SQLite3 against YCSB workloads. Figure-7(a) and 7(b) show the normalized throughput of YCSB-A (50% update and 50% query) with the page cache disabled and enabled in xv6fs, separately. We use the same baseline as the basic operation evaluation. Even for seL4, which is the most efficient among the three microkernels, UnderBridge improves the application's throughput from 35% to 105%. UnderBridge also brings a better performance (from 7% to 35%) than SkyBridge. Besides, it is only slightly slower (3.3% on average) than the monolithic kernel. Other YCSB workloads give similar results.

Furthermore, Figure-7(c) gives a detailed analysis of the experiments with page cache *enabled* in xv6fs. First, the ratio of IPCs from SQLite3 to xv6fs (application-to-server) and xv6fs to RAMdisk (cross-server) is about 1:2. Thus, UnderBridge outperforms SkyBridge, according to Table-3. Second, it helps to reduce the ratio of time spent on IPCs to around 11% while the other three microkernels spend at least 30% of the time on IPCs. Third, it makes the application and the servers execute faster (about 10%) owing to less indirect costs such as cache/TLB pollution.

Server Migration. We also evaluate the performance of server migration, although it should rarely happen. We still run SQLite3, xv6fs, and RAMdisk as above on Zircon and trigger the server migration. Taking RAMdisk (128 MB virtual memory range) as an example, migrating it from kernel to user takes about 84,361 cycles. Most of the cycles (83,517) are spent on modifying the kernel page table to free the domain ID (i.e., the third step for migrating a server specified in § 3.3). Migrating RAMdisk from user to kernel takes more cycles (90,189) mainly because more cycles are spent on waiting for finishes of on-going IPCs.

HTTP Server Evaluation. For running an HTTP server (a user-space application), we create three system servers: a socket server, a TCP/IP protocol stack server, and a loopback network device driver (not involving the real network device) atop lwIP [31] library. We measure the throughput of a simple HTTP server from the client-side, which receives requests from the network and sends back a static HTML page.

We perform this evaluation on Zircon. As shown in Figure-7(d), UnderBridge improves the throughput of the HTTP server by 4.4×. We also implement the same benchmark with SkyBridge. UnderBridge outperforms SkyBridge by about 24% because a network request also triggers multiple cross-server IPCs.

7 Related Work

Reconstructing monolithic kernels. The development of monolithic kernels follows the philosophy of modularization, but all the kernel components are not isolated from each other. With reliability and security attracting a fair amount of attention, we witness interest in reconstructing monolithic kernels to achieve better fault isolation and higher security [17, 25, 26, 38, 41, 59, 63, 65, 67, 74, 75, 84, 86]. Dautenhahn et al. [25] build one memory protection domain inside the BSD kernel and run a small trusted kernel in that domain to control memory mappings. Mondrix [84] implements a compartmentalized Linux kernel with eleven isolated modules based on customized security hardware [83]. Proskurin et al. [65] propose to use Intel EPT and *vmfunc* to isolate critical kernel data in different domains. Nooks [74] and LXFI [59] focus on improving the reliability of Linux by isolating kernel modules, especially device drivers.

Our work does share some similarities with prior work on intra-(monolithic)kernel isolation. Nevertheless, we fo-

Figure 7: (a), (b), and (d) share the same legend. (a) and (b) show the normalized throughput of YCSB-A with xv6fs's page cache disabled and enabled separately. (c) shows the time breakdown of YCSB-A benchmark. (d) demonstrates the normalized throughput of a HTTP server.

cus on accelerating IPCs for microkernel architectures while maintaining strong isolation (both ends). We need to do little modification/instrumentation on system servers of a microkernel. This is because system servers of a microkernel are designed to run in different user processes, and all the interactions are explicit IPCs, which is different from the subsystems in Linux (no clear boundaries and have complex shared memory references). We achieve intra-kernel isolation by retrofitting Intel MPK, which is lightweight and commercially-available, to build multiple execution domains in kernel space. Furthermore, UnderBridge may also be generalized to other kernel scopes with more efforts in the future. On one side, the proposed abstraction of the execution domain can be extended to accommodate different kernel modules in monolithic kernels, and the IPC gates can still be used to handle interactions between those modules. On the other side, our design can also be applied in kernels written in memory-safe languages [11, 24] to isolate some unsafe code (e.g., the code with "unsafe" tag in Rust).

Accelerating IPCs. Optimizing the performance of IPC in microkernels is continuously studied for a long time [19, 36, 44, 50, 52, 82]. For example, LRPC [19] eliminates the scheduling overhead during an IPC by using the thread-migration model [36, 37]; seL4 [44] provides the fast-path IPC, which also avoids scheduling and passes arguments through registers. Nevertheless, even with these software-based optimizations, IPC-intensive applications on microkernels still suffer from the IPC overhead.

Recent studies present new designs to accelerate IPCs with advanced hardware features. SkyBridge [62] utilizes the *vmfunc* to allow a process to invoke a function in another process directly without the kernel's involvement. XPC [30] is a hardware proposal that accelerates IPCs by implementing efficient context switch and memory granting. dIPC relies on another hardware proposal [78] to put processes into the same address space and thus make IPCs faster. Our design shows better performance than SkyBridge and requires no hardware modification.

Usage of Intel MPK. Intel MPK/PKU has been utilized by [39, 64, 77] to achieve efficient intra-process isolation, which can build mutual-distrusted execution environments in a single user process. There are two main differences between UnderBridge and them. First, UnderBridge retrofits MPK that designed for user space in kernel space to improve the IPC performance for microkernels (the first effort to our knowledge) and also faces more security challenges. Applications can still utilize MPK in user space as they want since they have different page tables from the kernel. Second, UnderBridge authenticates the caller of each MPK gate for enforcing IPC capability to prevent illegal domain switches, while prior work allows arbitrary domain switches.

There exist two concurrent studies [38, 73] to UnderBridge. They also propose to utilize MPK in kernel mode but with different goals and designs. IskiOS [38] leverages MPK to defend against code-reuse attacks (e.g., protecting shadow stacks) in the kernel. Sung et al. [73] uses MPK to enhance the isolation for a unikernel while does not solve the security challenges identified in UnderBridge.

MPK-like features on other architectures. Tagged memory [28, 43, 85], which can provide MPK-like features, is added in other architectures, which brings the potential to make UnderBridge more general to those architectures. Recently, the RISC-V security community also considers enhancing the PMP (physical memory protection) isolation with the tagged memory mechanism [12]. However, UnderBridge cannot work on current ARMv8 (aarch64). Yet, ARM v8.5 has included memory tagging extensions [10], by extending which with more mechanisms, we may provide a similar mechanism workable on future ARM platforms.

8 Conclusion

This paper introduces UnderBridge, a redesign of the runtime structure of microkernel OSes for faster OS services. To demonstrate UnderBridge's efficiency, we have built a prototype microkernel named ChCore and ported it to three existing microkernels. Performance evaluations showed that UnderBridge can achieve better performance in IPC-intensive workloads compared with prior work.

FAASM: Lightweight Isolation for Efficient Stateful Serverless Computing

Simon Shillaker
Imperial College London

Peter Pietzuch
Imperial College London

Abstract

Serverless computing is an excellent fit for big data processing because it can scale quickly and cheaply to thousands of parallel functions. Existing serverless platforms isolate functions in ephemeral, stateless containers, preventing them from directly sharing memory. This forces users to duplicate and serialise data repeatedly, adding unnecessary performance and resource costs. We believe that a new lightweight isolation approach is needed, which supports sharing memory directly between functions and reduces resource overheads.

We introduce *Faaslets*, a new isolation abstraction for high-performance serverless computing. Faaslets isolate the memory of executed functions using *software-fault isolation* (SFI), as provided by *WebAssembly*, while allowing memory regions to be shared between functions in the same address space. Faaslets can thus avoid expensive data movement when functions are co-located on the same machine. Our runtime for Faaslets, FAASM, isolates other resources, e.g. CPU and network, using standard Linux *cgroups*, and provides a low-level POSIX host interface for networking, file system access and dynamic loading. To reduce initialisation times, FAASM restores Faaslets from already-initialised snapshots. We compare FAASM to a standard container-based platform and show that, when training a machine learning model, it achieves a 2× speed-up with 10× less memory; for serving machine learning inference, FAASM doubles the throughput and reduces tail latency by 90%.

1 Introduction

Serverless computing is becoming a popular way to deploy data-intensive applications. A function-as-a-service (FaaS) model decomposes computation into many functions, which can effectively exploit the massive parallelism of clouds. Prior work has shown how serverless can support map/reduce-style jobs [42, 69], machine learning training [17, 18] and inference [40], and linear algebra computation [73, 88]. As a result, an increasing number of applications, implemented in diverse programming languages, are being migrated to serverless platforms.

Existing platforms such as Google Cloud Functions [32], IBM Cloud Functions [39], Azure Functions [50] and AWS Lambda [5] isolate functions in ephemeral, stateless *containers*. The use of containers as an isolation mechanisms introduces two challenges for data-intensive applications, *data access overheads* and the *container resource footprint*.

Data access overheads are caused by the stateless nature of the container-based approach, which forces state to be maintained externally, e.g. in object stores such as Amazon S3 [6], or passed between function invocations. Both options incur costs due to duplicating data in each function, repeated serialisation, and regular network transfers. This results in current applications adopting an inefficient "data-shipping architecture", i.e. moving data to the computation and not vice versa—such architectures have been abandoned by the data management community many decades ago [36]. These overheads are compounded as the number of functions increases, reducing the benefit of unlimited parallelism, which is what makes serverless computing attractive in the first place.

The container resource footprint is particularly relevant because of the high-volume and short-lived nature of serverless workloads. Despite containers having a smaller memory and CPU overhead than other mechanisms such as virtual machines (VMs), there remains an impedance mismatch between the execution of individual short-running functions and the process-based isolation of containers. Containers have start-up latencies in the hundreds of milliseconds to several seconds, leading to the *cold-start* problem in today's serverless platforms [36, 83]. The large memory footprint of containers limits scalability—while technically capped at the process limit of a machine, the maximum number of containers is usually limited by the amount of available memory, with only a few thousand containers supported on a machine with 16 GB of RAM [51].

Current data-intensive serverless applications have addressed these problems individually, but never solved both—instead, either exacerbating the container resource overhead or breaking the serverless model. Some systems avoid data movement costs by maintaining state in long-lived VMs or services, such as ExCamera [30], Shredder [92] and Cirrus [18], thus introducing non-serverless components. To address the performance overhead of containers, systems typically increase the level of trust in users' code and weaken isolation guarantees. PyWren [42] reuses containers to execute multiple functions; Crucial [12] shares a single instance of the Java virtual machine (JVM) between functions; SAND [1] executes multiple functions in long-lived containers, which also run an additional message-passing service; and Cloudburst [75] takes a similar approach, introducing a local key-value-store cache. Provisioning containers to execute multiple functions and extra services amplifies resource overheads, and breaks the fine-grained elastic scaling inherent to serverless. While several of these systems reduce data access overheads with local storage, none provide *shared memory* between functions, thus still requiring duplication of data in separate process memories.

Other systems reduce the container resource footprint by moving away from containers and VMs. Terrarium [28] and Cloudflare Workers [22] employ software-based isolation using WebAssembly and V8 Isolates, respectively; Krustlet [54] replicates containers using WebAssembly for memory safety; and SEUSS [16] demonstrates serverless unikernels. While these approaches have a reduced resource footprint, they do not address data access overheads, and the use of software-based isolation alone does not isolate resources.

We make the observation that serverless computing can better support data-intensive applications with a new isolation abstraction that (i) provides strong memory and resource isolation between functions, yet (ii) supports efficient state sharing. Data should be *co-located* with functions and accessed directly, minimising data-shipping. Furthermore, this new isolation abstraction must (iii) allow scaling state across multiple hosts; (iv) have a low memory footprint, permitting many instances on one machine; (v) exhibit fast instantiation times; and (vi) support multiple programming languages to facilitate the porting of existing applications.

In this paper, we describe **Faaslets**, a new *lightweight isolation abstraction* for data-intensive serverless computing. Faaslets support stateful functions with efficient shared memory access, and are executed by our **FAASM** distributed serverless runtime. Faaslets have the following properties, summarising our contributions:

(1) Faaslets achieve lightweight isolation. Faaslets rely on *software fault isolation* (SFI) [82], which restricts functions to accesses of their own memory. A function associated with a Faaslet, together with its library and language runtime dependencies, is compiled to WebAssembly [35]. The FAASM runtime then executes multiple Faaslets, each with a dedicated thread, within a single address space. For resource isolation, the CPU cycles of each thread are constrained using Linux *cgroups* [79] and network access is limited using *network namespaces* [79] and *traffic shaping*. Many Faaslets can be executed efficiently and safely on a single machine.

(2) Faaslets support efficient local/global state access. Since Faaslets share the same address space, they can access shared memory regions with local state efficiently. This allows the co-location of data and functions and avoids serialisation overheads. Faaslets use a two-tier state architecture, a *local* tier provides in-memory sharing, and a *global* tier supports distributed access to state across hosts. The FAASM runtime provides a state management API to Faaslets that gives fine-grained control over state in both tiers. Faaslets also support stateful applications with different consistency requirements between the two tiers.

(3) Faaslets have fast initialisation times. To reduce cold-start time when a Faaslet executes for the first time, it is launched from a suspended state. The FAASM runtime pre-initialises a Faaslet ahead-of-time and snapshots its memory to obtain a *Proto-Faaslet*, which can be restored in hundreds of microseconds. Proto-Faaslets are used to create fresh Faaslet instances quickly, e.g. avoiding the time to initialise a language runtime. While existing work on snapshots for serverless takes a single-machine approach [1, 16, 25, 61], Proto-Faaslets support cross-host restores and are OS-independent.

(4) Faaslets support a flexible host interface. Faaslets interact with the host environment through a set of POSIX-like calls for networking, file I/O, global state access and library loading/linking. This allows them to support dynamic language runtimes and facilitates the porting of existing applications, such as CPython by changing fewer than 10 lines of code. The host interface provides just enough virtualisation to ensure isolation while adding a negligible overhead.

The FAASM runtime[1] uses the LLVM compiler toolchain to translate applications to WebAssembly and supports functions written in a range of programming languages, including C/C++, Python, Typescript and Javascript. It integrates with existing serverless platforms, and we describe the use with *Knative* [33], a state-of-the-art platform based on Kubernetes.

To evaluate FAASM's performance, we consider a number of workloads and compare to a container-based serverless deployment. When training a machine learning model with SGD [68], we show that FAASM achieves a 60% improvement in run time, a 70% reduction in network transfers, and a 90% reduction in memory usage; for machine learning inference using TensorFlow Lite [78] and MobileNet [37], FAASM achieves over a 200% increase in maximum throughput, and a 90% reduction in tail latency. We also show that FAASM executes a distributed linear algebra job for matrix multiplication using Python/Numpy with negligible performance overhead and a 13% reduction in network transfers.

2 Isolation vs. Sharing in Serverless

Sharing memory is fundamentally at odds with the goal of isolation, hence providing shared access to in-memory state

[1] FAASM is open-source and available at github.com/lsds/Faasm

		Containers	VMs	Unikernel	SFI	Faaslet

Table 1: Isolation approaches for serverless (Initialisation times include ahead-of-time snapshot restore where applicable [16,25,61].)

in a multi-tenant serverless environment is a challenge.

Tab. 1 contrasts *containers* and *VMs* with other potential serverless isolation options, namely *unikernels* [16] in which minimal VM images are used to pack tasks densely on a hypervisor and *software-fault isolation* (SFI) [82], providing lightweight memory safety through static analysis, instrumentation and runtime traps. The table lists whether each fulfils three key functional requirements: memory safety, resource isolation and sharing of in-memory state. A fourth requirement is the ability to share a filesystem between functions, which is important for legacy code and to reduce duplication with shared files.

The table also compares these options on a set of non-functional requirements: low initialisation time for fast elasticity; small memory footprint for scalability and efficiency, and the support for a range of programming languages.

Containers offer an acceptable balance of features if one sacrifices efficient state sharing—as such they are used by many serverless platforms [32, 39, 50]. Amazon uses Firecracker [4], a "micro VM" based on KVM with similar properties to containers, e.g. initialisation times in the hundreds of milliseconds and memory overheads of megabytes.

Containers and VMs compare poorly to unikernels and SFI on initialisation times and memory footprint because of their level of virtualisation. They both provide complete virtualised POSIX environments, and VMs also virtualise hardware. Unikernels minimise their levels of virtualisation, while SFI provides none. Many unikernel implementations, however, lack the maturity required for production serverless platforms, e.g. missing the required tooling and a way for non-expert users to deploy custom images. SFI alone cannot provide resource isolation, as it purely focuses on memory safety. It also does not define a way to perform isolated interactions with the underlying host. Crucially, as with containers and VMs, neither unikernels nor SFI can share state efficiently, with no way to express shared memory regions between compartments.

2.1 Improving on Containers

Serverless functions in containers typically share state via external storage and duplicate data across function instances. Data access and serialisation introduces network and compute overheads; duplication bloats the memory footprint of containers, already of the order of megabytes [51]. Containers contribute hundreds of milliseconds up to seconds in cold-start latencies [83], incurred on initial requests and when scaling. Existing work has tried to mitigate these drawbacks by recycling containers between functions, introducing static VMs, reducing storage latency, and optimising initialisation.

Recycling containers avoids initialisation overheads and allows data caching but sacrifices isolation and multi-tenancy. PyWren [42] and its descendants, Numpywren [73], IBMPywren [69], and Locus [66] use recycled containers, with long-lived AWS Lambda functions that dynamically load and execute Python functions. Crucial [12] takes a similar approach, running multiple functions in the same JVM. SAND [1] and Cloudburst [75] provide only process isolation between functions of the same application and place them in shared long-running containers, with at least one additional background storage process. Using containers for multiple functions and supplementary long-running services requires over-provisioned memory to ensure capacity both for concurrent executions and for peak usage. This is at odds with the idea of fine-grained scaling in serverless.

Adding static VMs to handle external storage improves performance but breaks the serverless paradigm. Cirrus [18] uses large VM instances to run a custom storage back-end; Shredder [92] uses a single long-running VM for both storage and function execution; ExCamera [30] uses long-running VMs to coordinate a pool of functions. Either the user or provider must scale these VMs to match the elasticity and parallelism of functions, which adds complexity and cost.

Reducing the latency of auto-scaled storage can improve performance within the serverless paradigm. Pocket [43] provides ephemeral serverless storage; other cloud providers offer managed external state, such as AWS Step Functions [3], Azure Durable Functions [53], and IBM Composer [8]. Such approaches, however, do not address the data-shipping problem and its associated network and memory overheads.

Container initialisation times have been reduced to mitigate the cold-start problem, which can contribute several seconds of latency with standard containers [36, 72, 83]. SOCK [61] improves the container boot process to achieve cold starts in the low hundreds of milliseconds; Catalyzer [25] and SEUSS [16] demonstrate snapshot and restore in VMs and unikernels to achieve millisecond serverless cold starts. Although such reductions are promising, the resource overhead and restrictions on sharing memory in the underlying mechanisms still remain.

2.2 Potential of Software-based Isolation

Software-based isolation offers memory safety with initialisation times and memory overheads up to two orders of magnitude lower than containers and VMs. For this reason, it is an attractive starting point for serverless isolation. However, software-based isolation alone does not support resource isolation, or efficient in-memory state sharing.

It has been used in several existing edge and serverless computing systems, but none address these shortcomings.

Fastly's Terrarium [28] and Cloudflare Workers [22] provide memory safety with WebAssembly [35] and V8 Isolates [34], respectively, but neither isolates CPU or network use, and both rely on data shipping for state access; Shredder [92] also uses V8 Isolates to run code on a storage server, but does not address resource isolation, and relies on co-locating state and functions on a single host. This makes it ill-suited to the level of scale required in serverless platforms; Boucher et al. [14] show microsecond initialisation times for Rust microservices, but do not address isolation or state sharing; Krustlet [54] is a recent prototype using WebAssembly to replace Docker in Kubernetes, which could be integrated with Knative [33]. It focuses, however, on replicating container-based isolation, and so fails to meet our requirement for in-memory sharing.

Our final non-functional requirement is for multi-language support, which is not met by language-specific approaches to software-based isolation [11, 27]. Portable Native Client [23] provides multi-language software-based isolation by targeting a portable intermediate representation, LLVM IR, and hence meets this requirement. Portable Native Client has now been deprecated, with WebAssembly as its successor [35].

WebAssembly offers strong memory safety guarantees by constraining memory access to a single linear byte array, referenced with offsets from zero. This enables efficient bounds checking at both compile- and runtime, with runtime checks backed by traps. These traps (and others for referencing invalid functions) are implemented as part of WebAssembly runtimes [87]. The security guarantees of WebAssembly are well established in existing literature, which covers formal verification [84], taint tracking [31], and dynamic analysis [45]. WebAssembly offers mature support for languages with an LLVM front-end such as C, C++, C#, Go and Rust [49], while toolchains exist for Typescript [10] and Swift [77]. Java bytecode can also be converted [7], and further language support is possible by compiling language runtimes to WebAssembly, e.g. Python, JavaScript and Ruby. Although WebAssembly is restricted to a 32-bit address space, 64-bit support is in development.

The WebAssembly specification does not yet include mechanisms for sharing memory, therefore it alone cannot meet our requirements. There is a proposal to add a form of synchronised shared memory to WebAssembly [85], but it is not well suited to sharing serverless state dynamically due to the required compile-time knowledge of all shared regions. It also lacks an associated programming model and provides only local memory synchronisation.

The properties of software-based isolation highlight a compelling alternative to containers, VMs and unikernels, but none of these approaches meet all of our requirements. We therefore propose a new isolation approach to enable efficient serverless computing for big data.

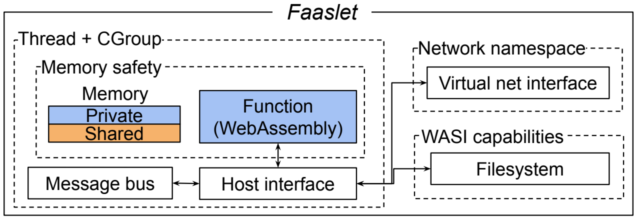

Figure 1: Faaslet abstraction with isolation

3 Faaslets

We propose *Faaslets*, a new isolation mechanism that satisfies all the requirements for efficient data-intensive serverless computing. Tab. 1 highlights Faaslets' strong memory and resource isolation guarantees, and efficient *shared in-memory state*. Faaslets provide a minimal level of lightweight virtualisation through their *host interface*, which supports serverless-specific tasks, memory management, a limited filesystem and network access.

In terms of non-functional requirements, Faaslets improve on containers and VMs by having a memory footprint below 200 KB and cold-start initialisation times of less than 10 ms. Faaslets execute functions compiled to secure IR, allowing them to support multiple programming languages.

While Faaslets cannot initialise as quickly as pure SFI, they mitigate the cold-start problem through ahead-of-time initialisation from snapshots called *Proto-Faaslets*. Proto-Faaslets reduce initialisation times to hundreds of microseconds, and a single snapshot can be restored across hosts, quickly scaling horizontally on clusters.

3.1 Overview

Fig. 1 shows a function isolated inside a Faaslet. The function itself is compiled to WebAssembly [35], guaranteeing memory safety and control flow integrity. By default, a function is placed in its own *private* contiguous memory region, but Faaslets also support *shared regions* of memory (§3.3). This allows a Faaslet to access shared in-memory state within the constraints of WebAssembly's memory safety guarantees.

Faaslets also ensure fair resource access. For CPU isolation, they use the CPU subset of Linux *cgroups* [79]. Each function is executed by a dedicated *thread* of a shared runtime process. This thread is assigned to a cgroup with a share of CPU equal to that of all Faaslets. The Linux CFS [79] ensures that these threads are scheduled with equal CPU time.

Faaslets achieve secure and fair network access using *network namespaces*, *virtual network interfaces* and *traffic shaping* [79]. Each Faaslet has its own network interface in a separate namespace, configured using *iptables* rules. To ensure fairness between co-located tenants, each Faaslet applies traffic shaping on its virtual network interface using `tc`, thus enforcing ingress and egress traffic rate limits.

As functions in a Faaslet must be permitted to invoke standard system calls to perform memory management and I/O operations, Faaslets offer an interface through which to in-

Class	Function	Action	Standard
Calls	`byte* read_call_input()`	Read input data to function as byte array	*none*
	`void write_call_output(out_data)`	Write output data for function	
	`int chain_call(name, args)`	Call function and return the `call_id`	
	`int await_call(call_id)`	Await the completion of `call_id`	
	`byte* get_call_output(call_id)`	Load the output data of `call_id`	
State	`byte* get_state(key, flags)`	Get pointer to state value for `key`	
	`byte* get_state_offset(key, off, flags)`	Get pointer to state value for `key` at offset	
	`void set_state(key, val)`	Set state value for `key`	
	`void set_state_offset(key, val, len, off)`	Set `len` bytes of state value at offset for `key`	
	`void push/pull_state(key)`	Push/pull global state value for `key`	
	`void push/pull_state_offset(key, off)`	Push/pull global state value for `key` at offset	
	`void append_state(key, val)`	Append data to state value for `key`	
	`void lock_state_read/write(key)`	Lock local copy of state value for `key`	
	`void lock_state_global_read/write(key)`	Lock state value for `key` globally	
Dynlink	`void* dlopen/dlsym(...)`	Dynamic linking of libraries	POSIX
	`int dlclose(...)`	*As above*	
Memory	`void* mmap(...)`, `int munmap(...)`	Memory grow/shrink only	
	`int brk(...)`, `void* sbrk(...)`	Memory grow/shrink	
Network	`int socket/connect/bind(...)`	Client-side networking only	WASI
	`size_t send/recv(...)`	Send/recv via virtual interface	
File I/O	`int open/close/dup/stat(...)`	Per-user virtual filesystem access	
	`size_t read/write(...)`	*As above*	
Misc	`int gettime(...)`	Per-user monotonic clock only	
	`size_t getrandom(...)`	Uses underlying host `/dev/urandom`	

Table 2: Faaslet host interface (The final column indicates whether functions are defined as part of POSIX or WASI [57].)

teract with the underlying host. Unlike containers or VMs, Faaslets do not provide a fully-virtualised POSIX environment but instead support a minimal serverless-specific host interface (see Fig. 1). Faaslets virtualise system calls that interact with the underlying host and expose a range of functionality, as described below.

The host interface integrates with the serverless runtime through a *message bus* (see Fig. 1). The message bus is used by Faaslets to communicate with their parent process and each other, receive function calls, share work, invoke and await other functions, and to be told by their parent process when to spawn and terminate.

Faaslets support a *read-global write-local* filesystem, which lets functions read files from a global object store (§5), and write to locally cached versions of the files. This is primarily used to support legacy applications, notably language runtimes such as CPython [67], which need a filesystem for loading library code and storing intermediate bytecode. The filesystem is accessible through a set of POSIX-like API functions that implement the WASI capability-based security model, which provides efficient isolation through unforgeable file handles [56]. This removes the need for more resource-intensive filesystem isolation such as a layered filesystem or `chroot`, which otherwise add to cold start latencies [61].

3.2 Host Interface

The Faaslet host interface must provide a virtualisation layer capable of executing a range of serverless big data applications, as well as legacy POSIX applications. This interface necessarily operates outside the bounds of memory safety, and hence is trusted to preserve isolation when interacting with the host.

In existing serverless platforms based on containers and VMs, this virtualisation layer is a standard POSIX environment, with serverless-specific tasks executed through language- and provider-specific APIs over HTTP [5, 32, 39]. Instantiating a full POSIX environment with the associated isolation mechanisms leads to high initialisation times [61], and heavy use of HTTP APIs contributes further latency and network overheads.

In contrast, the Faaslet host interface targets minimal virtualisation, hence reducing the overheads required to provide isolation. The host interface is a low-level API built exclusively to support a range of high-performance serverless applications. The host interface is dynamically linked with function code at runtime (§3.4), making calls to the interface more efficient than performing the same tasks through an external API.

Tab. 2 lists the Faaslet host interface API, which supports: (i) chained serverless function invocation; (ii) interacting with shared state (§4); (iii) a subset of POSIX-like calls for memory management, timing, random numbers, file/network I/O and dynamic linking. A subset of these POSIX-like calls are implemented according to WASI, an emerging standard for a server-side WebAssembly interface [57]. Some key details of the API are as follows:

Function invocation. Functions retrieve their input data serialised as byte arrays using the `read_call_input` function, and similarly write their output data as byte arrays using `write_call_output`. Byte arrays constitute a generic, language-agnostic interface.

Non-trivial serverless applications invoke multiple functions that work together as part of chained calls, made with the `chain_call` function. Users' functions have unique names, which are passed to `chain_call`, along with a byte array containing the input data for that call.

A call to `chain_call` returns the call ID of the invoked function. The call ID can then be passed to `await_call` to perform a blocking wait for another call to finish or fail, yielding its return code. The Faaslet blocks until the function has completed, and passes the same call ID to `get_call_output` to retrieve the chained call's output data.

Calls to `chain_call` and `await_call` can be used in loops to spawn and await calls in a similar manner to standard multi-threaded code: one loop invokes `chain_call` and records the call IDs; a second loop calls `await_call` on each ID in turn. We show this pattern in Python in Listing 1.

Dynamic linking. Some legacy applications and libraries require support for dynamic linking, e.g. CPython dynamically links Python extensions. All dynamically loaded code must first be compiled to WebAssembly and undergo the same validation process as other user-defined code (§3.4). Such modules are loaded via the standard Faaslet filesystem abstraction and covered by the same safety guarantees as its parent function. Faaslets support this through a standard POSIX dynamic linking API, which is implemented according to WebAssembly dynamic linking conventions [86].

Memory. Functions allocate memory dynamically through calls to `mmap()` and `brk()`, either directly or through `dlmalloc` [44]. The Faaslet allocates memory in its private memory region, and uses `mmap` on the underlying host to extend the region if necessary. Each function has its own predefined memory limit, and these calls fail if growth of the private region would exceeded this limit.

Networking. The supported subset of networking calls allows simple client-side send/receive operations and is sufficient for common use cases, such as connecting to an external data store or a remote HTTP endpoint. The functions `socket`, `connect` and `bind` allow setting up the socket while `read` and `write` allow the sending and receiving of data. Calls fail if they pass flags that are not related to simple send/receive operations over IPv4/IPv6, e.g. the `AF_UNIX` flag.

The host interface translates these calls to equivalent socket operations on the host. All calls interact exclusively with the Faaslet's virtual network interface, thus are constrained to a private network interface and cannot exceed rate limits due to the traffic shaping rules.

Byte arrays. Function inputs, results and state are represented as simple byte arrays, as is all function memory. This avoids the need to serialise and copy data as it passes through the API, and makes it trivial to share arbitrarily complex in-memory data structures.

3.3 Shared Memory Regions

As discussed in §2, sharing in-memory state while otherwise maintaining isolation is an important requirement for efficient serverless big data applications. Faaslets do this by adding the new concept of *shared regions* to the existing WebAssembly memory model [35]. Shared regions give functions concurrent access to disjoint segments of shared process memory, allowing them direct, low-latency access to shared data structures. Shared regions are backed by standard OS virtual memory, so there is no extra serialisation or overhead, hence Faaslets achieve efficient concurrent access on a par with native multi-threaded applications. In §4.2, we describe how Faaslets use this mechanism to provide shared in-memory access to global state.

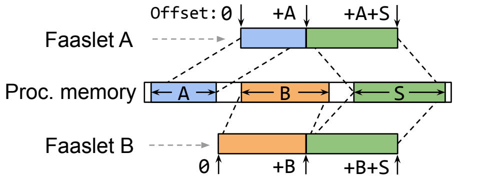

Figure 2: Faaslet shared memory region mapping

Shared regions maintain the memory safety guarantees of the existing WebAssembly memory model, and use standard OS virtual memory mechanisms. WebAssembly restricts each function's memory to a contiguous linear byte array, which is allocated by the Faaslet at runtime from a disjoint section of the process memory. To create a new shared region, the Faaslet extends the function's linear byte array, and remaps the new pages onto a designated region of common process memory. The function accesses the new region of linear memory as normal, hence maintaining memory safety, but the underlying memory accesses are mapped onto the shared region.

Fig. 2 shows Faaslets A and B accessing a shared region (labelled S), allocated from a disjoint region of the common process memory (represented by the central region). Each Faaslet has its own region of private memory (labelled A and B), also allocated from the process memory. Functions inside each Faaslet access all memory as offsets from zero, forming a single linear address space. Faaslets map these offsets onto either a private region (in this case the lower offsets), or a shared region (in this case the higher offsets).

Multiple shared regions are permitted, and functions can also extend their private memory through calls to the memory management functions in the host interface such as `brk` (§3.2). Extension of private memory and creation of new shared regions is handled by extending a byte array, which represents the function's memory, and then remapping the underlying pages to regions of shared process memory. This means the function continues to see a single densely-packed linear address space, which may be backed by several virtual memory mappings. Faaslets allocate shared process memory through calls to `mmap` on the underlying host, passing `MAP_SHARED` and `MAP_ANONYMOUS` flags to create shared and private regions, respectively, and remap these regions with `mremap`.

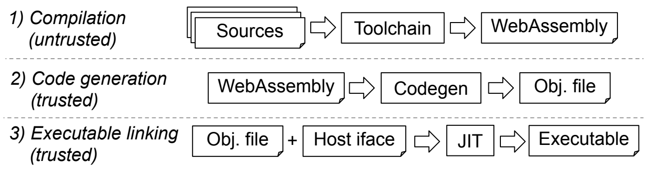

Figure 3: Creation of a Faaslet executable

3.4 Building Functions for Faaslets

Fig. 3 shows the three phases to convert source code of a function into a Faaslet executable: (1) the user invokes the Faaslet toolchain to compile the function into a WebAssembly binary, linking against a language-specific declaration of the Faaslet host interface; (2) code generation creates an object file with machine code from WebAssembly; and (3) the host interface definition is linked with the machine code to produce the Faaslet executable.

When Faaslets are deployed, the compilation phase to generate the WebAssembly binary takes place on a user's machine. Since that is untrusted, the code generation phase begins by validating the WebAssembly binary, as defined in the WebAssembly specification [35]. This ensures that the binary conforms to the specification. Code generation then takes place in a trusted environment, after the user has uploaded their function.

In the linking phase, the Faaslet uses LLVM JIT libraries [49] to link the object file and the definition of the host interface implementation. The host interface functions are defined as *thunks*, which allows injecting the trusted host interface implementation into the function binary.

Faaslets use WAVM [70] to perform the validation, code generation and linking. WAVM is an open-source WebAssembly VM, which passes the WebAssembly conformance tests [84] and thus guarantees that the resulting executable enforces memory safety and control flow integrity [35].

4 Local and Global State

Stateful serverless applications can be created with Faaslets using *distributed data objects (DDO)*, which are language-specific classes that expose a convenient high-level state interface. DDOs are implemented using the key/value state API from Tab. 2.

The state associated with Faaslets is managed using a *two-tier* approach that combines local sharing with global distribution of state: a *local tier* provides shared in-memory access to state on the same host; and a *global tier* allows Faaslets to synchronise state across hosts.

DDOs hide the two-tier state architecture, providing transparent access to distributed data. Functions, however, can still access the state API directly, either to exercise more fine-grained control over consistency and synchronisation, or to implement custom data structures.

Listing 1: Distributed SGD application with Faaslets

```
1  t_a = SparseMatrixReadOnly("training_a")
2  t_b = MatrixReadOnly("training_b")
3  weights = VectorAsync("weights")
4
5  @faasm_func
6  def weight_update(idx_a, idx_b):
7    for col_idx, col_a in t_a.columns[idx_a:idx_b]:
8      col_b = t_b.columns[col_idx]
9      adj = calc_adjustment(col_a, col_b)
10     for val_idx, val in col_a.non_nulls():
11       weights[val_idx] += val * adj
12       if iter_count % threshold == 0:
13         weights.push()
14
15 @faasm_func
16 def sgd_main(n_workers, n_epochs):
17   for e in n_epochs:
18     args = divide_problem(n_workers)
19     c = chain(update, n_workers, args)
20     await_all(c)
21     ...
```

4.1 State Programming Model

Each DDO represents a single state value, referenced throughout the system using a string holding its respective state key.

Faaslets write changes from the local to the global tier by performing a *push*, and read from the global to the local tier by performing a *pull*. DDOs may employ push and pull operations to produce variable consistency, such as delaying updates in an eventually-consistent list or set, and may lazily pull values only when they are accessed, such as in a distributed dictionary. Certain DDOs are immutable, and hence avoid repeated synchronisation.

Listing 1 shows both implicit and explicit use of two-tier state through DDOs to implement stochastic gradient descent (SGD) in Python. The `weight_update` function accesses two large input matrices through the `SparseMatrixReadOnly` and `MatrixReadOnly` DDOs (lines 1 and 2), and a single shared weights vector using `VectorAsync` (line 3). `VectorAsync` exposes a `push()` function which is used to periodically push updates from the local tier to the global tier (line 13). The calls to `weight_update` are chained in a loop in `sgd_main` (line 19).

Function `weight_update` accesses a randomly assigned subset of columns from the training matrices using the `columns` property (lines 7 and 8). The DDO implicitly performs a pull operation to ensure that data is present, and only replicates the necessary subsets of the state values in the local tier—the entire matrix is not transferred unnecessarily.

Updates to the shared weights vector in the local tier are made in a loop in the `weight_update` function (line 11). It invokes the `push` method on this vector (line 13) sporadically to update the global tier. This improves performance and reduces network overhead, but introduces inconsistency between the tiers. SGD tolerates such inconsistencies and it does not affect the overall result.

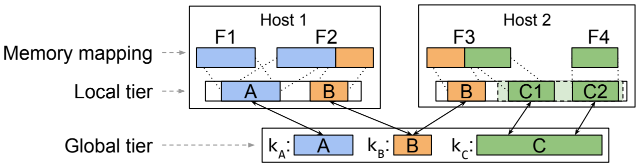

Figure 4: Faaslet two-tier state architecture

4.2 Two-Tier State Architecture

Faaslets represent state with a key/value abstraction, using unique *state keys* to reference *state values*. The authoritative state value for each key is held in the global tier, which is backed by a distributed key-value store (KVS) and accessible to all Faaslets in the cluster. Faaslets on a given host share a local tier, containing replicas of each state value currently mapped to Faaslets on that host. The local tier is held exclusively in Faaslet shared memory regions, and Faaslets do not have a separate local storage service, as in SAND [1] or Cloudburst [75].

Fig. 4 shows the two-tier state architecture across two hosts. Faaslets on host 1 share state value A; Faaslets on both hosts share state value B. Accordingly, there is a replica of state value A in the local tier of host 1, and replicas of state value B in the local tier of both hosts.

The `columns` method of the `SparseMatrixReadOnly` and `MatrixReadOnly` DDOs in Listing 1 uses *state chunks* to access a subset of a larger state value. As shown in Fig. 4, state value C has state chunks, which are treated as smaller independent state values. Faaslets create replicas of only the required chunks in their local tier.

Ensuring local consistency. State value replicas in the local tier are created using Faaslet shared memory (§3.3). To ensure consistency between Faaslets accessing a replica, Faaslets acquire a *local read lock* when reading, and a *local write lock* when writing. This locking happens implicitly as part of all state API functions, but not when functions write directly to the local replica via a pointer. The state API exposes the `lock_state_read` and `lock_state_write` functions that can be used to acquire local locks explicitly, e.g. to implement a list that performs multiple writes to its state value when atomically adding an element. A Faaslet creates a new local replica after a call to `pull_state` or `get_state` if it does not already exist, and ensures consistency through a write lock.

Ensuring global consistency. DDOs can produce varying levels of consistency between the tiers as shown by `VectorAsync` in Listing 1. To enforce strong consistency, DDOs must use *global read/write locks*, which can be acquired and released for each state key using `lock_state_global_read` and `lock_state_global_write`, respectively. To perform a consistent write to the global tier, an object acquires a global write lock, calls `pull_state` to update the local tier, applies its write to the local tier, calls `push_state` to update the global tier, and releases the lock.

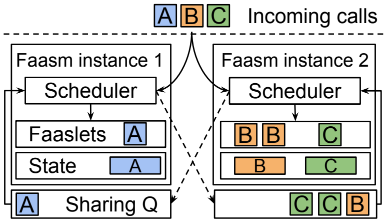

Figure 5: FAASM system architecture

5 FAASM Runtime

FAASM is the serverless runtime that uses Faaslets to execute distributed stateful serverless applications across a cluster. FAASM is designed to integrate with existing serverless platforms, which provide the underlying infrastructure, auto-scaling functionality and user-facing frontends. FAASM handles the scheduling, execution and state management of Faaslets. The design of FAASM follows a distributed architecture: multiple FAASM runtime instances execute on a set of servers, and each instance manages a pool of Faaslets.

5.1 Distributed Scheduling

A local scheduler in the FAASM runtime is responsible for the scheduling of Faaslets. Its scheduling strategy is key to minimising data-shipping (see §2) by ensuring that executed functions are co-located with required in-memory state. One or more Faaslets managed by a runtime instance may be *warm*, i.e. they already have their code and state loaded. The scheduling goal is to ensure that as many function calls as possible are executed by warm Faaslets.

To achieve this without modifications to the underlying platform's scheduler, FAASM uses a *distributed shared state* scheduler similar to Omega [71]. Function calls are sent round-robin to local schedulers, which execute the function locally if they are warm and have capacity, or share it with another warm host if one exists. The set of warm hosts for each function is held in the FAASM state global tier, and each scheduler may query and atomically update this set during the scheduling decision.

Fig. 5 shows two FAASM runtime instances, each with its own local scheduler, a pool of Faaslets, a collection of state stored in memory, and a sharing queue. Calls for functions A–C are received by the local schedulers, which execute them locally if they have warm Faaslets, and share them with the other host if not. Instance 1 has a warm Faaslet for function A and accepts calls to this function, while sharing calls to functions B and C with Instance 2, which has corresponding warm Faaslets. If a function call is received and there are no instances with warm Faaslets, the instance that received the call creates a new Faaslet, incurring a "cold start".

5.2 Reducing Cold Start Latency

While Faaslets typically initialise in under 10 ms, FAASM reduces this further using *Proto-Faaslets*, which are Faaslets that contain snapshots of arbitrary execution state that can be restored on any host in the cluster. From this snapshot, FAASM spawns a new Faaslet instance, typically reducing initialisation to hundreds of microseconds (§6.5).

Different Proto-Faaslets are generated for a function by specifying user-defined *initialisation code*, which is executed before snapshotting. If a function executes the same code on each invocation, that code can become initialisation code and be removed from the function itself. For Faaslets with dynamic language runtimes, the runtime initialisation can be done as part of the initialisation code.

A Proto-Faaslet snapshot includes a function's stack, heap, function table, stack pointer and data, as defined in the WebAssembly specification [35]. Since WebAssembly memory is represented by a contiguous byte array, containing the stack,heap and data, FAASM restores a snapshot into a new Faaslet using a copy-on-write memory mapping. All other data is held in standard C++ objects. Since the snapshot is independent of the underlying OS thread or process, FAASM can serialise Proto-Faaslets and instantiate them across hosts.

FAASM provides an *upload* service that exposes an HTTP endpoint. Users upload WebAssembly binaries to this endpoint, which then performs code generation (§3.4) and writes the resulting object files to a shared *object store*. The implementation of this store is specific to the underlying serverless platform but can be a cloud provider's own solution such as AWS S3 [6]. Proto-Faaslets are generated and stored in the FAASM global state tier as part of this process. When a Faaslet undergoes a cold start, it loads the object file and Proto-Faaslet, and restores it.

In addition, FAASM uses Proto-Faaslets to reset Faaslets after each function call. Since the Proto-Faaslet captures a function's initialised execution state, restoring it guarantees that no information from the previous call is disclosed. This can be used for functions that are *multi-tenant*, e.g. in a serverless web application. FAASM guarantees that private data held in memory is cleared away after each function execution, thereby allowing Faaslets to handle subsequent calls across tenants. In a container-based platform, this is typically not safe, as the platform cannot ensure that the container memory has been cleaned entirely between calls.

6 Evaluation

Our experimental evaluation targets the following questions: (i) how does FAASM state management improve efficiency and performance on parallel machine learning training? (§6.2) (ii) how do Proto-Faaslets and low initialisation times impact performance and throughput in inference serving? (§6.3) (iii) how does Faaslet isolation affect performance in a linear algebra benchmark using a dynamic language runtime? (§6.4) and (iv) how do the overheads of Faaslets compare to Docker containers? (§6.5)

6.1 Experimental Set-up

Serverless baseline. To benchmark FAASM against a state-of-the-art serverless platform, we use Knative [33], a container-based system built on Kubernetes [80]. All experiments are implemented using the same code for both FAASM and Knative, with a Knative-specific implementation of the Faaslet host interface for container-based code. This interface uses the same undelrying state management code as FAASM, but cannot share the local tier between co-located functions. Knative function chaining is performed through the standard Knative API. Redis is used for the distributed KVS and deployed to the same cluster.

FAASM integration. We integrate FAASM with Knative by running FAASM runtime instances as Knative functions that are replicated using the default autoscaler. The system is otherwise unmodified, using the default endpoints and scheduler.

Testbed. Both FAASM and Knative applications are executed on the same Kubernetes cluster, running on 20 hosts, all Intel Xeon E3-1220 3.1 GHz machines with 16 GB of RAM, connected with a 1 Gbps connection. Experiments in §6.5 were run on a single Intel Xeon E5-2660 2.6 GHz machine with 32 GB of RAM.

Metrics. In addition to the usual evaluation metrics, such as execution time, throughput and latency, we also consider *billable memory*, which quantifies memory consumption over time. It is the product of the peak function memory multiplied by the number and runtime of functions, in units of GB-seconds. It is used to attribute memory usage in many serverless platforms [5, 32, 39]. Note that all memory measurements include the containers/Faaslets and their state.

6.2 Machine Learning Training

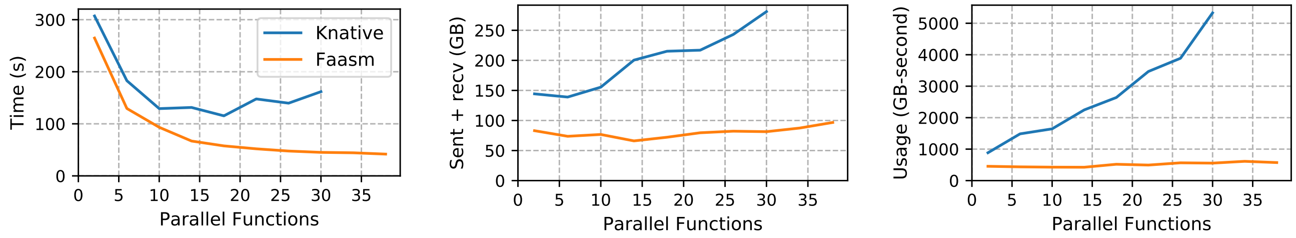
This experiment focuses on the impact of FAASM's state management on runtime, network overheads and memory usage.

We use distributed *stochastic gradient descent* (SGD) using the HOGWILD! algorithm [68] to run text classification on the Reuters RCV1 dataset [46]. This updates a central weights vector in parallel with batches of functions across multiple epochs. We run both Knative and FAASM with increasing numbers of parallel functions.

Fig. 6a shows the training time. FAASM exhibits a small improvement in runtime of 10% compared to Knative at low parallelism and a 60% improvement with 15 parallel functions. With more than 20 parallel Knative functions, the underlying hosts experience increased memory pressure and they exhaust memory with over 30 functions. Training time continues to improve for FAASM up to 38 parallel functions, at which point there is a more than an 80% improvement over 2 functions.

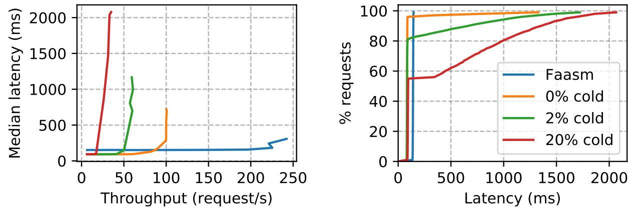
Fig. 6b shows that, with increasing parallelism, the volume of network transfers increases in both FAASM and Knative. Knative transfers more data to start with and the volume increase more rapidly, with 145 GB transferred with 2 parallel functions and 280 GB transferred with 30 functions. FAASM transfers 75 GB with 2 parallel functions and 100 GB with 38 parallel functions.

Fig. 6c shows that billable memory in Knative increases with more parallelism: from 1,000 GB-seconds for 2 func-



(a) Training time **(b) Network transfers** **(c) Memory usage**

Figure 6: Machine learning training with SGD with Faaslets (FAASM) and containers (Knative)



(a) Throughput vs. latency **(b) Latency CDF**

Figure 7: Machine learning inference with TensorFlow Lite

tions to over 5,000 GB-second for 30 functions. The billable memory for FAASM increases slowly from 350 GB-second for 2 functions to 500 GB-second with 38 functions.

The increased network transfer, memory usage and duration in Knative is caused primarily by data shipping, e.g. loading data into containers. FAASM benefits from sharing data through its local tier, hence amortises overheads and reduces latency. Further improvements in duration and network overhead come from differences in the updates to the shared weights vector: in FAASM, the updates from multiple functions are batched per host; whereas in Knative, each function must write directly to external storage. Billable memory in Knative and FAASM increases with more parallelism, however, the increased memory footprint and duration in Knative make this increase more pronounced.

To isolate the underlying performance and resource overheads of FAASM and Knative, we run the same experiment with the number of training examples reduced from 800K to 128. Across 32 parallel functions, we observe for FAASM and Knative: training times of 460 ms and 630 ms; network transfers of 19 MB and 48 MB; billable memory usage of 0.01 GB-second and 0.04 GB-second, respectively.

In this case, increased duration in Knative is caused by the latency and volume of inter-function communication through the Knative HTTP API versus direct inter-Faaslet communication. FAASM incurs reduced network transfers versus Knative as in the first experiment, but the overhead of these transfers in both systems are negligible as they are small and amortized across all functions. Billable memory is increased in Knative due to the memory overhead of each function container being 8 MB (versus 270 kB for each Faaslet). These improvements are negligible when compared with those derived from reduced data shipping and duplication of the full dataset.

6.3 Machine Learning Inference

This experiment explores the impact of the Faaslet initialisation times on cold-starts and function call throughput.

We consider a machine learning inference application because they are typically user-facing, thus latency-sensitive, and must serve high volumes of requests. We perform inference serving with TensorFlow Lite [78], with images loaded from a file server and classified using a pre-trained MobileNet [37] model. In our implementation, requests from each user are sent to different instances of the underlying serverless function. Therefore, each user sees a cold-start on their first request. We measure the latency distribution and change in median latency when increasing throughput and varying the ratio of cold-starts.

Figs. 7a and 7b show a single line for FAASM that covers all cold-start ratios. Cold-starts only introduce a negligible latency penalty of less than 1 ms and do not add significant resource contention, hence all ratios behave the same. Optimal latency in FAASM is higher than that in Knative, as the inference calculation takes longer due to the performance overhead from compiling TensorFlow Lite to WebAssembly.

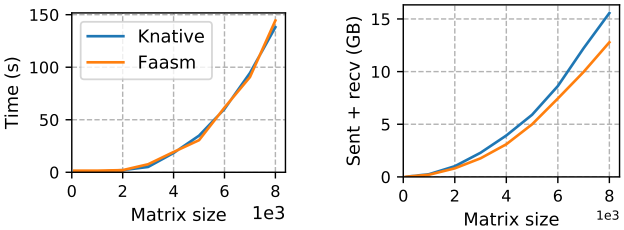
Fig. 7a shows that the median latency in Knative increases sharply from a certain throughput threshold depending on the cold-start ratio. This is caused by cold starts resulting in queuing and resource contention, with the median latency for the 20% cold-start workload increasing from 90 ms to over 2 s at around 20 req/s. FAASM maintains a median latency of 120 ms at a throughput of over 200 req/s.

Fig. 7b shows the latency distribution for a single function that handles successive calls with different cold-start ratios. Knative has a tail latency of over 2 s and more than 35% of calls have latencies of over 500 ms with 20% cold-starts. FAASM achieves a tail latency of under 150 ms for all ratios.

6.4 Language Runtime Performance with Python

The next two experiments (i) measure the performance impact of Faaslet isolation on a distributed benchmark using an existing dynamic language runtime, the CPython interpreter; and (ii) investigate the impact on a single Faaslet running compute microbenchmarks and a suite of Python microbenchmarks.

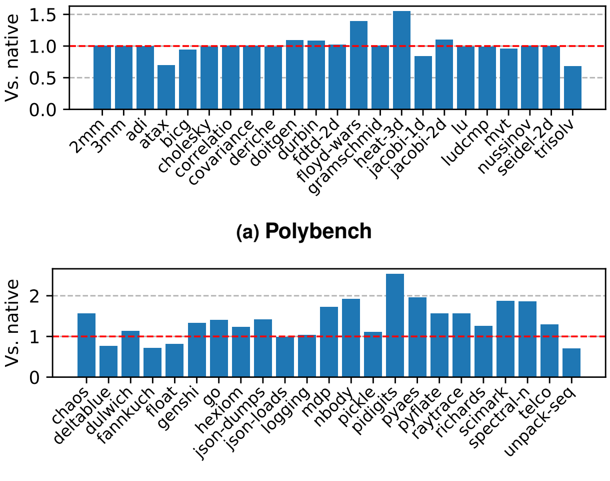
We consider a distributed divide-and-conquer matrix multiplication implemented with Python and Numpy. In the FAASM implementation, these functions are executed using



(a) **Duration**

(b) **Network transfer**

Figure 8: Comparison of matrix multiplication with Numpy



(a) **Polybench**

(b) **Python Performance Benchmark**

Figure 9: Performance of Faaslets with Python

CPython inside a Faaslet; in Knative, we use standard Python. As there is no WebAssembly support for BLAS and LAPACK, we do not use them in either implementation.

While this experiment is computationally intensive, it also makes use of the filesystem, dynamic linking, function chaining and state, thus exercising all of the Faaslet host interface. Each matrix multiplication is subdivided into multiplications of smaller submatrices and merged. This is implemented by recursively chaining serverless functions, with each multiplication using 64 multiplication functions and 9 merging functions. We compare the execution time and network traffic when running multiplications of increasingly large matrices.

Fig. 8a shows that the duration of matrix multiplications on FAASM and Knative are almost identical with increasing matrix sizes. Both take around 500 ms with 100×100 matrices, and almost 150 secs with 8000×8000 matrices. Fig. 8b shows that FAASM results in 13% less network traffic across all matrix sizes, and hence gains a small benefit from storing intermediate results more efficiently.

In the next experiment, we use Polybench/C [64] to measure the Faaslet performance overheads on simple compute functions, and the Python Performance Benchmarks [76] for overheads on more complex applications. Polybench/C is compiled directly to WebAssembly and executed in Faaslets; the Python code executes with CPython running in a Faaslet.

	Docker	Faaslets	Proto-Faaslets	vs. Docker
Initialisation	2.8 s	5.2 ms	0.5 ms	**5.6K**×
CPU cycles	251M	1.4K	650	**385K**×
PSS memory	1.3 MB	200 KB	90 KB	**15**×
RSS memory	5.0 MB	200 KB	90 KB	**57**×
Capacity	~8 K	~70 K	>100 K	**12**×

Table 3: Comparison of Faaslets vs. container cold starts (no-op function)

Fig. 9 shows the performance overhead when running both sets of benchmarks compared to native execution. All but two of the Polybench benchmarks are comparable to native with some showing performance gains. Two experience a 40%–55% overhead, both of which benefit from loop optimisations that are lost through compilation to WebAssembly. Although many of the Python benchmarks are within a 25% overhead or better, some see a 50%–60% overhead, with `pidigits` showing a 240% overhead. `pidigits` stresses big integer arithmetic, which incurs significant overhead in 32-bit WebAssembly.

Jangda et al. [41] report that code compiled to WebAssembly has more instructions, branches and cache misses, and that these overheads are compounded on larger applications. Serverless functions, however, typically are not complex applications and operate in a distributed setting in which distribution overheads dominate. As shown in Fig. 8a, FAASM can achieve competitive performance with native execution, even for functions interpreted by a dynamic language runtime.

6.5 Efficiency of Faaslets vs. Containers

Finally we focus on the difference in footprint and cold-start initialisation latency between Faaslets and containers.

To measure memory usage, we deploy increasing numbers of parallel functions on a host and measure the change in footprint with each extra function. Containers are built from the same minimal image (`alpine:3.10.1`) so can access the same local copies of shared libraries. To highlight the impact of this sharing, we include the proportional set size (PSS) and resident set size (RSS) memory consumption. Initialisation times and CPU cycles are measured across repeated executions of a no-op function. We observe the capacity as the maximum number of concurrent running containers or Faaslets that a host can sustain before running out of memory.

Tab. 3 shows several orders of magnitude improvement in CPU cycles and time elapsed when isolating a no-op with Faaslets, and a further order of magnitude using Proto-Faaslets. With an optimistic PSS memory measurement for containers, memory footprints are almost seven times lower using Faaslets, and 15× lower using Proto-Faaslets. A single host can support up to 10× more Faaslets than containers, growing to twelve times more using Proto-Faaslets.

To assess the impact of restoring a non-trivial Proto-Faaslet snapshot, we run the same initialisation time measurement for a Python no-op function. The Proto-Faaslet snapshot is a pre-initialised CPython interpreter, and the container uses a minimal `python:3.7-alpine` image. The container

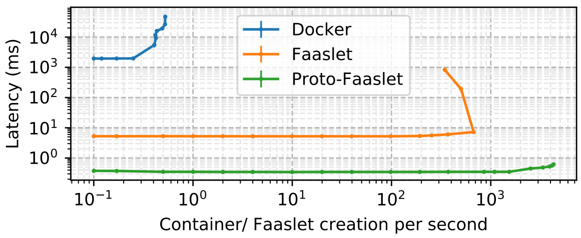


Figure 10: Function churn for Faaslets vs. containers

initialises in 3.2 s and the Proto-Faaslet restores in 0.9 ms, demonstrating a similar improvement of several orders of magnitude.

To further investigate cold-start initialisation times, we measure the time to create a new container/Faaslet at increasingly higher rates of cold-starts per second. We also measure this time when restoring the Faaslet from a Proto-Faaslet. The experiment executes on a single host, with the containers using the same minimal image.

Fig. 10 shows that both Faaslets and containers maintain a steady initialisation latency at throughputs below 3 execution/s, with Docker containers initialising in ~2 s and Faaslets in ~5 ms (or ~0.5 ms when restored from a Proto-Faaslet). As we increase the churn in Docker past 3 execution/s, initialisation times begin to increase with no gain in throughput. A similar limit for Faaslets is reached at around 600 execution/s, which grows to around 4000 execution/s with Proto-Faaslets.

We conclude that Faaslets offer a more efficient and performant form of serverless isolation than Docker containers, which is further improved with Proto-Faaslets. The lower resource footprint and initialisation times of Faaslets are important in a serverless context. Lower resource footprints reduce costs for the cloud provider and allow a higher packing density of parallel functions on a given host. Low initialisation times reduce cost and latency for the user, through their mitigation of the cold-start problem.

7 Related Work

Isolation mechanisms. Shreds [20] and Wedge [13] introduce new OS-level primitives for memory isolation, but focus on intra-process isolation rather than a complete executable as Faaslets do. Light-weight Contexts [48] and Picoprocesses [38] offer lightweight sandboxing of complete POSIX applications, but do not offer efficient shared state.

Common runtimes. Truffle [90] and GraalVM [26] are runtimes for language-independent bytecode; the JVM also executes multiple languages compiled to Java bytecode [21]. Despite compelling multi-language support, none offer multi-tenancy or resource isolation. GraalVM has recently added support for WebAssembly and could be adapted for Faaslets.

Autoscaling storage. FAASM's global state tier is currently implemented with a distributed Redis instance scaled by Kubernetes horizontal pod autoscaler [81]. Although this has not been a bottleneck, better alternatives exist: Anna [89] is a distributed KVS that achieves lower latency and more granular autoscaling than Redis; Tuba [9] provides an autoscaling KVS that operates within application-defined constraints; and Pocket [43] is a granular autoscaled storage system built specifically for a serverless environments. Crucial [12] uses Infinispan [52] to build its distributed object storage, which could also be used to implement FAASM's global state tier.

Distributed shared memory (DSM). FaRM [24] and RAMCloud [63] demonstrate that fast networks can overcome the historically poor performance of DSM systems [19], while DAL [60] demonstrates the benefits of introducing locality awareness to DSM. FAASM's global tier could be replaced with DSM to form a distributed object store, which would require a suitable consensus protocol, such as Raft [62], and a communication layer, such as Apache Arrow [65].

State in distributed dataflows. Spark [91] and Hadoop [74] support stateful distributed computation. Although focuses on fixed-size clusters and not fine-grained elastic scaling or multi-tenancy, distributed dataflow systems such as Naiad [58], SDGs [29] and CIEL [59] provide high-level interfaces for distributed state, with similar aims to those of distributed data objects—they could be implemented in or ported to FAASM. Bloom [2] provides a high-level distributed programming language, focused particularly on flexible consistency and replication, ideas also relevant to FAASM.

Actor frameworks. Actor-based systems such as Orleans [15], Akka [47] and Ray [55] support distributed stateful tasks, freeing users from scheduling and state management, much like FAASM. However, they enforce a strict asynchronous programming model and are tied to a specific languages or language runtimes, without multi-tenancy.

8 Conclusions

To meet the increasing demand for serverless big data, we presented FAASM, a runtime that delivers high-performance efficient state without compromising isolation. FAASM executes functions inside Faaslets, which provide memory safety and resource fairness, yet can share in-memory state. Faaslets are initialised quickly thanks to Proto-Faaslet snapshots. Users build stateful serverless applications with distributed data objects on top of the Faaslet state API. FAASM's two-tier state architecture co-locates functions with required state, providing parallel in-memory processing yet scaling across hosts. The Faaslet host interface also supports dynamic language runtimes and traditional POSIX applications.

Abstract

In modern server CPUs, individual cores can run at different frequencies, which allows for fine-grained control of the performance/energy tradeoff. Adjusting the frequency, however, incurs a high latency. We find that this can lead to a problem of *frequency inversion*, whereby the Linux scheduler places a newly active thread on an idle core that takes dozens to hundreds of milliseconds to reach a high frequency, just before another core already running at a high frequency becomes idle.

In this paper, we first illustrate the significant performance overhead of repeated frequency inversion through a case study of scheduler behavior during the compilation of the Linux kernel on an 80-core Intel® Xeon-based machine. Following this, we propose two strategies to reduce the likelihood of frequency inversion in the Linux scheduler. When benchmarked over 60 diverse applications on the Intel® Xeon, the better performing strategy, S_{move}, improves performance by more than 5% (at most 56% with no energy overhead) for 23 applications, and worsens performance by more than 5% (at most 8%) for only 3 applications. On a 4-core AMD Ryzen we obtain performance improvements up to 56%.

1 Introduction

Striking a balance between performance and energy consumption has long been a battle in the development of computing systems. For several decades, CPUs have supported Dynamic Frequency Scaling (DFS), allowing the hardware or the software to update the CPU frequency at runtime. Reducing CPU frequency can reduce energy usage, but may also decrease overall performance. Still, reduced performance may be acceptable for tasks that are often idle or are not very urgent, making it desirable to save energy by reducing the frequency in many use cases. While on the first multi-core machines, all cores of a CPU had to run at the same frequency, recent server CPUs from Intel® and AMD® make it possible to update the frequency of individual cores. This feature allows for much finer-grained control, but also raises new challenges.

One source of challenges in managing core frequencies is the *Frequency Transition Latency* (*FTL*). Indeed, transitioning a core from a low to a high frequency, or conversely, has an FTL of dozens to hundreds of milliseconds. FTL leads to a problem of *frequency inversion* in scenarios that are typical of the use of the standard POSIX `fork()` and `wait()` system calls on process creation, or of synchronization between lightweight threads in a producer-consumer application. The problem occurs as follows. First, a task T_{waker} running on core C_{waker} creates or unblocks a task T_{woken}. If the *Completely Fair Scheduler* (*CFS*), *i.e.*, the default scheduler in Linux, finds an idle core C_{CFS}, it will place T_{woken} on it. Shortly thereafter, T_{waker} terminates or blocks, because *e.g.*, it was a parent process that `fork`ed a child process and `wait`ed just afterwards, or because it was a thread that was done producing data and woke up a consumer thread as its last action before going to sleep. Now C_{waker} is idle and yet executing at a high frequency because it was running T_{waker} until recently, and C_{CFS}, on which T_{woken} is running, is likely to be executing at a low frequency because it was previously idle. Consequently, the frequencies at which C_{waker} and C_{CFS} operate are *inverted* as compared to the load on the cores. This frequency inversion will not be resolved until C_{waker} reaches a low frequency and C_{CFS} reaches a high frequency, *i.e.*, for the duration of the FTL. Current hardware and software DFS policies, including the `schedutil` policy [9] that was recently added to CFS cannot prevent frequency inversion as their only decisions consist in updating core frequencies, thus paying the FTL each time. Frequency inversion reduces performance and may increase energy usage.

In this paper, we first exhibit the problem of frequency inversion in a real-world scenario through a case study of the behavior of CFS when building the Linux kernel on a Intel® Xeon-based machine with 80 cores (160 hardware threads). Our case study finds repeated frequency inversions when processes are created through the `fork()` and `wait()` system calls, and our profiling traces make it clear that frequency inversion leads to tasks running on low frequency cores for a significant part of their execution.

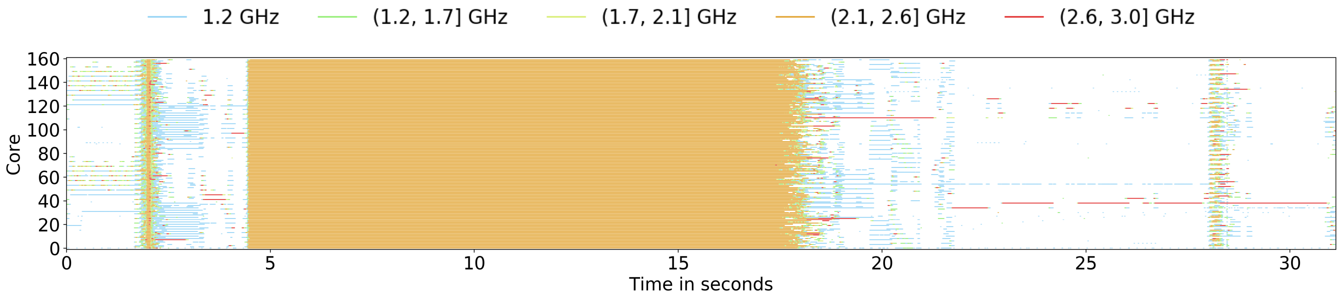

Figure 1: Execution trace when building the Linux kernel version 5.4 using 320 jobs.

Based on the results of the case study, we propose to address frequency inversion at the scheduler level. Our key observation is that the scheduler can avoid frequency inversion by taking core frequencies into account when placing a task on a core. For this, we propose and analyze two strategies. Our first strategy S_{local} is for the scheduler to simply place T_{woken} on C_{waker}, as frequency inversion involves a core C_{waker} that is likely at a high frequency, and may soon be idle. This strategy improves the kernel build performance. It runs the risk, however, that T_{waker} does not promptly terminate or block, causing a long wait before T_{woken} is scheduled. Accordingly, our second strategy S_{move} additionally arms a high-resolution timer when it places T_{woken} on C_{waker}, and if the timer expires before T_{woken} is scheduled, then T_{woken} is migrated to C_{CFS}, *i.e.*, the core CFS originally chose for it. Furthermore, even slightly delaying T_{woken} by placing it on C_{waker} is not worthwhile when C_{CFS} is above the minimum frequency. Thus, S_{move} first checks whether the frequency of C_{CFS} is above the minimum, and if so places T_{woken} on C_{CFS} directly.

The contributions of this paper are the following.

- The identification of the *frequency inversion* phenomenon, which leads to some idle cores running at a high frequency while some busy cores run at a low frequency for a significant amount of time.
- A case study, building the Linux kernel on an 80-core server, with independent per-core frequencies.
- Two strategies, S_{local} and S_{move}, to prevent frequency inversion in CFS. Implementing these policies only required minor code changes: 3 (resp. 124) lines were modified in the Linux kernel to implement S_{local} (resp. S_{move}).
- A comprehensive evaluation of our strategies on 60 diverse applications, including popular Linux benchmarks as well as applications from the Phoronix [23] and NAS [5] benchmark suites. The evaluation considers both the `powersave` CPU governor, which is currently used by default in Linux, and the experimental `schedutil` governor. It also considers two machines: a large 80-core Intel® Xeon E7-8870 v4 server and a smaller 4-core AMD® Ryzen 5 3400G desktop machine.

With the `powersave` governor on the server machine, we find that both S_{local} and S_{move} perform well overall: out of the 60 applications used in the evaluation, S_{local} and S_{move} improve the performance of 27 and 23 applications by more than 5% respectively, and worsen the performance of only 3 applications by more than 5%. In the best case, S_{local} and S_{move} improve application performance by 58% and 56% respectively with no energy overhead. However, S_{local} performs very poorly with two of the applications, even worsening performance by 80% in the worst case, which may not be acceptable for a general-purpose scheduler. S_{move} performs much better in the worst case: the increase in application execution time is only 8% and mitigated by a 9% improvement in terms of energy usage. Evaluation results with `schedutil` show that this governor does not address the frequency inversion issue, and exhibits several more cases in which S_{local} performs very poorly—while S_{move} again has much better worst-case performance. The evaluation on the desktop machine shows similar trends, albeit on a smaller scale. Again, S_{move} performs better than S_{local} on edge cases.

2 A Case Study: Building the Linux Kernel

We present a case study of the workload that led us to discover the frequency inversion phenomenon: building the Linux kernel version 5.4 with 320 jobs (`-j`) on a 4-socket Intel® Xeon E7-8870 v4 machine with 80 cores (160 hardware threads), with a nominal frequency of 2.1 GHz. Thanks to the Intel® SpeedStep and Turbo Boost technologies, our CPUs can individually vary the frequency of each core between 1.2 and 3.0 GHz. The frequency of the two hardware threads of a core is the same. In the rest of the paper, for simplicity, we use the term "core" for hardware threads.

Figure 1 shows the frequency of each core of the machine while the kernel build workload is running. This plot was produced with two tools that we have developed, SchedLog and SchedDisplay [10]. SchedLog collects the execution trace of an application with very low overhead. SchedDisplay produces a graphical view of such a trace. We have used SchedDisplay to generate all execution traces presented in this paper. SchedLog records the frequency information shown in

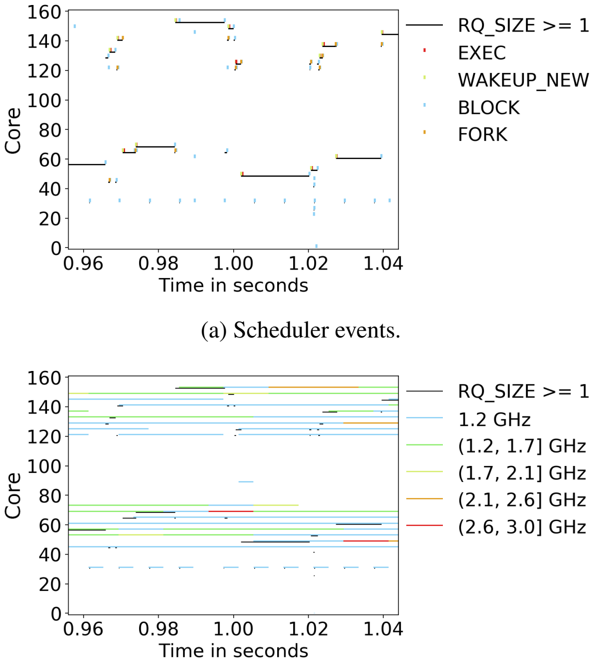
Figure 1 at each tick event (4ms in CFS). Consequently, the absence of a colored line in such traces means that ticks have been disabled by CFS on that core. CFS disables ticks on inactive cores to allow them to switch to a low-power state.

In Figure 1, we notice different phases in the execution. For a short period around 2 seconds, for a longer period between 4.5 and 18 seconds, and for a short period around 28 seconds, the kernel build has highly parallel phases that use all of the cores at a high frequency. The second of these three phases corresponds to the bulk of the compilation. In these three phases, the CPUs seem to be exploited to their maximum. Furthermore, between 22 and 31 seconds, there is a long phase of mostly sequential code with very few active cores, of which there is always one running at a high frequency. In this phase, the bottleneck is the CPU's single-core performance.

Between 0 and 4.5 seconds, and between 18 and 22 seconds however, there are phases during which all cores are used but they run at the CPU's lowest frequency (1.2 GHz). Upon closer inspection, these phases are actually mainly sequential: zooming in reveals that while all cores are used across the duration of the phase, only one or two cores are used at any given time. This raises two questions: why are so many cores used for a nearly sequential execution, and why are those cores running at such a low frequency.

We focus on the first couple of seconds where core utilization seems to be suboptimal. Zooming around 1 second, we first look at runqueue sizes and scheduling events, as illustrated in Figure 2a. We are in the presence of a pattern that is typical of mostly-sequential shell scripts: processes are created through the `fork()` and `exec()` system calls, and generally execute one after the other. These processes can easily be recognized on Figure 2a as they start with *WAKEUP_NEW* and *EXEC* scheduler events. After the process that runs on Core 56 blocks around the 0.96 s mark, three such short-lived processes execute one after the other on Cores 132, 140, and 65. After that, two longer-running ones run on Core 69 around the 0.98 s mark, and on Core 152 between the 0.98 s and 1.00 s mark. This pattern goes on for the entire duration of the execution shown in Figure 2a, with tasks created one after the other on Cores 148, 125, 49, 52, 129, 156, 60 and finally 145.

Looking at the core frequencies in the same part of the execution, as illustrated by Figure 2b, gives us a hint as to why cores are running slowly in this phase: there seems to be a significant delay between the time when a task starts running on a core, and the time when the core frequency starts increasing. For instance, between 1.00 s and 1.02 s, the task on Core 49 runs at a low frequency, and only when it is over at around 1.04 s does the frequency of the core rise to its maximum—before starting to decrease again almost instantly as the hardware notices that no task is running anymore on that core. The same issue can be observed shortly before 1.00 s on Core 152, and around 0.98 s on Core 69. In this last example, the core's frequency was even on a downward slope when the task started, and the frequency keeps going down even after the task ended before finally increasing again around 1.00 s. It appears that in the considered phase of the execution, the FTL is much higher than the duration of the tasks. Since tasks that follow each other tend to be scheduled on different cores, they are likely to always run at a low frequency as most cores are idle most of the time in this phase of the execution.



(a) Scheduler events.

(b) Core frequencies.

Figure 2: Zoom over a sparse region of Figure 1.

To confirm our intuition about the FTL, we develop a fine-grained tool [1] to monitor the frequency of a single core around the execution of an isolated busy loop, using the `powersave` governor. As shown in Figure 3, the task runs for 0.20 s, as illustrated by the *start* and *end* vertical lines in the figure. It takes an FTL of 29 ms for the core to go from its minimum frequency of 1.25 GHz to its maximum frequency of 3.00 GHz in order to accommodate the task. When the task ends, it takes approximately 10 ms for the core to go back to its initial frequency, but the duration of the FTL is compounded by the fact that the frequency tends to bounce back several times for around 98 ms before stabilizing at the core's lowest frequency. These measurements are consistent with our interpretation of Figure 2b: a FTL of several dozens of milliseconds is significantly longer than the execution of the tasks that are visible in the figure, as the longest task runs for around 20 ms between the 1.00 s and 1.02 s marks. Note that the duration of the FTL is mainly due to the time for the hardware to detect a load change and then decide to change the frequency. Previous work [22] shows that the actual latency for the core to change its frequency is only

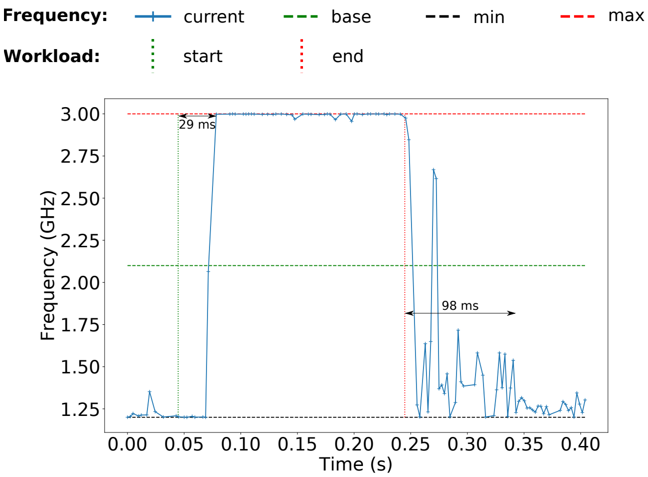


Figure 3: FTL for the Xeon E7-8870 v4 CPU.

tens of microseconds on Intel® CPUs.

Coming back to Figure 2a, the phenomenon we have been observing is the following. Computations in the (near) sequential phases of the build of Linux are launched sequentially as processes through the `fork()` and `wait()` system calls, and the execution of these computations is shorter than the FTL. Consequently, cores speed up after they have performed a computation, even though at that point, computation has moved to newly `fork`ed processes, which are likely to run on cores that were not recently used if the machine is not very busy. Indeed, CFS often selects different cores for tasks to wake up on, and if most cores are idle, it is likely that the selected cores were not used recently, and therefore run at a low frequency. The tasks that initiated the `fork()` perform `wait()` operations shortly afterwards, which means that the frequency increase they initiated is mostly wasted. We are in the presence of recurring *frequency inversion*, which is caused by a very common scenario: launching a series of sequential processes, as is commonly done in a shell script.

Sequential creation of processes through the `fork()` and `wait()` system calls is not the only cause of recurring frequency inversion. This phenomenon can also occur with lightweight threads that unblock and block each other, as is common in producer-consumer applications. Indeed, the CFS code that selects a core for a new task to wake up on is also used to select a core for already existing tasks that wake up. Note that CFS does not use different code paths depending on the type of task, namely, a process or a thread.

3 Strategies to Prevent Frequency Inversion

Since frequency inversion is the result of scheduling decisions, we believe it must be addressed at the scheduler level. In our experience, every change to the scheduler may have unpredictable consequences on some workloads, and the more complex the change, the less predictable the consequences. Therefore, proposing extensive or complex changes to the scheduler, or a complete rewrite, would make it unclear where performance gains come from. Striving for minimal, simple changes allows for an apples-to-apples comparison with CFS.

We propose two strategies to solve the frequency inversion problem. The first one is a simple strategy that offers good performance but suffers from large performance degradations in some scheduling scenarios. The second solution aims to have the same benefits as the first solution while minimizing worst cases at the expense of some simplicity.

3.1 Placing Threads Locally

The first strategy that we propose to prevent frequency inversion is S_{local}: when a thread is created or unblocked, it is placed on the same core as the process that created or unblocked it. In the context of creating a single process through the `fork()` and `wait()` system calls, this strategy implies that the created process is more likely to run on a high-frequency core, as the frequency of the core may already be high due to the activity of the parent. Furthermore, the duration in which there are two processes running on the same core will be limited, if the parent process calls `wait()` shortly afterwards. In the context of a producer-consumer application, when a producer thread wakes up a consumer thread, this strategy again implies that the consumer thread is more likely to run on a high-frequency core, and the duration in which there are two processes running on the same core will again be limited, if the last action of the producer is to wake up the consumer before blocking or terminating.

However, there are cases in which S_{local} might hurt performance: if the task that created or woke another task does not block or terminate quickly afterwards, the created or woken task will wait for the CPU resource for a certain period of time. This issue is mitigated by the periodic load balancer of the Linux scheduler that will migrate one of the tasks to another less loaded core. However, waiting for the next load balancing event might be quite long. In CFS, periodic load balancing is performed hierarchically, with different periods: cores in the same cache domain are more frequently balanced than cores on different NUMA nodes. These periods can vary from 4 to hundreds of milliseconds on large machines.

S_{local} significantly changes the behavior of CFS by fully replacing its thread placement strategy. Additionally, the aforementioned shortcomings make it a high risk solution for certain workloads. Both issues make this solution unsatisfactory given the prerequisites that we previously set.

3.2 Deferring Thread Migrations

In order to fix core oversubscription without waiting for periodic load balancing, we propose a second strategy, S_{move}. With vanilla CFS, when a thread is created or woken, CFS

CPU vendor	Intel®	AMD®
CPU model	Xeon E7-8870 v4	Ryzen 5 3400G
Cores (SMT)	80 (160)	4 (8)
Min freq	1.2 GHz	1.4 GHz
Base freq	2.1 GHz	3.7 GHz
Turbo freq	3.0 GHz	4.2 GHz
Memory	512 GB	8 GB
OS	Debian 10 (buster)	Arch Linux

Table 1: Configurations of our experimental machines.

decides on which core it should run. S_{move} defers the use of this chosen core to allow waking threads to take advantage of a core that is more likely to run at a high frequency.

Let T_{woken} be the newly created or waking task, C_{waker} the core where task T_{waker} that created or woke T_{woken} is running and C_{CFS} the destination core chosen by CFS. The normal behavior of the scheduler is to directly enqueue task T_{woken} into C_{CFS}'s runqueue. We propose to delay this migration to allow T_{woken} to be more likely to use a high-frequency core if C_{CFS} is running at a low frequency. First, if C_{CFS} is running at a frequency higher than the CPU's minimum one, we enqueue T_{woken} in C_{CFS}'s runqueue. Otherwise, we arm a high-resolution timer interrupt that will perform the migration in D μs and we enqueue T_{woken} into C_{waker}'s runqueue.The timer is cancelled if T_{woken} is scheduled on C_{waker}.

The rationale behind S_{move} is that we want to avoid waking low frequency cores if the task can be performed quickly when placed locally on a core that is likely to run at a high frequency. Indeed, T_{waker} is running at the time of the placement, meaning that C_{waker} is likely to run at a high frequency. The delay D can be changed at run time by writing to a parameter file in the `sysfs` pseudo file system. We have chosen a default value of 50 μs, which is close to the delay between a fork and a wait system call during our Linux kernel build experiments. We have found that varying the value of this parameter between 25 μs and 1 ms has insignificant impact on the benchmarks used in Section 4.

4 Evaluation

This section aims to demonstrate that our strategies improve performance on most workloads, while not degrading energy consumption. We run a wide range of applications from the Phoronix benchmark suite [23], the NAS benchmark suite [5], as well as other applications, such as `hackbench` (a popular benchmark in the Linux kernel scheduler community) and `sysbench OLTP` (a database benchmark). These experiments are run on a server-grade 4-socket NUMA machine with an 80-core Intel® CPU and on a desktop machine equipped with a 4-core AMD® CPU (Table 1). Both CPUs can select independent frequencies for each core[1] We have implemented S_{local} and S_{move} in the latest LTS kernel, Linux 5.4, released in November 2019 [3], and compare our strategies to Linux 5.4.

Implementing S_{local} (resp. S_{move}) only required modifying 3 (resp. 124) lines in CFS. We run all experiments 10 times. Energy consumption is evaluated on both machines using the Intel® RAPL [19] feature, which measures the energy consumption of the CPU socket and the DRAM. The performance results are those reported by each benchmark, and thus they involve different metrics, such as execution time, throughput, or latency, with inconsistent units. For better readability, all the following graphs show the improvement in terms of performance and energy usage compared to the mean of the runs with CFS. Therefore, higher is always better, regardless of the measured unit. The mean of the results for CFS is displayed on top of the graph for all benchmarks with the benchmark's unit.

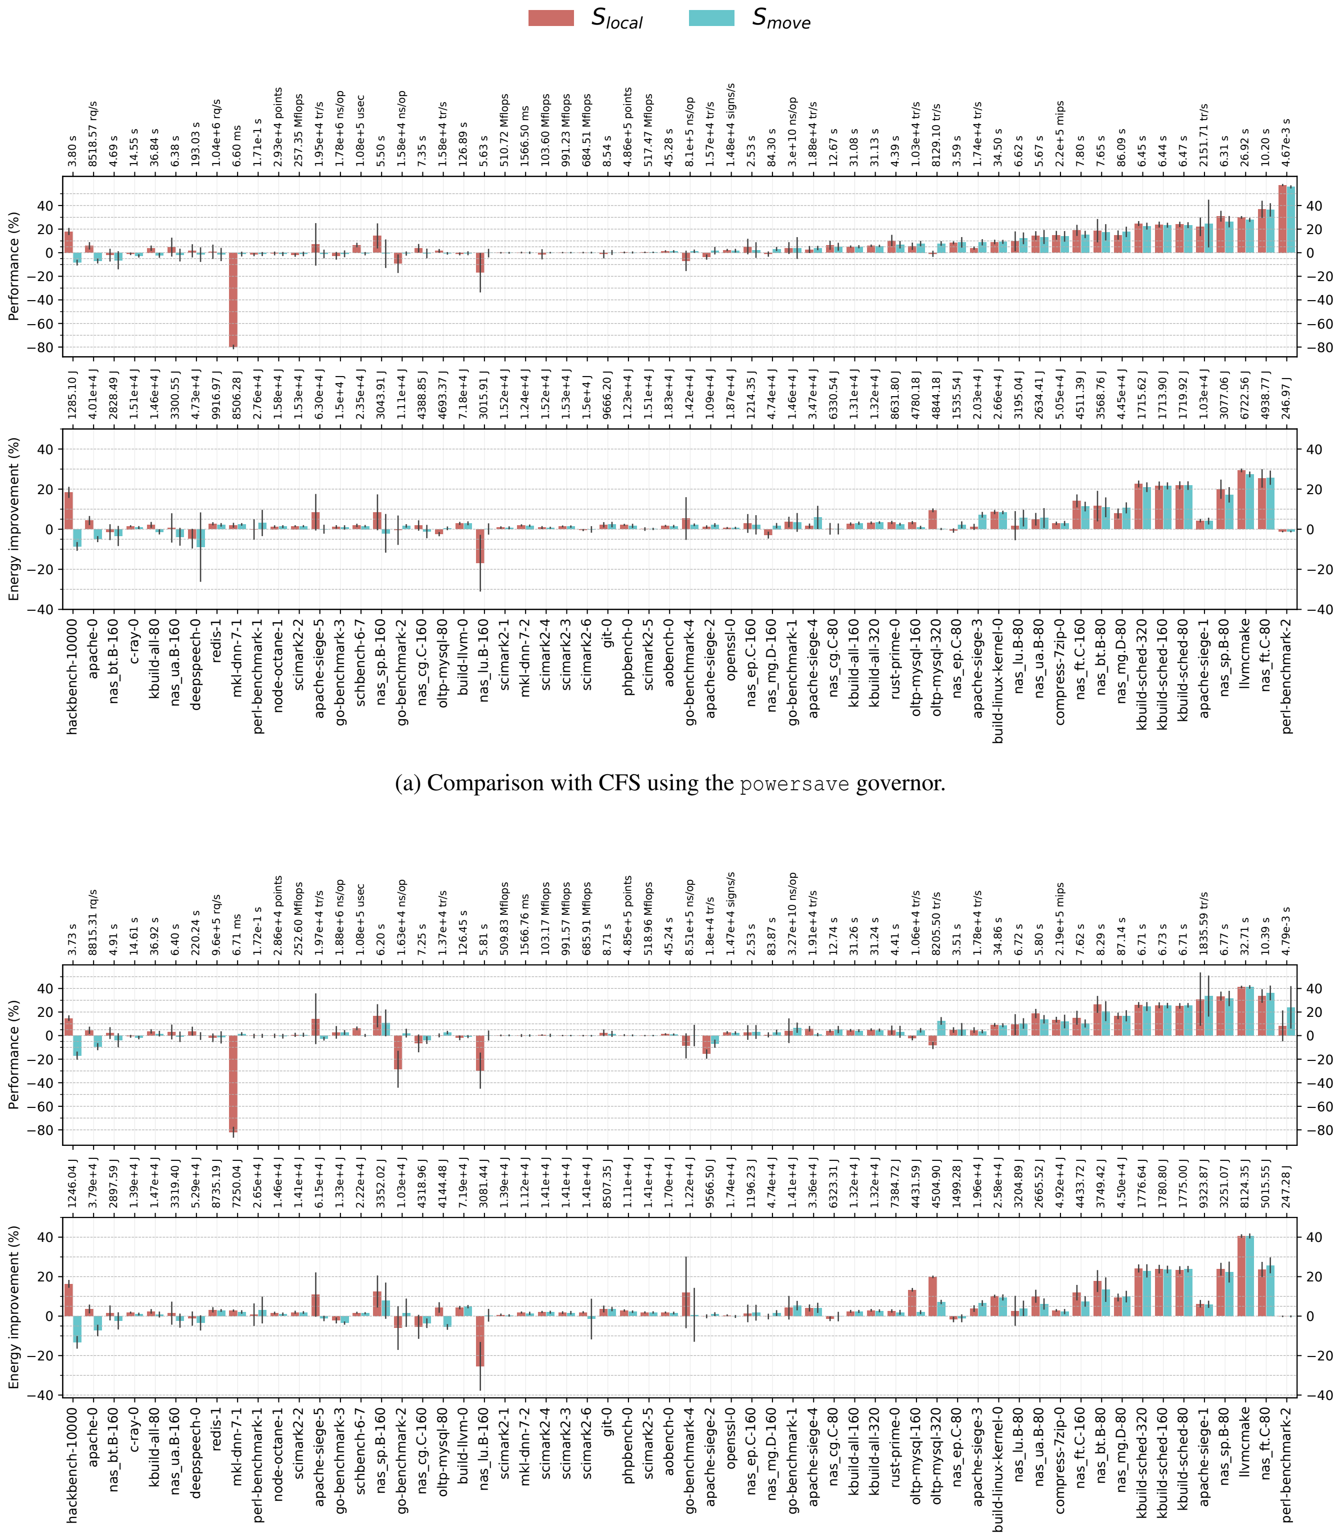
In Linux, frequency is controlled by a subsystem called a *governor*. On modern Intel® hardware, the `powersave` governor delegates the choice of the frequency to the hardware since it can perform more fine-grained adjustments. The hardware frequency-selection algorithm tries to save energy with a minimal impact on performance. The hardware estimates the load of a core based on various heuristics such as the number of retired instructions. This is the default governor for Intel® hardware on most Linux distributions. The `schedutil` governor, in development by the Linux community since Linux 4.7 (July 2016), tries to give control back to the operating system. It uses the internal data of the kernel scheduler, CFS, to estimate the load on each core, and changes the frequency accordingly. Two other governors, `performance` and `ondemand`, are available in Linux but are of no interest to us: the former runs all cores at the highest frequency, thus disabling dynamic scaling, while the latter is not supported on modern Intel® processors. To demonstrate that our work is orthogonal to the used governor, we evaluate our strategies using both `powersave` and the `schedutil`.

We first present the complete results on the Intel® server and summarize the results on the AMD® desktop machine. We then revisit our kernel build case study and study some worst case results (`mkl`, `hackbench`). Finally, we discuss the overhead of our S_{move} strategy.

4.1 Execution Using `powersave`

We first consider the execution under `powersave`. Figure 4a shows the improvement in terms of performance and energy consumption of S_{local} and S_{move} as compared to CFS. We consider that improvements or deteriorations that do not exceed 5% to be on par with CFS.

[1] This is different from turbo frequencies: many desktop and laptop CPUs have per-core DFS in order to support turbo frequencies, but in practice, all cores not using the turbo range run at the same frequency.



(a) Comparison with CFS using the `powersave` governor.

(b) Comparison with CFS using the `schedutil` governor.

Figure 4: Performance and energy consumption improvement w.r.t. Linux 5.4 on the server machine (higher is better).

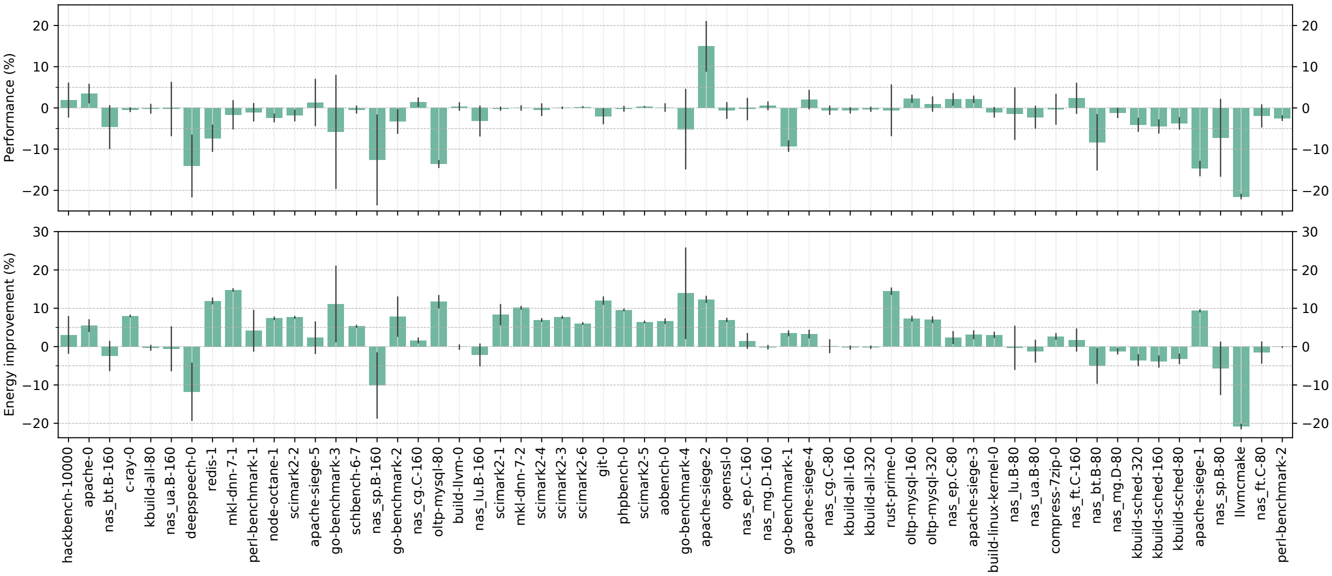


Figure 5: Performance of `schedutil` compared to `powersave` with CFS on the server machine.

Performance. Both S_{local} and S_{move} perform well overall with respectively 27 and 23 out of 60 applications outperforming CFS. The best results for these policies are seen, as expected, on benchmarks that extensively use the `fork/wait` pattern, and therefore exhibit a large number of frequency inversions. In the best case, S_{local} and S_{move} gain up to 58% and 56% respectively on `perl-benchmark-2`, that measures the startup time of the `perl` interpreter. This benchmark benefits greatly from avoiding frequency inversions since it mostly consists of `fork/wait` patterns. In terms of performance losses, both strategies deteriorate the performance of only 3 applications, but on very different scales. S_{local} deteriorates `mkl-dnn-7-1` by 80% and `nas_lu.B-160` by 17% while S_{move} has a worst case deterioration of 8.4% on `hackbench`.

Energy consumption. Overall, both S_{local} and S_{move} improve energy usage. Out of our 60 applications, we improve energy consumption by more than 5% for 16 and 14 applications, respectively, compared to CFS. Most of the improvements are seen on benchmarks where performance is also improved. In these cases, the energy savings are likely mostly due to the shorter execution times of the applications. However, we also see some improvements on applications where the performance is on par with that on CFS. This is due to the fact that we avoid waking up cores that are in low power states, therefore saving the energy necessary to power up and run those cores. In terms of loss, S_{local} consumes more energy than CFS on only one application, `nas_lu.B-160`. This loss is explained by the bad performance of S_{local} on this application. This benchmark's metric is its execution time, and increasing the execution time without correspondingly reducing the frequency increases the energy consumption. S_{move} consumes more energy than CFS on two applications: `hackbench`, because of the performance loss, and `deepspeech` that has too high a standard deviation for its results to have significance.

Overall score. To compare the overall impact of our strategies, we compute the geometric mean of all runs, where each run is normalized to the mean result of CFS. S_{move} has a performance improvement of 6%, a reduction in energy usage of 3% and an improvement of 4% with both metrics combined. S_{local} has similar overall scores (always 5%), but its worst cases suggest that S_{move} is a better option for a general-purpose scheduler. These small differences are expected because most of the applications we evaluate perform similarly with CFS and with our strategies. We also evaluate the statistical significance of our results with a t-test. With p-values of at most $3 \cdot 10^{-20}$, we deem our results statistically significant.

4.2 Execution Using `schedutil`

Next, we consider execution under the `schedutil` governor. As a baseline, Figure 5 first shows the performance and energy improvements of the `schedutil` governor compared to the `powersave` governor with CFS. Overall, we observe that the `schedutil` governor deteriorates the performance of most applications while improving energy usage. This indicates that this new governor is more aggressive in terms of power savings than the one implemented in hardware. We omit raw values since they are already available in Figures 4a and 4b. Figure 4b then shows the improvement in terms of performance and energy consumption of our strategies compared to CFS, when using the `schedutil` governor.

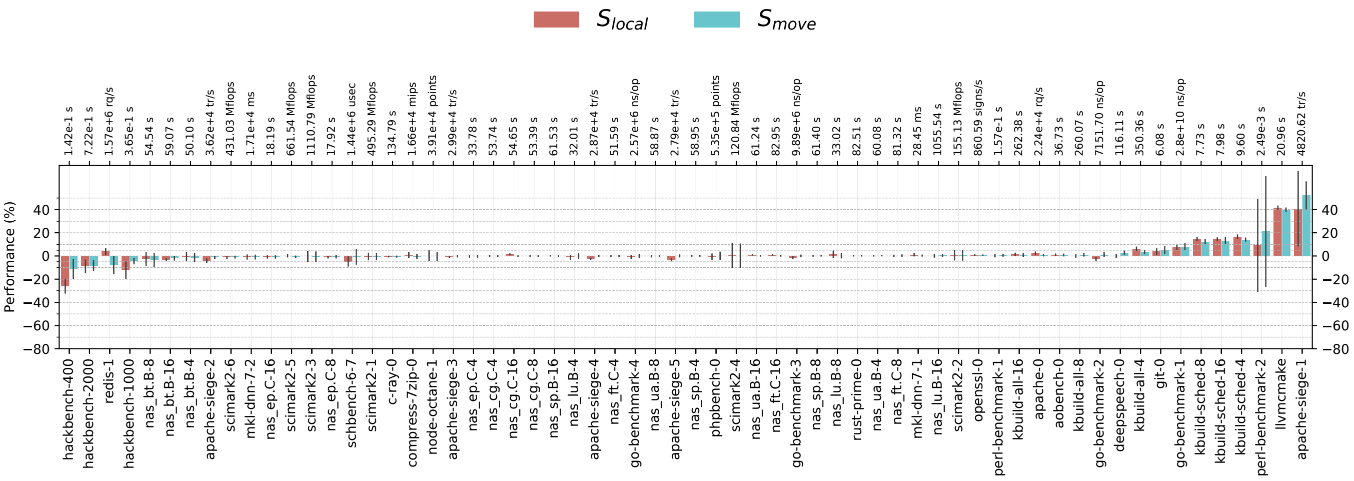

Figure 6: Performance improvement w.r.t. Linux 5.4 on the desktop machine (higher is better).

Performance. S_{local} and S_{move} outperform CFS on 22 and 20 applications out of 60 respectively. The applications concerned are the same that were improved with the `powersave` governor. In terms of performance losses, however, S_{local} is more impacted by the `schedutil` governor than S_{move}, with 7 applications performing worse than CFS versus only 2.

Energy consumption. The overall improvement in terms of energy usage of `schedutil` with CFS would suggest that we might see the same trend with S_{local} and S_{move}. And indeed, the results are quite similar to what we observe with the `powersave` governor.

Overall score. The geometric means with this governor are the following for `schedutil` and S_{move}: 6% for performance, 4% for energy and 5% with both metrics combined. S_{local} has similar results (2%, 6% and 4% respectively), but the worst cases are still too detrimental for a general-purpose scheduler. These results are also statistically significant with p-values of at most $3 \cdot 10^{-20}$.

4.3 Evaluation on the Desktop Machine

We also evaluate our strategies on the smaller 4-core AMD® desktop CPU presented in Table 1. In contrast to Intel® CPUs, the `powersave` governor on AMD® CPUs always uses the lowest available frequency, making it unusable in our context. We therefore use the `schedutil` governor on this machine.

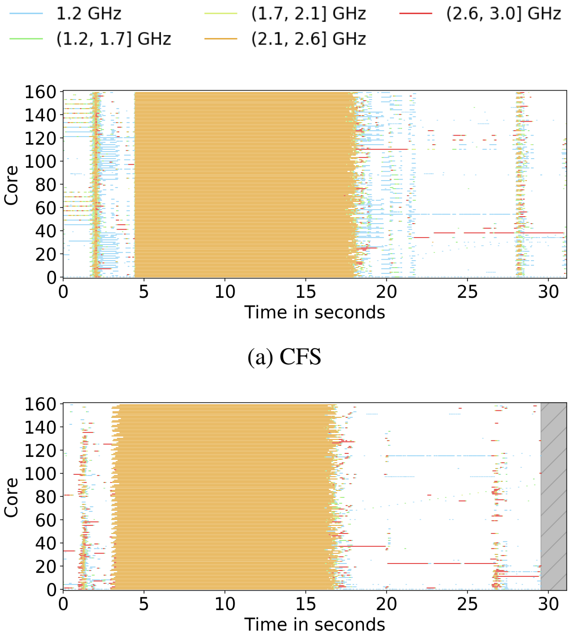
As shown in Figure 6, we observe the same general trend as on our server machine. S_{local} and S_{move} behave similarly when there is improvement, and S_{move} behaves better on the few benchmarks with performance degradation. We measure at worst an 11% slowdown and at best a 52% speedup for S_{move}, with an aggregate performance improvement of 2%. Additionally, S_{move} improves the performance of 7 applications by more than 5% while only degrading the performance of 4 applications at the same scale. The S_{local} strategy gives the same results regarding the number of improved and degraded applications, but suffers worse edge cases. Its best performance improvement is 42% while its worst deterioration is 25%, with an aggregate performance improvement of 1%. We conclude that even if there is no major global improvement, S_{move} is still a good strategy to eliminate frequency inversions on machines with smaller core counts. Our performance results are statistically significant, with p-values of $5 \cdot 10^{-4}$ for S_{move} and $3 \cdot 10^{-2}$ for S_{local}.

In terms of energy consumption, both S_{local} and S_{move} seem to have little to no impact as compared to CFS. However, the measures we were able to gather with all three strategies had a large variance that we did not observe on our Intel® CPU. We suspect that this is due to the energy-related hardware counters available on AMD® processors or the lack of good software support for these counters.

4.4 In-Depth Analysis

We now present a detailed analysis of specific benchmarks that either performed particularly well or particularly poorly with our solutions. In this section all traces were obtained with the `powersave` governor.

`kbuild` Figure 7 shows the execution of the build of the Linux kernel as presented in the case study, with CFS (top) and S_{move} (bottom). During the mostly sequential phases with multiple cores running at a low frequency on CFS (0-2 s, 2.5-4.5 s, 17-22 s), S_{move} uses fewer cores at a higher frequency. This is mainly due to the `fork()`/`wait()` pattern: as the waker thread calls `wait()` shortly after the `fork()`, the S_{move} timer does not expire and the woken threads remain on the local core running at a high frequency, thus avoiding fre-



(a) CFS

(b) S_{move}

Figure 8: Execution trace when building the `sched` directory of the Linux kernel version 5.4 using 320 jobs.

quency inversion. As a result, for example, the phase before the long parallel phase is executed in 4.4 seconds on CFS and in only 2.9 seconds with S_{move}.

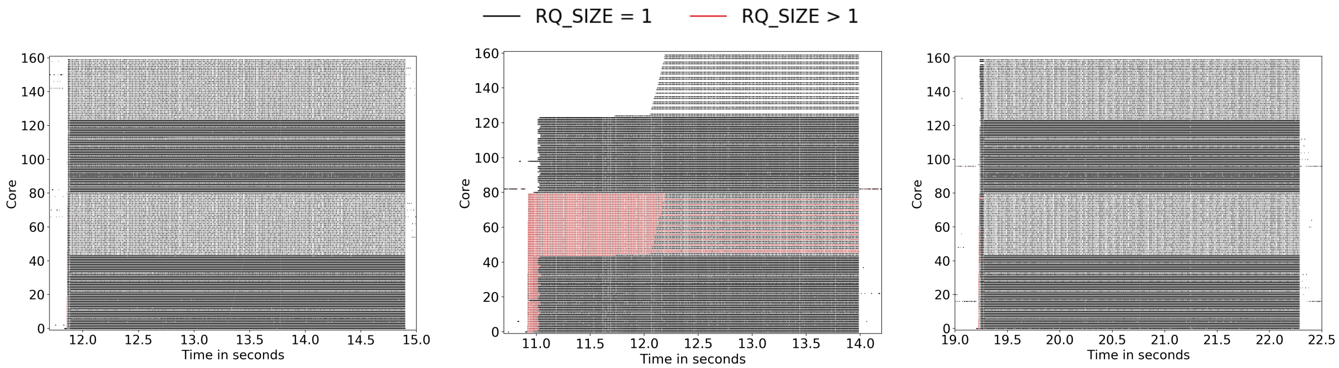
To understand the impact of S_{move} better, Figure 8 shows the `kbuild-sched-320` benchmark, which builds only the scheduler subsystem of the Linux kernel. Here, the parallel phase is much shorter than with a complete build, as there are fewer files to compile, making the sequential phases of the execution more visible. Again, we see that fewer cores are used, at a higher frequency.

`mkl` The `mkl-dnn-7-1` benchmark is the worst-case scenario for S_{local}: all threads keep blocking and unblocking and therefore avoid periodic load balancing and continue returning to the same set of cores. Thus, threads that are sharing a core with another thread will tend to remain there with the S_{local} strategy. Figure 9 shows the number of threads on the runqueue of each core with all three schedulers with the `powersave` governor. A black line indicates that there is one thread in the runqueue, and a red line indicates that there is more than one. CFS spreads the threads on all cores rapidly, and achieves a balanced machine with one thread per core in less than 0.2 seconds. On the other hand, S_{local} tries to maximize core reuse and oversubscribes 36 cores. This leads to never using all cores, achieving at most 85% CPU utilization with multiple cores overloaded. This is a persistent violation of the *work-conservation* property, as defined by Lozi *et al.* [21], *i.e.*, no core is idle if a core has more than one thread in its runqueue.

Interestingly, in our experiment, the balancing operations that spread threads are due to system or daemon threads (e.g. `systemd`) that wake up and block immediately, thus triggering an idle balancing from the scheduler. On a machine with nothing running in the background, we could have stayed in an overloaded situation for a long period of time, as ticks are deactivated on idle cores, removing opportunities for periodic balancing. We can see the same pattern on `nas-lu.B-160`, another benchmark that does not work well with S_{local}. S_{move} solves the problem by migrating, after a configurable delay, the threads that overload cores to available idle cores.

`hackbench` The `hackbench-10000` benchmark is the worst application performance-wise for the S_{move} strategy. This micro-benchmark is particularly stressful for the scheduler, with 10,000 running threads. However, the patterns exhibited are interesting to better understand the shortcomings of S_{move} and give insights on how to improve our strategies.

This benchmark has three phases: thread creation, communication and thread termination. Figure 10 shows the frequency of all cores during the execution of `hackbench` with CFS, S_{local} and S_{move}. The first phase corresponds to the first two seconds on all three schedulers. A main thread creates 10,000 threads with the `fork()` system call, and all child threads immediately wait on a barrier. With CFS, child threads are placed on idle cores that become idle again when the threads arrive at the barrier. This means that all cores remain



(a) CFS

(b) S_{local}

(c) S_{move}

mostly idle. This also leads to the main thread remaining on the same core during this phase. However, S_{local} and S_{move} place the child threads locally, causing oversubscription of the main thread's core and migrations by the load balancer. The main thread itself is thus sometimes migrated from core to core. When all threads are created, the main thread releases the threads waiting on the barrier and waits for their termination, thus beginning the second phase. During this phase, the child threads communicate by reading and writing in pipes. CFS tries to even out the load between all cores, but its heuristics give a huge penalty to migrations across NUMA nodes, so a single node runs at a high frequency (cores 0, 4, 8, etc. share the same node on our machine) while the others have little work to perform and run at lower frequencies. This phase finishes at 2.8 seconds. The remainder of the execution is the main thread reaping its children and terminating.

S_{local} packs threads aggressively, leading to long runqueues in the second phase, and therefore facilitating load balancing across nodes because of the large induced overload. However, S_{local} still does not use all cores, mainly avoiding running on hyperthreaded pairs of cores (cores n and $n+80$ are hyperthreaded on our machine). S_{local} runs the second phase faster than CFS, terminating it at 2.5 seconds, because it uses half of the cores at a high frequency all the time, and many of the other cores run at a medium frequency.

On the other hand, S_{move} performs poorly in the second phase, completing it at 3.4 seconds. The behavior seems very close to that of CFS, with one core out of four running at a high frequency. However, S_{move} results in more idleness or low frequency on the other cores. This is due to S_{move} placing threads locally: many threads contend for the local core; some are able to use the resource while others are migrated when the timer interrupt is triggered. The delays cause idleness compared to CFS, and the migrations leave cores idle, lowering their frequency compared to S_{local}. Additionally, when threads are migrated because of timers expiring, they are all placed on the same core, and oversubscribe it. For `hackbench`, choosing the middle ground is the worst strategy. We can also note that load balancing is not able to mitigate this situation because of the high volatility of this workload. This problem was also demonstrated by Lozi et al. [21] on a database application.

This hackbench setup is an extreme situation that is unlikely to happen in real life, with a largely overloaded machine (10,000 threads) and a highly volatile application. This microbenchmark is only interesting to study the behavior of our strategies. Still, overall, S_{move} gives better performance than S_{local}.

4.5 Scheduling Overhead of S_{move}

S_{move} is more complex than S_{local}, and so we analyze its overhead as compared to CFS, as an upper bound for our strategies. We identify two possible sources of overhead: querying frequency and using timers.

First, we evaluate the cost of querying the core frequency. Querying the frequency of a core mostly consists in reading two hardware registers and performing some arithmetic operations, as the current frequency is the division of these two registers times the base frequency of the CPU. Even though this is a very small amount of computation compared to the rest of the scheduler, we minimize it furthermore by querying this information at every tick instead of every time it is needed. In our benchmarks, we notice no difference in performance with or without querying the frequency at every tick.

Second, we evaluate the cost of triggering a large number of timers in the scheduler. To do so, we run schbench on two versions of Linux: the vanilla 5.4 kernel and a modified version with timers armed under the same condition as S_{move}. Here, however, the timer handler does not migrate the thread as in S_{move}. We choose schbench because it performs the same workload as hackbench but provides, as a performance evaluation, the latencies of the messages sent through pipes instead of the completion time. Table 2 shows the results of this benchmark. Overall, the 99.5^{th} percentile of latencies is the same for both versions of the kernel, except for 256 threads where timers have a negative impact. We can also observe that the number of timers triggered increases with the number of threads but drops after 256 threads. This behavior is expected: more threads means more wake-ups, but when the machine starts being overloaded, all cores run at high frequencies, and the timers are less frequently armed. This tipping point arrives around 256 threads because schbench threads constantly block, meaning that typically fewer than 160 threads are runnable at a time.

5 Discussion

As previously stated, our proposed solutions S_{local} and S_{move} are purposefully simple. We now discuss other more complex solutions to the frequency inversion problem.

Threads	Latency		Timers triggered
	vanilla	with timers	
64	78	77	2971
128	86	84	13910
192	119	144	63965
256	2292	3188	93001
512	36544	36544	512
768	60224	60480	959
1024	76416	76928	1290

Table 2: schbench latencies (99.5^{th} percentile, in μsec) and number of timers triggered.

High frequency pool. A possible solution would be to keep a pool of cores running at a high frequency even though no thread is running on them. This would allow threads to be placed on an idle core running at a high frequency instantaneously. This pool could, however, waste energy and reduce the maximal frequency attainable by busy cores, which diminishes when the number of active cores increases.

Tweaking the placement heuristic. We could add a new frequency heuristic to the existing placement strategy. However, the tradeoff between using a core running at a higher frequency and e.g., cache locality is not clear, and may vary greatly according to the workload and the architecture.

Frequency model. The impact of the frequency of one core on the performance of other cores is hardware-specific. If the scheduler were to take frequency-related decisions, it would also need to account for the impact its decision would have on the frequency of all cores. Such models are not currently available, and would be complicated to create.

6 Related Work

Dynamic frequency scaling. Using DFS to reduce energy usage has been studied for over two decades. Weiser *et al.* [33] were the first to propose to adjust the frequency of the CPU according to its load, with the aim to maximize the *millions of instructions per joule* metric. Following this, in the early 2000s, Chase *et al.* [11] as well as Elnozahy *et al.* [17] proposed to reduce the frequency of underutilized servers in farms that exhibit workload concentration. Bianchini and Rajamony summarized these early works in a survey from 2004 [6]. Nowadays, on the hardware side, most CPUs support DFS, with the most recent series having elaborate hardware algorithms that are able to dynamically select very different frequencies for cores on the same chip, with technologies such as Enhanced Intel SpeedStep® [2] and AMD® SenseMI [4]. Despite this shift of DFS logic from the software side to the hardware side in recent years, the decision to develop the experimental `schedutil` [9] governor in Linux was based on the idea that software still has a role to play in DFS, as it knows better the load being executed. Similarly, our strategies show that the software placing tasks on high-frequency cores can be more efficient than waiting for the hardware to increase the frequency of cores after task placement, due to the FTL.

Tracking inefficient scheduler behavior. Perf [15, 16, 32], which is provided with the Linux kernel, supports monitoring scheduler behavior through the `perf sched` command. While `perf sched` makes it possible to analyze the behavior of the scheduler on simple workloads with good accuracy, it has significant overhead on the Linux kernel build and other real-world workloads. Lozi et al. [21] identify performance bugs in the Linux scheduler. To analyze them, they write a basic profiler that monitors, for each core, the number of queued threads and the load. Their basic profiler does not monitor scheduling events. SchedLog and SchedDisplay [10], which we use in this paper, make it possible to record relevant information about all scheduler events with low overhead, and to efficiently navigate through the large amount of recorded data with a powerful and scriptable graphical user interface.

Mollison et al [25] apply regression testing to schedulers. Their focus is limited to real-time schedulers, and they do not take DFS into account. More generally, there has been an ongoing effort to test and understand the impact of the Linux scheduler on performance. Since 2005, the LKP project [12] has focused on hunting performance regressions, and a myriad of tools that make it possible to identify performance bugs in kernels have been proposed by the community [7, 18, 26, 28]. The focus of these tools, however, is to detect slowdowns inside the kernel code, and not slowdowns in application code that were caused by decisions from the kernel. Consequently, they are unable to detect poor scheduling behavior.

Improving scheduler behavior. Most previous work focuses on improving general-purpose OS scheduling with new policies that improve a specific performance metric, such as reducing contention over shared resources [31, 35], optimizing the use of CPU caches [29, 30], improving NUMA locality [8, 14] or minimizing idleness [20]. These papers systematically disable DFS in their experiments. Merkel *et al.* [24] propose a scheduling algorithm that avoids resource contention by co-scheduling applications that use complementary resources. They reduce contention by lowering the frequency of cores that execute inauspicious workloads. Zhang et al. [34] propose a scheduling policy for multi-core architectures that facilitates DFS, although their main focus is reducing cache interference. They only consider per-chip DFS, as per-core DFS was not commonplace at the time.

Linux kernel developers have recently focused on DFS and turbo frequencies [13], as it was discovered that a short-lived jitter process that runs on a previously idle core can make that core switch to turbo frequencies, which can in turn reduce the frequencies used by other cores—even after the jitter process completes. To solve this issue, a patch [27] was proposed to explicitly mark jitter tasks. The scheduler then tries to place these marked tasks on cores that are active and expected to remain active. In contrast, the frequency inversion issue we identified is not specifically caused by turbo frequencies: it can occur with any DFS policy in which different cores may run at different frequencies.

Child runs first. CFS has a feature that may seem related to our solutions: `sched_child_runs_first`. At thread creation, this feature assigns a lower *vruntime* to the child thread, giving it a higher priority than its parent. If CFS places the thread on the same core as its parent, the thread will preempt the parent; otherwise, the thread will just run elsewhere. This feature does not affect thread placement and thus cannot address the frequency inversion problem. Using this feature in combination with S_{move} would defeat S_{move}'s purpose by always canceling the timer. The strategy would resemble S_{local}, except that the child thread would always preempt its parent.

7 Conclusion

In this paper, we have identified the issue of frequency inversion in Linux, which occurs on multi-core CPUs with per-core DFS. Frequency inversion leads to running tasks on low-frequency cores and may severely degrade performance. We have implemented two strategies to prevent the issue in the Linux 5.4 CFS scheduler. Implementing these strategies required few code changes: they can easily be ported to other versions of the Linux kernel. On a diverse set of 60 applications, we show that our better solution, S_{move}, often significantly improves performance. Additionally, for applications that do not exhibit the frequency inversion problem, S_{move} induces a penalty of 8% or less with 3 of the evaluated applications. As independent core frequency scaling becomes a standard feature on latest generation processors, our work will target a larger number of machines.

In future work, we want to improve thread placement in the scheduler by including the cores' frequencies directly in the placement algorithm. This improvement will need to account for various parameters such as architecture-specific DFS, simultaneous multi-threading and maintaining cache locality.

vSMT-IO: Improving I/O Performance and Efficiency on SMT Processors in Virtualized Clouds

Abstract

The paper focuses on an under-studied yet fundamental issue on Simultaneous Multi-Threading (SMT) processors — how to schedule I/O workloads, so as to improve I/O performance and efficiency. The paper shows that existing techniques used by CPU schedulers to improve I/O performance are inefficient on SMT processors, because they incur excessive context switches and spinning when workloads are waiting for I/O events. Such inefficiency makes it difficult to achieve high CPU throughput and high I/O throughput, which are required by typical workloads in clouds with both intensive I/O operations and heavy computation.

The paper proposes to use *context retention* as a key technique to improve I/O performance and efficiency on SMT processors. Context retention uses a hardware thread to hold the context of an I/O workload waiting for I/O events, such that overhead of context switches and spinning can be eliminated, and the workload can quickly respond to I/O events. Targeting virtualized clouds and x86 systems, the paper identifies the technical issues in implementing context retention in real systems, and explores effective techniques to address these issues, including long term context retention and retention-aware symbiotic scheduling.

The paper designs vSMT-IO to implement the idea and the techniques. Extensive evaluation based on the prototype implementation in KVM and diverse real-world applications, such as DBMS, web servers, AI workload, and Hadoop jobs, shows that vSMT-IO can improve I/O throughput by up to 88.3% and CPU throughput by up to 123.1%.

1 Introduction

Simultaneous Multi-Threading (SMT), or Hyper-Threading (HT) on x86 processors, is widely enabled on most cloud infrastructures [1–4]. For example, in Amazon EC2 [1], virtual instances can have their virtual CPUs (vCPUs) run on dedicated hardware threads or time-share hardware threads. With SMT, multiple hardware threads share the same set of execution resources in each core, such as functional units and caches. Thus, when enabled, SMT can effectively improve resource utilization and system throughput.

On SMT processors, CPU schedulers are critical for achieving high performance. To make optimal scheduling decisions, they must fully consider and leverage the performance features of SMT processors, particularly the intensive resource sharing between hardware threads. For example, intensive study has concentrated on symbiotic scheduling algorithms, which co-schedule the threads that can fully utilize the hardware resources with minimal conflicts on each core [5–10].

Existing scheduling optimizations for SMT processors, including symbiotic scheduling and other enhancements in existing system software [11–13], mainly target computation-intensive workloads and aim to improve processor throughput. However, the techniques that can effectively and efficiently improve the performance of I/O-intensive workloads on SMT-enabled systems have not been paid enough attention. These techniques are particularly important when a system has both computation workloads and I/O workloads, and requires both high processor throughput and high I/O throughput.

To improve I/O workload performance, existing CPU schedulers generally use two techniques, polling [14–16] and boosting the priority of I/O workloads [17–19]. However, with these techniques, I/O workloads incur high overhead on SMT processors due to busy-looping and increased context switches, which can significantly reduce the performance of computation running on other hardware threads.

This problem is particularly significant and detrimental in clouds. In clouds, I/O workloads and computation workloads are usually consolidated on the same server to improve system utilization [17, 19–22]. At the same time, virtualization is dominantly used in clouds, which causes busy-looping and context switches to incur higher overhead, because extra operations must be carried out to deschedule and reschedule virtual CPUs, as we will show in §2.

To control the overhead of polling and I/O workload priority boosting, existing system designs make trade-offs between the efficiency and the effectiveness of these techniques, which undermine the performance of I/O workloads. For polling, existing systems usually incorporate a short timeout to keep the busy-looping brief. For priority boosting, it has been a long-standing dilemma to make I/O workloads preempting the running workloads promptly or with some extra delay; to resolve this dilemma, Linux uses a scheduling delay parameter (tunable, usually a few milliseconds) as a knob to trade-off I/O workloads responsiveness and the increased context switch overhead.

Instead of improving the effectiveness-efficiency trade-off, the paper seeks a fundamental solution to the above problem. The key is a technique that can effectively improve the performance of I/O workloads with high efficiency. Our solution is motivated by the hardware-based design for efficient blocking synchronization on SMT processors [23]. With the design, blocking synchronizations can be finished efficiently without busy-looping or context switches. Specifically, the design allows a thread blocked at a synchronization point to free all its resources for other hardware threads to use, except for its hardware context; thus, when the thread is unblocked, it can resume its execution in a few cycles.

Our solution targets virtualized clouds and x86 SMT processors. It is built on a hardware-based blocking mechanism for vCPUs, named **Context Retention**. Context retention is implemented with Intel `MONITOR/MWAIT` support [24]. With context retention, when a vCPU is waiting for an I/O event, its execution context can be held on a hardware thread without busy-looping involved; upon the I/O event, the vCPU can resume execution quickly without a context switch.

1.1 Technical Issues

While the rationale of the context retention mechanism is straightforward, maximizing its potential on improving performance needs to address three technical issues listed below. These issues arise mainly because context retention may be long time periods. Many I/O operations have long latencies in millisecond scale, and the latencies may further increase due to queueing/scheduling delays. To avoid context switches, the contexts of the vCPUs waiting for the finish of these operations need to be retained on hardware threads for the same amount of time.

First, uncontrolled context retention can diminish the benefits from simultaneous multithreading, because context retention reduces the number of active hardware threads on a core. This issue is particularly serious for x86 processors, which only implement 2-way SMT[1]. When a hardware thread is used for context retention, only one hardware thread remains for computation.

Second, context retention consumes the timeslice of an I/O workload, and thus reduces its timeslice available for computation. We found that, if not well controlled, context retention can even reduce the throughput of I/O workloads.

Third, due to context retention and burstiness of I/O operations [25], the resource demand of an I/O workload may vary dramatically on a hardware thread. This makes it a challenging task to improve processor throughput with existing symbiotic scheduling methods. To determine which workloads may make fast progress if scheduled on the same core, existing symbiotic scheduling methods periodically profile workload executions and make predictions based on the profiling results. Thus, these methods are effective only when the workload on each vCPU changes steadily. They must be substantially extended to handle I/O workloads.

1.2 Major Techniques

We implement our solution and address the above issues by designing the vSMT-IO scheduling framework. It has two major components. The **Long-Term Context Retention (LTCR)** mechanism is mainly to maximize I/O throughput with high efficiency. The **Retention Aware Symbiotic Scheduling (RASS)** algorithm is mainly to maximize processor throughput.

The LTCR mechanism mainly addresses the first two issues identified in Section 1.1. It holds the context of the vCPU waiting for an I/O event on a hardware thread for an extended time period. If the expected I/O event happens in this period, the vCPU can quickly resume and respond to the event. Otherwise, the vCPU is descheduled. The maximum length of the time period is carefully adjusted in a way that both processor throughput and I/O throughput can be improved.

With LTCR, the context of an I/O workload can be held for as long as a few milliseconds, which is more than 10x longer than the busy-looping timeout used in system software (sub-millisecond) [14, 15]. This makes LTCR capable of dealing with relatively high I/O latencies, which are associated with slow I/O operations (e.g., HDD accesses and SSD writes) or caused by various system factors (e.g., queueing/scheduling delay and SSD block erase). In contrast, polling is used only when I/O workloads interact with low latency devices, e.g., local network and NVMe devices [16, 26].

The RASS algorithm mainly addresses the third issue identified in Section 1.1. On each core, it classifies the vCPUs into two categories, CPU-bound vCPUs and I/O-bound vCPUs. It uses one hardware thread for running CPU-bound vCPUs and the other hardware thread mainly for I/O-bound vCPUs. In this way, the computation on the CPU-bound vCPUs can overlap to the greatest extent with the context retention periods on the other hardware thread. This effectively improves processor throughput, since CPU-bound vCPUs can take advantage of the hardware resources released due to context retention to make fast progress. RASS schedules CPU-bound vCPUs on both hardware threads only when I/O-bound vCPUs are not ready to run. In this case, RASS selects CPU-bound vCPUs based on the symbiosis between vCPUs (i.e., how well the vCPUs can share the hardware resources and make progress when co-scheduled).

With RASS, the first two issues identified in Section 1.1 can

[1] Though some Xeon Phi processors implement 4-way SMT, the paper targets 2-way SMT x86 processors because of their overwhelming dominance in clouds.

be further mitigated. LTCR mainly targets long context retentions. It limits the lengths of context retentions to mitigate the resource underutilization they cause and reduce the timeslice they consume. However, it cannot deal with the issues caused by relatively short context retentions. For these context retentions, RASS mitigates the resource underutilization issue (the first issue in Section 1.1) by overlapping computation and context retention; to mitigate the second issue, it helps ensure the supply of timeslice to I/O-bound vCPUs by running them on dedicated hardware threads with high priorities.

The paper makes the following contributions. First, the paper identifies the efficiency issues in existing CPU schedulers when they are used to improve I/O performance on SMT-enabled systems, and proposes a novel idea, context retention, to improve efficiency. Second, it identifies the issues in implementing the idea, and explores effective techniques to address these issues, including long term context retention and retention-aware symbiotic scheduling. Third, targeting virtualized clouds and x86 processors, the paper designs vSMT-IO to implement the idea and the techniques, and builds a system prototype based on KVM [27]. Forth, it has evaluated vSMT-IO with extensive experiments and a diverse set of 18 programs, including DBMS, web servers, AI workloads, and Hadoop jobs, and compared the performance of vSMT-IO with the vanilla system and widely-adopted enhancements. The experiments show that vSMT-IO can improve I/O throughput by up to 88.3% and processor throughput by up to 123.1%.

2 Background and Motivation

Targeting virtualized clouds, this section demonstrates the efficiency issues of existing schedulers in improving I/O performance on SMT-enabled systems. It first introduces these techniques, and experimentally verifies their inefficiency and the caused performance degradation (§2.1). Then, it explains why the issues are serious on virtualized platforms (§2.2).

2.1 Inefficient I/O-Improving Techniques

I/O-intensive applications are usually driven by I/O events. A pattern repeated in their executions is waiting for I/O events (e.g., queries received from network, or data read from disks), processing I/O events, and generating new I/O requests (e.g., responses to queries, or more disk reads). Thus, high I/O performance not only depends on fast and well-managed I/O devices to quickly respond to I/O requests. It also depends on the applications to promptly respond to various I/O events, such that new I/O requests can be generated and issued to I/O devices quickly.

Thus, CPU schedulers play an important role in improving I/O performance. To increase the responsiveness of I/O workloads to I/O events, existing schedulers use two general techniques — polling for low-latency I/O events and priority boosting for high-latency I/O events. With polling, an I/O workload waiting for an I/O event enters a busy loop (implemented with PAUSE on x86 processors) with a pre-set timeout. The workload keeps looping before it is interrupted upon the expected I/O event or is descheduled due to timeout. Thus, polling allows a workload to respond to I/O events with a minimal delay before timeouts. With priority boosting, upon an I/O event, the priority of the I/O workload is boosted, such that it can quickly preempt a running workload to respond to the I/O event.

On virtualized platforms, I/O workloads run on vCPUs; and vCPU scheduling becomes a key component affecting I/O performance. For vCPUs, polling may be implemented in guest OS kernel [28]. However, busy-looping in guest OS causes unnecessary VM_EXITs and extra overhead on x86 processors when Pause Loop Exiting (PLE) is enabled. Thus, recent designs (e.g., HALT-Polling [15]) usually implement polling at the VMM level. Priority boosting may be implemented by adjusting priorities explicitly [17] or by implicitly associating priorities with CPU time consumption. For example, Linux/KVM allows the vCPUs with lower CPU time consumption (e.g., I/O-bound vCPUs) to preempt the vCPUs with higher CPU time consumption [17, 29].

Though polling and priority boosting can improve the performance of I/O workloads, they are inefficient on SMT processors. The operations associated with these techniques, busy-looping and context switches, waste the hardware resource that can be otherwise utilized by the computation on other hardware threads. Thus, the inefficiency may not be an issue when a system has only I/O workloads; but it becomes detrimental when I/O workloads are consolidated with computation workloads. Efficiency can be improved by making these techniques less aggressive, e.g., enforcing a shorter timeout for polling. However, this sacrifices the effectiveness of these techniques and I/O performance.

We illustrate the inefficiency issue with polling and priority boosting using the experiments with two combinations of applications, `Sockperf` with `Matmul`, and `Redis` with `PageRank`. `Sockperf` and `Redis` are I/O-bound. `Matmul` and `PageRank` are CPU-bound. We run each combination on a 24-core server (48 hyperthreads) with each application running in a 48-vCPU VM. This results in 2 vCPUs on each hyperthread. The VMs are managed by KVM/Linux. Detailed server/VMs configurations and application descriptions can be found in §6.

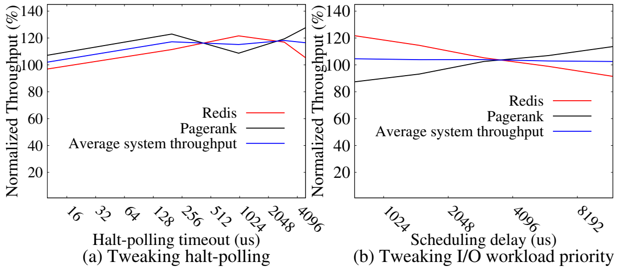
To illustrate the inefficiency issue on a well-tuned system with high efficiency, we have enhanced the HALT-Polling implementation in KVM. The enhancement makes HALT-Polling more effective, so as to further reduce context switches between vCPUs and make vCPUs more responsive to I/O events. Specifically, with the "vanilla" implementation, an idle vCPU is not allowed to perform HALT-Polling when there is another vCPU ready to run on the same hyperthread. The enhancement removes this restriction. It also increases the maximum timeout that is allowed in HALT-Polling. (HALT-Polling adjusts timeout value dynamically between 0 and

workloads	KVM w/ enhanced HALT-Polling			VSMT-IO		
	vCPU switches	spinning time	perf. imprv.	vCPU switches	spinning time	perf. imprv.
`Sockperf`	12.5K	40.1%	16.1%	3.3K	-	56.5%
`Matmul`			8.2%			57.4%
`Redis`	43.9K	27.5%	8.4%	15.1K	-	88.3%
`PageRank`			7.7%			123.1%

Table 1: ***Existing techniques handling I/O workloads incur frequent vCPU switches and massive spinning, and are inefficient on SMT processors.*** **"vCPU switches" are counts of context switches between vCPUs every second in the server. The performance improvements are relative to "vanilla" KVM.**

a maximum value.) The enhancement improves the performance of the applications by 7.7% ∼ 16.1%.

As shown in Table 1, both application combinations incur frequent vCPU switches. For example, `Redis` and `PageRank` incur a vCPU switch about every 1 millisecond on each hyperthread. At the same time, a substantial portion of CPU time is spent by polling (e.g., 40.1% for `Sockperf` and `Matmul`). vCPU switches and such massive polling inevitably degrade performance, as we will show later.



(a) Tweaking halt-polling

(b) Tweaking I/O workload priority

Figure 1: ***Tweaking existing techniques for scheduling I/O workload cannot substantially improve performance.*** **(The throughputs are normalized to those with vanilla KVM.)**

The performance advantage of the enhanced HALT-Polling is achieved by increasing polling to reduce costly vCPU switches. This demonstrates some potential to tweak existing designs. However, to improve performance significantly, major changes must be made. To illustrate this, Figure 1 shows how the performance of `Redis` and `PageRank` changes when tweaking the key parameters of polling and priority boosting. We first tweak the timeout used in HALT-Polling and vary it from 10 microseconds to 5 milliseconds. Figure 1(a) shows that increasing timeout only slightly improves performance when timeout value is small. However, the performance improvement of these two applications hits a plateau at about 10% after the timeout value reaches 200 microseconds.

Then, we adjust the scheduling delay parameter in Linux. The parameter controls the delay between a vCPU being woken up upon an I/O event and the vCPU preempting another vCPU. Thus, increasing the parameter essentially reduces the priority of I/O-bound vCPUs and reduces vCPU switches. As Figure 1(b) shows, the average performance barely changes; and increasing this parameter is basically sacrificing I/O performance for higher processor throughputs.

The aim of VSMT-IO is to substantially reduce the overhead caused by spinning and vCPU switches. The reduced overhead improves the performance of computation workloads. As shown in Table 1, reducing more than 2/3 of vCPU switches and eliminating spinning lead to significant performance improvement to `PageRank` (123.1% relative to vanilla KVM or 107.1% relative to enhanced KVM). More importantly, the performance improvement of computation workload is not at the cost of I/O performance. With VSMT-IO, the throughput of `Redis` is increased by 88.3% over vanilla KVM or 73.7% over enhanced KVM. The system I/O throughput is also increased by 75.1% over enhanced KVM.

2.2 Overhead of Polling and Context Switches

Existing techniques for improving I/O performance are inefficient on SMT processors, because context switches and polling waste the resource that can be otherwise utilized by the computation on other hardware threads. Targeting virtualized clouds, this subsection highlights the overhead of these operations with experiments and explains how such high overhead is incurred.

Hyperthread 1	Hyperthread 2	Relative performance
-	`Matmul`	100%
vCPUs Switches	`Matmul`	32%
HALT-Polling	`Matmul`	73%

Table 2: ***vCPU switches and HALT-Polling on a hyperthread slow down the computation on the other hyperthread.***

In the experiments, we run a `Matmul` thread on a hyperthread. Then, on the other hyperthread, we make two vCPUs switch back and forth or make a vCPU repeat the HALT-Polling loop. We check how the performance of `Matmul` is impacted by these operations.

The experiments show that vCPU switches slow down `Matmul` by about 70%, and HALT-Polling slows it down by about 30% (Table 2). While the slowdowns explain the inefficiency of polling and priority boosting techniques, we were surprised at these slowdowns. We expected the slowdown caused by vCPU switches to be around 50%, because there are two streams of instructions compete for CPU resource on the hyperthreads, and expected the slowdown caused by HALT-Polling to be minimal, because PAUSE instruction is designed to consume minimal resource.

We have diagnosed the slowdowns. vCPU switches cause large slowdowns mainly because the L1 data cache shared by both hyperthreads needs to be flushed during vCPU switches to address the *L1 Terminal Fault* problem [30, 31]. Other costly operations, including TLB flush [32], handling rescheduling IPIs [33], and the execution of scheduling algorithm, also contribute to the performance impact incurred by vCPU switches. The slowdown caused by HALT-Polling is larger than expected because the operations other than PAUSE are executed. HALT-Polling is implemented in the VMM. Thus, VM_EXIT is incurred when a vCPU enters HALT-Polling. VM_EXITs are costly operations [34]. During the polling, the instructions controlling the busy-loop are executed repeatedly. They are also more costly than PAUSE.

3 Basic Idea and Technical Issues

As Section 2 shows, polling and priority boosting incur high overhead on SMT processors; tweaking these techniques yields only marginal performance improvements. This requires that a new and efficient technique be developed to handle I/O workloads.

On a SMT processor, an efficient technique must consume minimal hardware resources. In a scheduling technique for improving I/O performance, two factors determine its hardware resource consumption. One is how to handle an I/O workload while it is waiting for the completion of an I/O operation. The other is how to quickly resume the execution of the I/O workload upon the completion of the expected I/O operation. Polling and priority boosting each concentrate on reducing the resource consumption of only one factor, but at the cost of high resource consumption in the other factor. Our solution aims to minimize the resource consumption of both factors.

Our solution leverages two features of SMT processors: 1) hardware-based blocking support, and 2) intense resource sharing between hardware threads. With these features, we implement a **Context Retention** mechanism for vCPUs. While a vCPU is waiting for the completion of I/O operations, it can "block" itself on a hardware thread, and release all its resources for other hardware threads to use, except for its hardware context. This minimizes the resource consumption required by waiting for the completion of I/O operations. With the hardware context, the vCPU can be quickly "unblocked" without context switches upon the completion of the I/O operations. This minimizes the resource consumption required to quickly resume the execution of I/O workloads. Table 3 summarizes the benefits of context retention from the perspectives of both I/O workloads and computation workloads.

	Benefit	**Overhead**
I/O	better responsiveness	timeslice charged for context retention
Computation	extra resources from reduced context switches and polling	resource underutilization

Table 3: ***A summary of benefit and overhead of context retention.***

Though context retention consumes minimal hardware resources, it does incur some overhead, which are as summarized in Table 3 and must be reduced for better efficiency. From the perspective of computation workloads, because not all the hardware threads can be used for computation, the overhead is reflected by resource underutilization. Given that a x86 core has two hyperthreads, to avoid low utilization, one must be doing computation while the other does context retention. Even with this arrangement, full utilization may not be achieved.

From the perspective of I/O workloads, they are charged for vCPU usage while they retain contexts; so only short context retention periods are cheaper than descheduling and rescheduling vCPUs; but longer retention periods are not. This problem can be illustrated by the performance of I/O workload `Redis` in Figure 1(a). Increasing HALT-Polling timeout improves the performance of `Redis` when the timeout value is low. However, after the timeout exceeds 0.5 millisecond, further increasing the timeout degrades its performance. This is because, with a longer timeout, polling consumes more timeslice and reduces the timeslice available to the computation in `Redis`. Though polling is used in this experiment, if polling is replaced with context retention, the performance trend would be similar.

For the above overhead issues, a natural solution is to control the maximum length of context retention, such that extended context retention periods will not cause high overhead. However, this solution cannot deal with the overhead of the context retention periods that are relatively short. Reducing this overhead requires some enhancement in vCPU scheduling. For example, resource underutilization can be mitigated by scheduling a resource-demanding vCPU on a hyperthread when context retention is in progress on the other hyperthread; the vCPUs with much timeslice consumed by context retention can be compensated with extra timeslice.

In addition to the overhead issues, context retention also creates some challenge on the integration of symbiotic scheduling methods, which are needed for improving CPU performance. The key of symbiotic scheduling is to estimate how well a group of workloads can corun on a SMT core (i.e., symbiosis level) [6–9, 35]. This is achieved by monitoring workload executions periodically. For instance, SOS (Sample, Optimize and Symbiosis) [5] samples workload executions periodically in sample phases to determine their symbiosis levels, and preferentially coschedules tasks with the highest symbiosis levels in symbiosis phases. Thus, existing symbiotic scheduling methods require that the resource demand of a workload change steadily during its execution. Due to context retention and burstiness of I/O operations [25], the resource demand of an I/O workload changes dramatically during its execution on a vCPU. Existing symbiotic scheduling methods cannot handle such workloads. This issue may be addressed by coscheduling I/O workloads with computation workloads, such that symbiosis levels can be lifted by overlapping context retention with resource-demanding computation. Existing symbiotic scheduling methods can still be used to handle computation workloads.

4 vSMT-IO Design

We implement our idea and address the technical issues in vSMT-IO. In this section, we present the overall architecture of vSMT-IO and its major components.

4.1 Overview

Figure 2 shows the overall architecture of vSMT-IO. vSMT-IO incorporates four major components:

• The **Long Term Context Retention (LTCR)** mechanism on each core implements context retention. To prevent extended context retention periods causing high overhead (re-

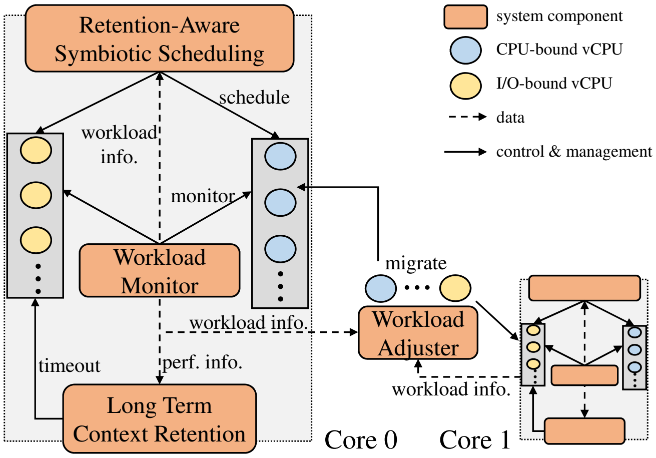


Figure 2: vSMT-IO *Architecture.* Key components are in orange.

source underutilization and timeslice consumption), it enforces a context retention timeout, and dynamically adjusts the timeout value.

- The **Retention Aware Symbiotic Scheduling (RASS)** algorithm is mainly to increase the symbiosis levels of the vCPUs running on the hypertheads in each core. To achieve this, RASS classifies vCPUs into two categories, CPU-bound vCPUs and I/O-bound vCPUs, and schedules CPU-bound vCPUs on a hyperthread and I/O-bound vCPUs on the other hyperthread. CPU-bound vCPUs run on both hyperthreads only when I/O-bound vCPUs are not ready to run. In this way, the resource-demanding computation on CPU-bound vCPUs can overlap to the greatest extent with the resource-conserving context retention periods on I/O-bound vCPUs. Increased symbiosis levels improve CPU performance and reduce the overhead of context retentions. At the same time, using a dedicated hyperthread for I/O-bound vCPUs allows them to use extra CPU time as a "compensation" for the timeslice charged in context retention periods, and further prevents them from being unfairly penalized.
- The **Workload Monitor** on each core monitors vCPU executions. It characterizes the workloads on the vCPUs and measures performance. It provides workload information for RASS to classify and schedule vCPUs and for the workload adjuster introduced below to adjust the workloads between cores. It provides performance information for LTCR to adjust the timeout value.
- The effectiveness of RASS relies on the heterogeneity of the workloads on each core, some being CPU-bound and some others being I/O-bound. The **Workload Adjuster** supplements RASS. It adjusts the workloads on each core to maintain their heterogeneity by migrating vCPUs between cores.

4.2 Long Term Context Retention (LTCR)

On x86 processors, we implement vCPU context retention with the `MONITOR/MWAIT` support. Specifically, to wait for an I/O event, a vCPU calls a `MWAIT` instruction paired with a `MONITOR` instruction that specifies a memory location in guest OS. The `MWAIT` instruction "blocks" the vCPU and keeps its context on the hyperthread. With the `MONITOR/MWAIT` support, the `MWAIT` instruction ends automatically when the content at the memory location is updated or an interrupt is directed to the hyperthread. Since both I/O events and timeouts can be notified with interrupts, we choose to use interrupts to stop `MWAIT`. To prevent `MWAIT` from being terminated by memory writes prematurely, we set the memory location used in `MONITOR` read-only.

Algorithm 1 Context Retention Timeout Adjustment

```
$T_d$: desired timeout value; $T_e$: effective timeout value; $T_{init}$: initial time-
  out value; $P$: time period between two adjustments
$T_d \leftarrow T_{init}$
while true do
    $T_e \leftarrow T_d$, collect performance data for a time period of $P$
    if TESTTIMEOUT($T_d$ * 1.1) then
        $T_d \leftarrow T_d * 1.1$; continue
    else
        $T_e \leftarrow T_d$, collect performance data for a time period of $P$
    end if
    if TESTTIMEOUT($T_d$ * 0.9) then
        $T_d \leftarrow T_d * 0.9$; continue
    end if
end while
function TESTTIMEOUT($T$)
    $T_e \leftarrow T$, collect performance data for a time period of $P$
    $S_{cpu} \leftarrow$ average speed-up of CPU-bound vCPUs
    $S_{io} \leftarrow$ average speed-up of I/O bound vCPUs
    if $S_{cpu} > 1$ and $S_{io} > 1$ then return true; end if
    return false
end function
```

The context retention timeout is to balance the cost and benefit of context rentention. Based on the summary in Table 3, for I/O workloads, lengthening a context retention is always a gain when it consumes less timeslice than descheduling and then rescheduling a vCPU. For computation workloads, context retention is rewarding when the amount of resource saved by reducing context switches and polling exceeds the amount of resource that cannot be utilized due to context retention. In the cases where one hyperthread does computation and the other hyperthread does context retention, context retention is always rewarding if it is not longer than the time spent on descheduling and then rescheduling a vCPU, based on the measurements shown in Table 2. Thus, context retention timeout can be set to be at least the time required by descheduling and rescheduling a vCPU. Then, longer timeouts can be tested.

LTCR uses algorithm 1 to adjust the context retention timeout periodically. The algorithm slightly increases or decreases the timeout value, checks whether performance is improved with the new value, and keeps the new value if it is. The algorithm uses the vCPU performance information collected by the workload monitor to determine whether performance is improved. Specifically, it uses IPC (instruction per cycle) to measure the performance of CPU-bound vCPUs, and uses the frequency of context retentions (i.e., number of context retentions per second) to measure the performance of I/O-bound vCPUs. Then, the algorithm calculates a speed-up for each vCPU. A speed-up value greater than 1 indicates that the performance of the vCPU has been improved with the new timeout value. It averages the speed-up values of CPU-bound vCPUs, and averages the speed-up values of I/O-bound vCPUs. The algorithm determines that the performance is improved and the new timeout value should be kept only if both average values are greater than 1.

4.3 Retention Aware Symbiotic Scheduling (RASS)

RASS schedules the vCPUs on each core with the main aim of maximizing the computation throughput of the core. This is achieved by increasing the symbiosis levels of the vCPUs running on the hypertheads. RASS combines two methods. One is *unbalanced scheduling* that maximizes the overlapping between resource-demanding computation and resource-conserving context retention periods (Section 4.3.1). The other is *symbiotic scheduling based-on cycle accounting* to select CPU-bound vCPUs with high symbiosis levels when both hardware threads need to run CPU-bound vCPUs (Section 4.3.2).

4.3.1 Unbalanced Scheduling

Unbalanced scheduling classifies vCPUs into two categories, CPU-bound vCPUs and I/O-bound vCPUs, and schedules them on paired hyperthreads (See Figure 3). The classification is based on how much time each vCPU spends on context retention. Specifically, for each vCPU, a context retention rate is calculated and updated periodically. It is the ratio between the time spent on context retention in last time period and the period length. When a new period begins, the vCPUs are ranked based on their context retention rates. The vCPUs with higher context retention rates are considered to be I/O-bound, and the rest are CPU-bound.

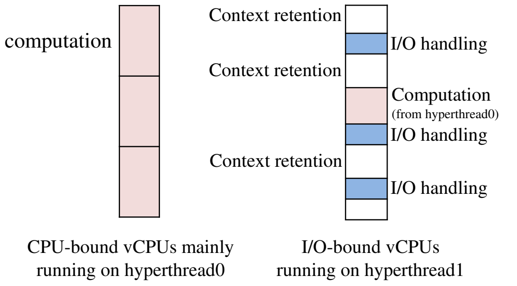

Figure 3: Computation and context retention are distributed to different hyperthreads with unbalanced scheduling.

When the hyperthread running I/O-bound vCPUs is idle, a CPU-bound vCPU is selected based on the symbiosis level (Section 4.3.2) and migrated to this hyperthread. This is to improve the utilization of CPU hardware to further increase CPU performance. The CPU-bound vCPU can only run with a priority lower than the I/O-bound vCPUs. It is preempted and migrated back when an I/O-bound vCPU becomes ready to run. This is to prevent the CPU-bound vCPU from blocking I/O-bound vCPUs and degrading I/O performance.

Unbalanced scheduling assumes that each vCPU has been attached with a weight, e.g., that used in Linux Completely Fair Scheduler (CFS). When classifying the vCPUs, it tries to balance the total weight of CPU-bound vCPUs and the total weight of I/O-bound vCPUs, and make them roughly equal. This is mainly to balance the load on the hyperthreads and reduce the migration of CPU-bound vCPUs.

The compensation to I/O-bound vCPUs for the timeslice consumed by context retentions can also be implemented by adjusting the weights of vCPUs. For example, the weights of the vCPUs can be increased based on their context retention rates. For the vCPUs that spend more time on context retentions than other vCPUs, their weights are increased by larger percentages. In this way, fewer vCPUs are classified as I/O-bound, and share the same hyperthread. However, we found that this adjustment is not necessary in most cases. The main reason is that I/O-bound vCPUs usually have low CPU utilization. Thus, even with context retention, some I/O-bound vCPUs still cannot fully consume their timeslice. Other I/O-bound vCPUs that need more timeslice acquire automatically extra timeslice as compensation. This is because the scheduler is work-conserving, and I/O-bound vCPUs have higher priority than CPU-bound vCPUs on the hyperthread and are supplied with extra timeslice first.

4.3.2 Symbiotic Scheduling Based on Cycle Accounting

When both hyperthreads need to run CPU-bound vCPUs, the symbiosis levels between vCPUs must be considered. RASS determines the symbiosis levels using the cycle accounting technique [36–39]. It is a symbiotic scheduling technique for threads. We only adapt its method that estimates the symbiosis levels between threads and use it on vCPUs.

We select this technique because of its high practicality. To estimate the symbiosis levels between threads, it samples and characterizes each individual thread, and inputs the characterization into an interference estimation model. Compared to SOS (Sample, Optimize and Symbiosis), which samples the execution of possible thread combinations [5], the cycle accounting technique has a much lower complexity ($O(n)$ vs. $O(n^2)$) and thus higher practicality.

The cycle accounting technique uses three parameters, which are the components of the CPI (cycler per instruction), to characterize a thread. The **b**ase component (**B**) is the number of cycles used to finish an instruction when all the required hardware resource and data are locally available; the **m**iss component (**M**) is the number of cycles used to handle misses (e.g., cache misses and TLB misses); the **w**aiting component (**W**) is the number of cycles waiting for hardware resource to become available. The CPI value is roughly the sum of B, M, and W.

When the parameters of a thread are being measured, the cycle accounting technique requires that the thread run alone on the core without any computation on the other hyperthread so as to eliminate interference. This incurs non-trivial overhead. To reduce this overhead, we take advantage of context retentions, and measure the parameters of a CPU-bound vCPU when it is running on a hyperthread and context retention is in progress in the other hyperthread. We obtain the base component, the miss component, and the CPI of the vCPU using hardware counters, and calculate the waiting component from this.

4.4 Workload Adjuster

The effectiveness of RASS relies on the heterogeneity of the workloads on each core, some being CPU-bound and some others being I/O-bound. Its performance advantage may diminish when workloads become homogeneous due to factors, such as load balancing and phase changes in workloads. The workload adjuster is designed to maintain the workload heterogeneity on each core.

The workload adjuster measures workload heterogeneity and characterizes the overall workload type by calculating the standard deviation and the average value of vCPU context retention rates. If a group of vCPUs have a small deviation value, their workloads are generally homogeneous; if the average context retention rate of a group of vCPUs is very high, these vCPUs are likely to be I/O-bound; if the average rate is very low, the vCPUs are likely to be CPU-bound. The workload adjuster calculates these values for each core, and updates them periodically to detect the need for workload adjustment. When the standard deviation drops below a pre-set threshold, workload adjustment starts.

To adjust the workloads, the adjuster finds the core with the smallest deviation. Then, based on the average context retention rate of the core (e.g., a very small average value of CPU-bound vCPUs), the adjuster searches for another core, which is dominated by the other type of vCPUs (e.g., I/O-bound vCPUs). The search is done by examining the average context contention rates of other cores. The desired core is the one with the average context contention rate that differs from the former average rate by the largest degree (e.g., a very large average value of I/O-bound vCPUs). After a such core is found, the adjuster ranks the vCPUs based on their context retention rates on each of these two cores, selects the vCPU ranked in the middle on each core, and swaps the two vCPUs.

5 Implementation Details

We have implemented a prototype of vSMT-IO based on Linux/KVM. We added/modified about 1300 lines of source code mainly in KVM kernel modules and Linux CFS [2]. The workload monitor and the long-term context retention (LTCR) components are mainly implemented in a KVM kernel module by changing *kvm_main.c*. In LTCR, the context retention mechanism needs to be implemented in guest OS to minimize overhead. Though it can be implemented as an idle driver kernel module [40], we choose to directly change the idle loop in *idle.c* to simplify the implementation. Context retention is implemented with a loop, which repeatedly calls `MONITOR`, `MWAIT`, and the *need_sched()* function of Linux kernel. It is inserted at the beginning of each iteration of the idle loop. Implementing context retention with a loop is to prevent it from being terminated prematurely by irrelevant interrupts. The loop terminates when a thread becomes "ready" on the vCPU (fulfilled with the *need_sched()* call). Thus, context retention can finish upon the expected I/O event. The loop also ends if a timer interrupt "marking" the timeout of the context retention is received by the vCPU. To differentiate this interrupt from regular timer interrupts, we change the two unused bits in the VM execution control register, and use them as a timeout flag.

Retention aware symbiotic scheduling and workload adjuster are implemented based on Linux CFS in *fair.c* and *core.c*. Thus, the original scheduling and load balancing policies implemented in CFS are followed in most cases, e.g., when deciding which I/O-bound vCPU is the next to run on a hyperthread. However, when deciding which CPU-bound vCPU is the next to run, the symbiotic scheduling policy in RASS and the fairness based scheduling policy in CFS have different objectives, and thus may decide to select different vCPUs. To coordinate these different objectives, our implementation let Linux CFS select a few vCPUs based on its policies. Then, among these vCPUs, RASS selects a vCPU based on symbiosis.

6 Performance Evaluation

With the prototype implementation, we have evaluated vSMT-IO extensively with a diverse set of workloads. The objectives of the evaluation are four-fold: 1) to show that vSMT-IO can improve I/O performance with high efficiency and benefit both I/O workload and computation workload, 2) to verify the effectiveness of the major techniques used in vSMT-IO, 3) to understand the performance advantages of vSMT-IO across diverse workload mixtures and different scenarios, and 4) to evaluate the overhead of vSMT-IO.

6.1 Experiment Settings

Our evaluation was done on a DELL^{TM} PowerEdge^{TM} R430 server with two 2.60GHz Intel Xeon E5-2690 processors (two NUMA zones), 64GB of DRAM, a 1TB HDD, and an Intel I350 Gigabit NIC. Each processor has 12 physical cores, and each physical core has two hyperthreads. With KVM, we built four VMs, each with 24 vCPUs and 16GB memory. Both the host OS and guest OS are Ubuntu Linux 18.04 with kernel updated to 5.3.1. We test vSMT-IO with a large and diverse set of workloads generated by typical applications from different domains, as summarized in Table 4. In the experiments, each VM encapsulates one workload.

We test vSMT-IO under two settings. Under the first setting, we launch two VMs; thus each vCPU has a dedicated

[2] Source code can be found at https://github.com/vSMT-IO/vSMT-IO.

App.	Workload Description
Redis	Serve requests (randomly chosen keys, 50% SET, 50% GET) [42].
HDFS	Read 10GB data sequentially with HDFS TestDFSIO [43].
Hadoop	TeraSort with Hadoop [43].
HBase	Read and update records sequentially with YCSB [44].
MySQL	OLTP workload generated by SysBench for MySQL [45].
Nginx	Serve web requests generated by ApacheBench [46].
ClamAV	Virus scan a large file set with clamscan [47].
RocksDB	Serve requests (randomly chosen keys, 50% SET, 50% GET) [48].
PgSQL	TPC-B-like workload generated by PgBench [49].
Spark	PageRank and Kmeans algorithms in Spark [50].
DBT1	TPC-W-like workload [51].
XGBoost	Four AI algorithms included in XGBoost [52] system.
Matmul	Multiply two 8000x8000 matrices of integers.
Sockperf	TCP ping-pong test with Sockperf [53].

Table 4: Benchmark applications used to test vSMT-IO.

hyperthread. We compare vSMT-IO against three competing solutions: 1) Blocking, which immediately deschedules the vCPUs waiting for I/O events, and is implemented by disabling HALT-Polling in KVM; 2) Polling, which is implemented by booting guest OS with parameter *idle=poll* configured [41] (timeout is not enforced for best I/O performance); and 3) HALT-Polling implemented in KVM, which combines polling and priority boosting techniques.

Under the second setting, we launch four VMs; thus, each hyperthread is time-shared by two vCPUs. Without a timeout, Polling is not a choice for improving I/O performance under this setting. Thus, we compare vSMT-IO against 1) vanilla KVM, which uses priority boosting to improve I/O performance, because HALT-Polling implemented in vanilla KVM is inactive under this setting, and 2) HALT-Polling enhanced to support time-sharing (described in Section 2.1).

We measure the throughputs of the workloads. We also collect response times if the workloads report them. The performance measurements may vary significantly across different workloads. When we present them in figures, for clarity, we normalize them against those of Blocking under the first setting and priority boosting (i.e., vanilla KVM) under the second setting.

6.2 One vCPU on Each Hyperthread

Under the first setting, I/O workloads can achieve the best performance with Polling. We want to compare the effectivenss of vSMT-IO on improving I/O performance against that of Polling by comparing the performance of I/O workloads managed with these two solutions. Without a timeout, Polling incurs high overhead on SMT processors, and degrades the performance of other workloads on the processors. Blocking and HALT-Polling are more efficient solutions than Polling under this setting. We want to compare the efficiency of vSMT-IO against that of Blocking and HALT-Polling by comparing the performance of computation workloads when they are collocated with I/O workloads managed with these three solutions.

With the above objectives, we launch two VMs. We run Matmul in one VM, which is computation-intensive, and run an I/O-intensive benchmark in the other VM. Figure 4 shows the normalized throughputs of Matmul and eight I/O-intensive benchmarks selected to co-run with Matmul. Note that the performance with Blocking is shown with the flat line at 100%.

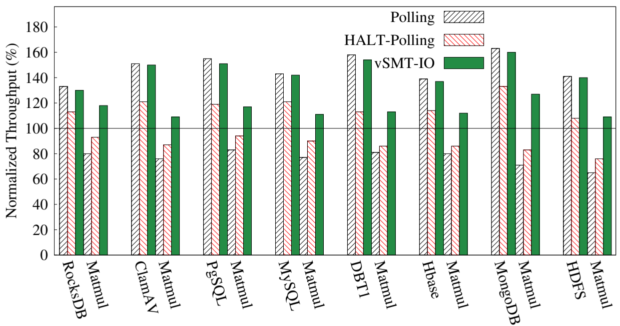

Figure 4: Throughputs of Matmul and eight I/O-intensive benchmarks when Matmul is collocated with each of the benchmarks in two VMs. Each vCPU runs on a dedicated hyperthread. Throughputs are normalized to those of Blocking.

With vSMT-IO, the I/O-intensive benchmarks achieve similar performance as they do with Polling. The largest difference is with DBT1, 4.1%. This is because DBT1 incurs a large number of random accesses to the HDD, which have long latencies exceeding the timeout value used in LTCR. On average, the I/O intensive benchmarks are only 2.3% slower with vSMT-IO. This shows that vSMT-IO is highly effective on improving I/O performance.

The high effectiveness of vSMT-IO is achieved with high efficiency. This is reflected by Matmul achieving higher performance with vSMT-IO consistently in all the experiments than it with the other three solutions. On average, with vSMT-IO the performance of Matmul is 37.9%, 14.5%, and 27.6% higher than it with Polling, Blocking, and HALT-Polling, respectively.

6.3 Multiple vCPUs Time-Sharing a Hyperthread

With multiple vCPUs on each hyperthread, context switches are usually incurred when improving I/O performance. It becomes more difficult for I/O-improving solutions to maintain high efficiency. We want to know to what extent the effectiveness and efficiency of vSMT-IO can be maintained. At the same time, vSMT-IO can be fully exercised under this setting. We want to verify the effectiveness of the major techniques in vSMT-IO.

In the experiments, we launch four VMs. On two of the VMs, we run two instances of the same benchmark, which is computation-intensive, e.g., Nginx, or AI algorithms in XGBoost. On the other two VMs, we run two instances of another benchmark, which is I/O-intensive, e.g., web server, or file server.

Figure 5 shows the normalized throughputs for eight benchmark pairs. In each pair, the first benchmark is I/O intensive, and the second benchmark is computation intensive. The enhanced HALT-Polling can effectively improve the throughputs of I/O-intensive benchmarks, because polling can "absorb" some context switches caused by I/O operations. Compared to vanilla KVM, the throughputs of I/O intensive benchmarks are increased by 36.9% on average. However, polling consumes CPU resources and may degrade the performance of other workloads (e.g., Nginx and Regression). Because the length of polling is carefully controlled in HALT-Polling, on average the throughputs of computation-intensive benchmarks are similar to those with vanilla KVM.

Compared to enhanced HALT-Polling, vSMT-IO can more effectively improve the throughputs of I/O-intensive benchmarks. On average, their throughputs are 29.5% higher than those with enhanced HALT-Polling. More importantly, this is achieved by improving the throughputs of computation-intensive workloads at the same time. On average, the throughputs of computation-intensive workloads with vSMT-IO are 22.8% and 18.4% higher than those with enhanced HALT-Polling and vanilla KVM, respectively.

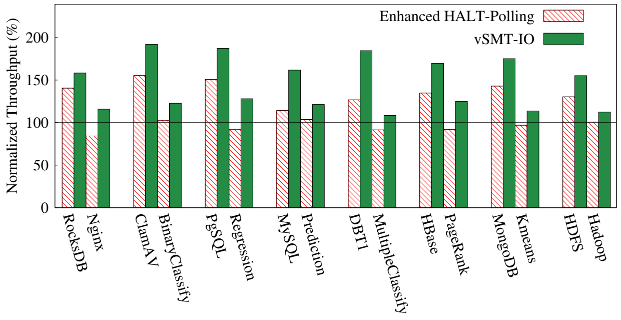

Figure 5: Throughputs of eight pairs of benchmarks. Each benchmark has two instances running on two VMs. Each hyperthread is time-shared by 2 vCPUs. Throughputs are normalized to those with vanilla KVM. Benchmarks BinaryClassify, MultipleClassify, Regression and Prediction are AI algorithms in XGBoost [52, 54].

The results in Figure 5 confirm that vSMT-IO can maintain its effectiveness and efficiency when each hyperthread is time-shared by vCPUs. To further investigate how the throughputs are improved with vSMT-IO, we collect the frequencies of vCPU switches (shown in Table 5) and profile the workload on the hyperthreads for I/O-bound vCPUs (results shown in Table 6).

The effectiveness of vSMT-IO on improving I/O performance relies on context retentions holding vCPU contexts on hyperthreads (the LTCR component). It is reflected by reduced context switches. As shown in Table 5, vSMT-IO can reduce vCPU switches significantly by up to 95% (80% on average). As a comparison, enhanced HALT-Polling can only reduce vCPU switches by at most 51% (32% on average). This explains the superiority of vSMT-IO over HALT-Polling.

Benchmark Pairs	Number of vCPU Switches Per Second		
	Vallina KVM	Enhanced HALT-Polling	vSMT-IO
(RocksDB,Nginx)	29.3k	15.2k	1.9k
(ClamAV,BinaryClassify)	11.8k	8.7k	3.2k
(PgSQL,Regression)	9.5k	8.0k	2.8k
(MySQL,Prediction)	11.5k	9.3k	4.5k
(DBT1,MultipleClassify)	61.3k	29.5k	3.9k
(HBase,PageRank)	23.4k	12.3k	3.9k
(MongoDB,Kmeans)	33.3k	20.8k	9.3k
(HDFS,Hadoop)	34.0k	30.6k	1.7k

Table 5: The number of vCPU switches is substantially reduced with vSMT-IO for the eight benchmark pairs.

Benchmark Pairs	Context Retentions	I/O Workload	Computation Workload
(RocksDB,Nginx)	28.1%	34.3%	37.6%
(ClamAV,BinaryClassify)	39.8%	31.6%	28.6%
(PgSQL,Regression)	42.3%	19.2%	38.5%
(MySQL,Prediction)	30.0%	33.5%	36.5%
(DBT1,MultipleClassify)	32.7%	54.4%	12.9%
(HBase,PageRank)	53.9%	31.9%	14.2%
(MongoDB,Kmeans)	34.4%	45.3%	20.3%
(HDFS,Hadoop)	33.0%	45.2%	21.8%

Table 6: Time (percentage) spent by context retentions, I/O-bound vCPU, and CPU-bound vCPU on the hyperthreads for I/O-bound vCPUs.

The high efficiency of vSMT-IO comes partially from its capability to reduce vCPU switches. It also comes from LTCR and RASS controlling the overhead incurred by context retentions. While the effectiveness of RASS on controlling the overhead is self-evident, the effectiveness of LTCR can be confirmed with the results shown in Table 6. LTCR limits the context retention lengths to prevent high overhead. As a result, on the hyperthreads for I/O-bound vCPUs, for most benchmark pairs, the time spent on context retentions is less than 40%. With context retention lengths well controlled, more than 20% of the CPU time on these hyperthreads can be used by CPU-bound vCPUs to improve CPU throughput.

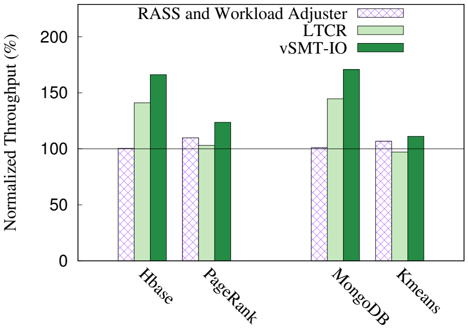

Figure 6: Normalized throughputs (relative to those achieved with vanilla KVM) of two pairs of benchmarks when LTCR and RASS are enabled separately.

To understand how the two major techniques in vSMT-IO, LTCR and RASS, improve performance, we enable these techniques separately, and show the performance of two pairs of benchmarks, HBase with PageRank, and MongoDB with

Kmeans, in Figure 6. Workload Adjuster is enabled along with RASS, because it is a supplement to RASS. Figure 6 shows that the performance improvements of I/O-intensive workloads are mainly from the LTCR technique; and the performance improvements of computation-intensive workloads are mainly from the RASS technique. When LTCR is enabled, the throughputs of I/O-intensive workloads, HBase and MongoDB, are significantly increased by 41.1% and 44.7%, respectively. However, it barely increases the throughputs of PageRank and Kmeans. Further enabling RASS (with Workload Adjuster) can effectively improve the throughputs of all the workloads.

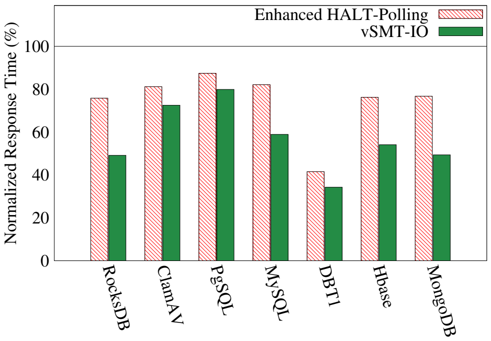

Figure 7: Response times of RocksDB, ClamAV, PgSQL, MySQL, DBT1, HBase, and MongoDB normalized to those with vanilla KVM (shown with the horizontal line at 100%).

Some benchmarks report response times. Figure 7 compares how their response times are reduced with vSMT-IO and HALT-Polling. Relative to vanilla KVM, HALT-Polling reduces the response times by 28.7% on average. vSMT-IO can reduce the response times by larger percentages (50.8% on average). To investigate how vSMT-IO reduces response times, we monitor the state changes of the vCPUs during the executions of these benchmarks, collect the time spent by vCPUs at the following states: 1) ***Running***, including context retention, on a hyperthread, 2) ***Ready*** and waiting to be scheduled, 2) ***Waiting*** for an event. In Table 7, for each benchmark, we show the time (in milliseconds) spent in these states for serving a request.

Benchmark	Vallina KVM			Enhanced HALT-Polling			vSMT-IO		
	Run	Ready	Wait	Run	Ready	Wait	Run	Ready	Wait
RocksDB	116.2	132.6	378.1	131.7	88.0	305.4	129.8	69.0	237.2
ClamAV	15.2	45.7	10.9	12.9	29.7	10.5	11.0	21.1	9.5
PgSQL	14.7	37.6	10.1	12.3	27.1	9.4	13.5	19.7	8.7
MySQL	111.4	319.7	88.9	90.7	167.9	89.5	87.5	136.7	80.6
DBT1	346.2	1831.4	1390.2	361.6	842.9	1035.8	306.9	643.2	641.6
HBase	266.2	655.0	901.8	237.8	323.3	795.9	241.6	315.0	654.3
MongoDB	376.1	528.6	1444.1	365.3	345.2	1276.6	351.7	256.0	897.9

Table 7: Time spent by vCPUs in three states when processing a request with vanilla KVM, enhanced HALT-Polling, and vSMT-IO.

The response times are reduced with vSMT-IO mainly because vCPUs spend less time on waiting to be scheduled or for events. As shown in Table 7, vSMT-IO can significantly reduce the time in the *Ready* state (53.6% on average). This is because context retention reduces context switches between vCPUs, and thus reduces the scheduling delay associated with the switches. We have noticed that the time in the *Waiting* state is substantially reduced for some benchmarks (e.g., DBT1). This is because finising an I/O operation sometimes need the collaboration of multiple vCPUs in the VM. For example, after a vCPU sends out an I/O request and becomes idle, another vCPU may receive the response and must notify the former vCPU by sending it an inter-processor interrupt (IPI). In this case, reducing the *Ready* time of the latter vCPU (i.e., scheduling it earlier) can also reduce the *Waiting* time of the former vCPU.

6.4 Applicability and Overhead

vSMT-IO targets heterogeneous workloads with intensive I/O operations and heavy computation. We want to know how well vSMT-IO performs for the workloads with different heterogeneity. This subsection tests the performance and overhead of vSMT-IO for different workload mixes. We still use 4 VMs to run 4 instances of 2 applications in the experiments. But we change VM sizes (i.e., the number of vCPUs in a VM) to change the workload mix. For example, to make the workload more I/O-intensive, we increase the sizes of the 2 VMs running I/O-intensive benchmarks and reduce the sizes of the VMs running computation-intensive benchmarks. The total number of vCPUs of the 4 VMs is kept fixed (96 vCPUs).

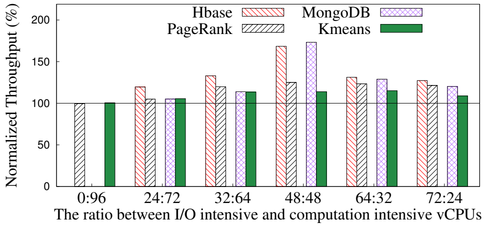

Figure 8: Normalized throughputs of vSMT-IO under different workload mixes. Throughputs are normalized to those with vanilla KVM.

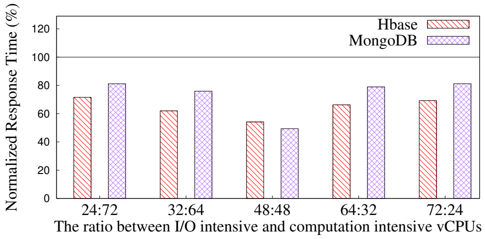

Figure 9: Normalized response times of vSMT-IO under different workload mixes. Response times are normalized to those with vanilla KVM.

Figure 8 shows the normalized throughputs of two benchmark paris, HBase with PageRank, and MongoDB with Kmeans, when the VM sizes for I/O-intensive benchmarks and computation-intensive benchmarks are changed from (12,36) to (36,12). (The ratios of the vCPUs running these benchmarks vary from 24:72 to 72:24.) Figure 9 shows the response times of HBase and MongoDB in these experiments. Though vSMT-IO can improve performance for all these workload mixes, it improves performance by the largest percentages when the number of vCPUs running I/O-intensive benchmarks is the same as the number of vCPUs running computation-intensive vCPUs.

We also run PageRank and Kmeans in two VMs with 48 vCPUs each, and show the normalized throughputs (labeled with "0:96") in Figure 8. Because both benchmarks are computation intensive, there is no space for vSMT-IO to improve performance. The performance difference between vSMT-IO and vanilla KVM is unnoticeable (less than 2%). This shows that the overhead of vSMT-IO is very low.

We have also evaluated the performance of vSMT-IO with 8 VMs (192 vCPUs). We find that vSMT-IO consistently shows better performance than vanilla KVM and enhanced HALT-Polling, for heterogeneous workloads; but the performance improvement is similar to that with 4 VMs. The performance advantage of vSMT-IO is more determined by the mix of workloads than the number of VMs on each server.

7 Related Work

Improving I/O performance in virtualized systems. I/O performance problems in virtualized systems have been intensively studied; and various solutions have been proposed, including shortening time slices [55–58], task-aware priority boosting [17, 18, 59–69], and task consolidation [19, 70–73]. These solutions are not designed for SMT processors, and are orthogonal to our work. Shortening time slices of vCPUs can reduce the latency of I/O workloads in virtualized systems. However, it may incur significant performance degradation caused by context switches. Task-aware priority boosting improves I/O performance in virtualized systems by prioritizing I/O-intensive workloads. For instance, xBalloon [17] maintains the high priority of I/O-intensive workloads by reserving CPU resource for them. However, this may hurt the performance of computation-intensive workloads. vMigrater [19] prioritizes I/O-intensive workloads by migrating them away from to-be-descheduled vCPUs to other vCPUs, such that they can keep running and generating I/O requests. However, it is designed for VMs with multiple vCPUs, and may incur high workload migration cost. Task consolidation solutions can improve I/O performance by reducing the descheduling and rescheduling of vCPUs. They consolidate workloads onto fewer vCPUs if the workloads are I/O-intensive, such that these vCPUs can be kept active with relatively low cost. These solutions may also incur high cost due to frequent workload migrations. Polling is used in these solutions to keep vCPUs active. This is inefficient on SMT processors and can be improved by replacing polling with context retention.

Symbiotic scheduling aims to maximize the throughput of SMT processors by selecting the tasks with complementary resource demands and coscheduling them on the same SMT core [5–10]. For instance, SOS (Sample, Optimize, Symbiosis) and its variants [5–10, 35] sample task executions when they are coscheduled onto the same core, and preferentially coschedule those with small slowdowns. These solutions only target processor throughput, and cannot be used to improve the performance of I/O-intensive workloads.

Other scheduling solutions for SMT processors. Instead of maximizing processor throughput, some scheduling solutions aim to secure resources for individual tasks on SMT processors to ensure their decent performance [11, 35, 74, 75]. For instance, ELFEN [11] aims to ensure the high performance of latency-critical tasks when they are collocated with batch tasks on SMT processors. It puts a latency-critical task and batch tasks on different hardware threads in the same core, and "blocks" batch tasks when the latency-ciritical task is making progress. The efficiency is low with this solution, because each core has only one active hardware thread at any moment, and resource is underutilized. Tasks on the same SMT processor may not share the resources in a fair way. Various solutions have been proposed to enforce fairness among the tasks in a SMT-enabled system [76–78]. For instance, progress-aware scheduler [76] periodically estimates the progress of tasks, and prioritizes the tasks with relatively slow progress. vSMT-IO is orthogonal to these solutions. It increases efficiency to improve both CPU performance and I/O performance.

8 Conclusion and Future Work

Despite the prevalence of SMT processors, the problems with how to improve I/O performance and efficiency on SMT processors are surprisingly under-studied. Existing techniques used in CPU schedulers to improve I/O performance are seriously inefficient on SMT processors, making it difficult to achieve high CPU throughput and high I/O throughput. Leveraging the hardware feature of SMT processors, the paper designs vSMT-IO as an effective solution. The key technique in vSMT-IO is context retention. vSMT-IO targets virtualized clouds and x86 systems and addresses a few challenges in implementing context retention in real systems. Extensive experiments confirm its effectiveness.

NUMA systems have become ubiquitous. Though our evaluation demonstrates that vSMT-IO achieves better performance than competing solutions, the designs in vSMT-IO have not been optimized for NUMA systems. As future work, we want to make vSMT-IO "NUMA-aware" to further improve its performance. For example, the workload adjuster can be enhanced by adjusting workloads within each NUMA node before it migrates vCPUs across NUMA nodes.

Lightweight Preemptible Functions

Abstract

Lamenting the lack of a natural userland abstraction for preemptive interruption and asynchronous cancellation, we propose lightweight preemptible functions, a mechanism for synchronously performing a function call with a precise timeout that is lightweight, efficient, and composable, all while being portable between programming languages. We present the design of *libinger*, a library that provides this abstraction, on top of which we build *libturquoise*, arguably the first general-purpose and backwards-compatible preemptive thread library implemented entirely in userland. Finally, we demonstrate this software stack's applicability to and performance on the problems of combatting head-of-line blocking and time-based DoS attacks.

1 Introduction

After years of struggling to gain adoption, the coroutine has finally become a mainstream abstraction for cooperatively scheduling function invocations. Languages as diverse as C#, JavaScript, Kotlin, Python, and Rust now support "async functions," each of which expresses its dependencies by "awaiting" a **future** (or promise); rather than polling, the language yields if the awaited result is not yet available.

Key to the popularity of this concurrency abstraction is the ease and seamlessness of parallelizing it. Underlying most futures runtimes is some form of green threading library, typically consisting of a scheduler that distributes work to a pool of OS-managed worker threads. Without uncommon kernel support (e.g., scheduler activations [3]), however, this logical threading model renders the operating system unaware of individual tasks, meaning context switches are purely cooperative. This limitation is common among userland thread libraries, and illustrates the need for a mechanism for *preemptive* scheduling at finer granularity than the kernel thread.

In this paper, we propose an abstraction for calling a function with a timeout: Once invoked, the function runs on the same thread as the caller. Should the function time out, it is preempted and its execution state is returned as a continuation in case the caller later wishes to resume it. The abstraction is exposed via a wrapper function reminiscent of a thread spawn interface such as `pthread_create()` (except *synchronous*). Despite their synchronous nature, **preemptible functions** are useful to programs that are parallel or rely on asynchronous I/O; indeed, we later demonstrate how our abstraction composes with futures and threads.

The central challenge of introducing preemption into the contemporary programming model is supporting existing code. Despite decades of improvement focused on thread safety, modern systems stacks still contain critical nonreentrancy, ranging from devices to the dynamic memory allocator's heap region. Under POSIX, code that interrupts other user code is safe only if it restricts itself to calling async-signal-safe (roughly, reentrant) functions [27]. This restriction is all too familiar to those programmers who have written signal handlers: it is what makes it notoriously difficult to write nontrivial ones. Preemption of a timed function constitutes its interruption by the rest of the program. This implies that *the rest of the program* should be restricted to calling reentrant functions; needless to say, such a rule would be crippling. Addressing this problem is one of the main contributions of this paper. Our main insight here, as shown in Figure 1, is that some libraries are naturally reentrant, while many others can be made reentrant by automatically cloning their internal state so that preempting one invocation does not leave the library "broken" for concurrent callers.

The most obvious approach to implementing preemptible functions is to map them to OS threads, where the function would run on a new thread that could be cancelled upon timeout. Unfortunately, cancelling a thread is also hard. UNIX's pthreads provide asynchronous cancelability, but according to the Linux documentation, it

> is rarely useful. Since the thread could be cancelled at *any* time, it cannot safely reserve resources (e.g., allocating memory with `malloc()`), acquire mutexes, semaphores, or locks, and so on... some internal data structures (e.g., the linked list of free blocks managed by the `malloc()` family of functions) may be left in an inconsistent state if cancellation occurs in the middle of the function call [25].

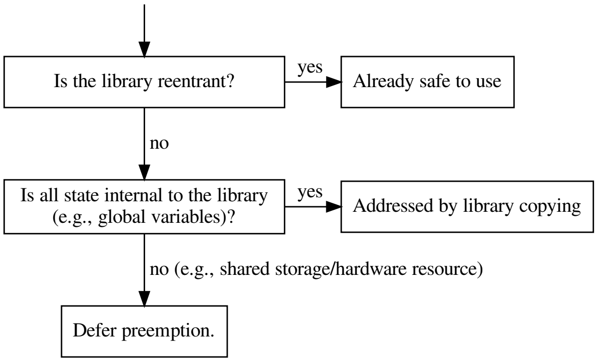
[‡] This author was *not* at Carnegie Mellon during this project.



Is the library reentrant?
yes
Already safe to use
no
Is all state internal to the library (e.g., global variables)?
yes
Addressed by library copying
no (e.g., shared storage/hardware resource)
Defer preemption.

Figure 1: Taxonomy of support for library code. In practice, we always apply one of the two mitigations. Library copying is used by default, and is discussed in Sections 5.1 and 5.2. Deferred preemption is needed to preserve the semantics of `malloc()` and users of uncopyable resources such as file descriptors or network adapters, and is applied according to a whitelist, as described in Section 5.5.

The same is true on Windows, whose API documentation warns that asynchronously terminating a thread

> can result in the following problems: If the target thread owns a critical section, the critical section will not be released. If the target thread is allocating memory from the heap, the heap lock will not be released...

and goes on from there [28].

One might instead seek to implement preemptible functions via the UNIX `fork()` call. Assuming a satisfactory solution to the performance penalty of this approach, one significant challenge would be providing bidirectional object visibility and ownership. In a model where each timed function executes in its own child process, not only must data allocated by the parent be accessible to the child, but the opposite must be true as well. The fact that the child may terminate before the parent raises allocation lifetime questions. And all this is without addressing the difficulty of even calling `fork()` in a multithreaded program: because doing so effectively cancels all threads in the child process except the calling one, the child process can experience the same problems that plague thread cancellation [4].

These naïve designs share another shortcoming: in reducing preemptible functions to a problem of parallelism, they hurt performance by placing thread creation on the critical path. Thus, the state-of-the-art abstractions' high costs limit their composability. We observe that, when calling a function with a timeout, it is concurrency alone—and not parallelism—that is fundamental. Leveraging this key insight, we present a design that *separates interruption from asynchrony* in order to provide *preemption at granularities in the tens of microseconds*, orders of magnitude finer than contemporary OS schedulers' millisecond timescales. Our research prototype[1] is implemented entirely in userland, and requires neither custom compiler or runtime support nor managed runtime features such as garbage collection.

This paper makes three primary contributions: (1) It proposes function calls that return a continuation upon preemption, a novel primitive for unmanaged languages. (2) It introduces selective relinking, a compiler-agnostic approach to automatically lifting safety restrictions related to nonreentrancy. (3) It demonstrates how to support asynchronous function cancellation, a feature missing from state-of-the-art approaches to preemption, even those that operate at the coarser granularity of a kernel thread.

2 Related work

A number of past projects (Table 1) have sought to provide bounded-time execution of chunks of code at subprocess granularity. For the purpose of our discussion, we refer to a portion of the program whose execution should be bounded as **timed code** (a generalization of a preemptible function); exactly how such code is delineated depends on the system's interface.

Interface notwithstanding, the systems' most distinguishing characteristic is the mechanism by which they enforce execution bounds. At one end of the spectrum are **cooperative** multitasking systems where timed code voluntarily cedes the CPU to another task via a runtime check. (This is often done implicitly; a simple example is a compiler that injects a conditional branch at the beginning of any function call from timed code.) Occupying the other extreme are **preemptive** systems that externally pause timed code and transfer control to a scheduler routine (e.g., via an interrupt service routine or signal handler, possibly within the language's VM).

The cooperative approach tends to be unable to interrupt two classes of timed code: (1) **blocking-call** code sections that cause long-running kernel traps (e.g., by making I/O system calls), thereby preventing the interruption logic from being run; and (2) **excessively-tight loops** whose body does not contain any yield points (e.g., spin locks or long-running CPU instructions). Although some cooperative systems refine their approach with mechanisms to tolerate either blocking-call code sections [1] or excessively-tight loops [32], we are not aware of any that are capable of handling both cases.

One early instance of timed code support was the *engines* feature of the Scheme 84 language [15]. Its in-

[1] Our system is open source; the code is available from `efficient.github.io/#lpf`.

†* = the third-party code must be written in the language without foreign dependencies
(beyond simple recompilation, this necessitates porting)

Table 1: Systems providing timed code at sub-process granularity

terface was a new `engine` keyword that behaved similarly to `lambda`, but created a special "thunk" accepting as an argument the number of ticks (abstract time units) it should run for. The caller also supplied a callback function to receive the timed code's return value upon successful completion. Like the rest of the Scheme language, engines were stateless: whenever one ran out of computation time, it would return a replacement engine recording the point of interruption. Engines' implementation relied heavily on Scheme's managed runtime, with ticks corresponding to virtual machine instructions and cleanup handled by the garbage collector. Although the paper mentions timer interrupts as an alternative, it does not evaluate such an approach.

Lilt [32] introduced a language for writing programs with statically-enforced timing policies. Its compiler tracks the possible duration of each path through a program and inserts yield operations wherever a timeout could possibly occur. Although this approach requires assigning the execution limit at compile time, the compiler is able to handle excessively-tight loops by instrumenting backward jumps. Blocking-call functions remained a challenge, however: handling them would have required operating system support, reminiscent of *Singularity*'s static language-based isolation [12].

Some recent languages offer explicit userland threading, which could be used to support timed code. One example is the Go language's [1] *goroutines*. Its runtime includes a cooperative scheduler that conditionally yields at function call sites. This causes problems with tight loops, which require the programmer to manually add calls to the `runtime.Gosched()` yield function [7].

The solutions described thus far all assume languages with a heavyweight, garbage-collected runtime. However, two recent systems seek to support timed code with fewer dependencies: the *C∀* language [8] and a C thread library for realtime systems (here, "*RT*") developed by Mollison and Anderson [22]. Both perform preemption using timer interrupts, as proposed in the early Scheme engines literature. They install a periodic signal handler for scheduling tasks and migrating them between cores, a lightweight approach that achieves competitive scheduling latencies. However, as explained later in this section, the compromise is interoperability with existing code.

Shinjuku [17] is an operating system designed to perform preemption at microsecond scale. Built on the Dune framework [5], it runs tasks on a worker thread pool controlled by a single centralized dispatcher thread. The latter polices how long each task has been running and sends an inter-processor interrupt (IPI) to any worker whose task has timed out. The authors study the cost of IPIs and the overheads imposed by performing them within a VT-x virtual machine, as required by Dune. They then implement optimizations to reduce these overheads at the expense of Shinjuku's isolation from the rest of the system.

As seen in Section 1, nonreentrant interfaces are incompatible with externally-imposed time limits. Because such interfaces are prolific in popular dependencies, no prior work allows timed code to transparently call into third-party libraries. Scheme engines and Lilt avoid this issue by only supporting functional code, which cannot have shared state. Go is able to preempt goroutines written in the language itself, but a goroutine that makes any foreign calls to other languages is treated as nonpreemptible by the runtime's scheduler [11]. The C∀ language's preemption model is only safe for functions guarded by its novel monitors: the authors caution that "any challenges that are not [a result of extending monitor semantics] are considered as solved problems and therefore not discussed." With its focus on realtime embedded systems, RT assumes that the timed code in its threads will avoid shared state; this assumption

```
struct linger_t {
    bool is_complete;
    cont_t continuation;
};

linger_t launch(Function func,
                u64 time_us,
                void *args);
void resume(linger_t *cont, u64 time_us);
```

Listing 1: Preemptible functions core interface

```
linger = launch(task, TIMEOUT, NULL);
if (!linger.is_complete) {
    // Save @linger to a task queue to
    // resume later
    task_queue.push(linger);
}

// Handle other tasks
...
// Resume @task at some later point
linger = task_queue.pop();
resume(&linger, TIMEOUT);
```

Listing 2: Preemptible function usage example

mostly precludes calls to third-party libraries, though the system supports the dynamic memory allocator by treating it as specifically nonpreemptible. Rather than dealing with shared state itself, Shinjuku asks application authors to annotate any code with potential concurrency concerns using a nonpreemptible `call_safe()` wrapper.

3 Timed functions: *libinger*

To address the literature's shortcomings, we have developed *libinger*,[2] a library providing a small API for timed function dispatch (Listing 1):

- `launch()` invokes an ordinary function `func` with a time cap of `time_us`. The call to `launch()` returns when `func` completes, or after approximately `time_us` microseconds if `func` has not returned by then. In the latter case, *libinger* returns an opaque continuation object recording the execution state.
- `resume()` causes a preemptible function to continue after a timeout. If execution again times out, `resume()` updates its continuation so the process may be repeated. Resuming a function that has already returned has no effect.

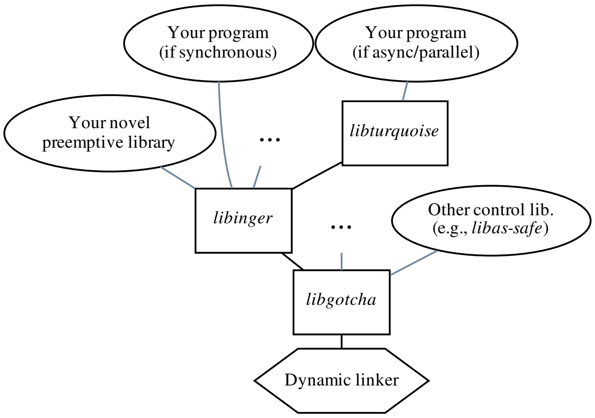

Figure 2: Preemptible functions software stack. Hexagonal boxes show the required runtime environment. Rectangular boxes represent components implementing the preemptible functions abstraction. Ovals represent components built on top of these. A preemptible function's body (i.e., `func`) may be defined directly in your program, or in some other loaded library.

Listing 2 shows an example use of *libinger* in a task queue manager designed to prevent latency-critical tasks from blocking behind longer-running ones. The caller invokes a task with a timeout. If the task does not complete within the allotted time, the caller saves its continuation in the task queue, handles other tasks, and later resumes the first task.

In accordance with our goal of language agnosticism, *libinger* exposes both C and Rust [2] APIs. To demonstrate the flexibility and composability of the preemptible function abstraction, we have also created *libturquoise*, a preemptive userland thread library for Rust, by porting an existing futures-based thread pool to *libinger*. We discuss this system in Section 4.

Figure 2 shows a dependency graph of the software components comprising the preemptible functions stack. The *libinger* library itself is implemented in approximately 2,500 lines of Rust. To support calls to nonreentrant functions, it depends on another library, *libgotcha*, which consists of another 3,000 lines of C, Rust, and x86-64 assembly. We cover the details in Section 5.

We now examine *libinger*, starting with shared state.

3.1 Automatic handling of shared state

As we found in Section 1, a key design challenge facing *libinger* is the shared state problem: Suppose a preemptible function F calls a stateful routine in a third-party library L, and that F times out and is preempted by *libinger*. Later, the user invokes another timed function F_0, which also calls a stateful routine in L. This pattern involves an unsynchronized concurrent access to L. To avoid introducing such bugs, *libinger* must hide state modifications in L by F from the execution of F_0.

One non-solution to this problem is to follow the ap-

[2] In the style of GNU's *libiberty*, we named our system for the command-line switch used to link against it. As the proverb goes, "Don't want your function calls to linger? Link with `-linger`."

proach taken by POSIX signal handlers and specify that preemptible functions may not call third-party code, but doing so would severely limit their usefulness (Section 2). We opt instead to automatically and dynamically create copies of L to isolate state from different timed functions. Making this approach work on top of existing systems software required solving many design and implementation challenges, which we cover when we introduce *libgotcha* in Section 5.

3.2 Safe concurrency

Automatically handling shared state arising from non-reentrant library interfaces is needed because the sharing is transparent to the programmer. A different problem arises when a programmer explicitly shares state between a preemptible function and any other part of the program. Unlike third-party library authors, this programmer knows they are using preemptible functions, a concurrency mechanism.

When using the C interface, the programmer bears complete responsibility for writing race-free code (e.g., by using atomics and mutexes wherever necessary). The *libinger* Rust API, however, leverages the language's first-class concurrency support to prevent such mistakes from compiling: `launch()`'s signature requires the wrapped function to be `Send` safe (only reference state in a thread-safe manner) [29].

While the Rust compiler rejects all code that shares state unsafely, it is still possible to introduce correctness bugs such as deadlock [30]. For example, a program might block on a mutex held by the preemptible function's caller (recall that invocation is synchronous, so blocking in a preemptible function does not cause it to yield!). It is sometimes necessary to acquire such a mutex, so *libinger* provides a way to do it: The API has an additional function, `pause()`, that is a rough analog of yield. After performing a try-lock operation, a preemptible function can call `pause()` to immediately return to its caller as if it had timed out. The caller can tell whether a function paused via a flag on its continuation.

3.3 Execution stacks

When a preemptible function times out, *libinger* returns a continuation object. The caller might pass this object around the program, which could later `resume()` from a different stack frame. To handle this case, the `launch()` function switches to a new, dedicated stack just before invoking the user-provided function. This stack is then stored in the continuation alongside the register context.

Because of the infeasibility of moving these stacks after a function has started executing, *libinger* currently heap-allocates large 2-MB stacks so it can treat them as having fixed size. To avoid an order of magnitude slowdown from having such large dynamic allocations on the critical path, *libinger* preallocates a pool of reusable stacks when it is first used.

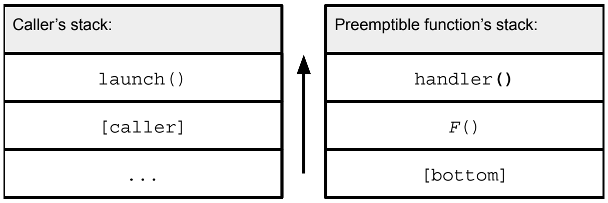

Figure 3: The stacks just before a timeout. Upon discovering that the preemptible function has exceeded its time bound, the handler jumps into the `launch()` (or `resume()`) function, which in turn returns to the original call site, removing its own stack frame in the process.

3.4 Timer interrupts

Whenever *libinger* is executing a user-provided function, we enable fine-grained timer interrupts to monitor that function's elapsed running time. A timer interrupt fires periodically,[3] causing our signal handler to be invoked. If the function exceeds its timeout, this handler saves a continuation by dumping the machine's registers. It then performs an unstructured jump out of the signal handler and back into the `launch()` or `resume()` function, switching back to the caller's stack as it does so. Figure 3 shows the two stacks of execution that are present while the signal handler is running.

A subsequent `resume()` call restores the registers from the stored continuation, thereby jumping back into the signal handler. The handler returns, resuming the preemptible function from the instruction that was executing when the preemption signal arrived.

To support blocking system calls, we use the `SA_RESTART` flag when installing the signal handler to instruct libc to restart system calls that are interrupted by the signal [26]. We direct signals at the process's specific threads that are running preemptible functions by allocating signal numbers from a pool, an approach that limits the number of simultaneous invocations to the number of available signals; this restriction could be lifted by instead using the Linux-specific `SIGEV_THREAD_ID` timer notification feature [31].

3.5 Cancellation

Should a caller decide not to finish running a timed-out preemptible function, it must deallocate it. In Rust, deal-

[3] Signal arrival is accurate to microsecond timescales, but exhibits a warmup effect. For simplicity, we use a fixed signal frequency for all preemptible functions, but this is not fundamental to the design. In the future, we plan to adjust each function's frequency based on its timeout, and to delay the first signal until shortly before the prescribed timeout (in the case of longer-running functions).

location happens implicitly via the `linger_t` type's destructor, whereas users of the C interface are responsible for explicitly calling the *libinger* `cancel()` function.

Cancellation cleans up *libinger* resources allocated by `launch()`; however, the current implementation does not automatically release resources already claimed by the preemptible function itself. While the lack of a standard resource deallocation API makes such cleanup inherently hard to do in C, it is possible in Rust and other languages in which destructor calls are ostensibly guaranteed. For instance, the approach proposed by Boucher et al. [6] could be employed to raise a panic (exception) on the preemptible function's stack. This in turn would cause the language runtime to unwind each stack frame, invoking local variables' destructors in the process.

4 Thread library: *libturquoise*

Until now, we have limited our discussion to synchronous, single-threaded programs. In this section, we will show that the preemptible function abstraction is equally relevant to asynchronous and parallel programs, and that it composes naturally with both futures and threads. As a proof of concept, we have created *libturquoise*,[4] a preemptive userland thread library.

That *libturquoise* provides preemptive scheduling is a significant achievement: *Shinjuku* observes that "there have been several efforts to implement efficient, user-space thread libraries. They all focus on cooperative scheduling" [17]. (Though *RT* from Section 2 could be a counterexample, its lack of nonreentrancy support renders it far from general purpose.) We attribute the dearth of preemptive userland thread libraries to a lack of natural abstractions to support them.

Before presenting the *libturquoise* design, we begin with some context about futures.

4.1 Futures and asynchronous I/O

As mentioned in Section 1, futures are a primitive for expressing asynchronous program tasks in a format amenable to cooperative scheduling. Structuring a program around futures makes it easy to achieve low latency by enabling the runtime to reschedule slow operations off the critical path. Alas, blocking system calls (which cannot be rescheduled by userland) defeat this approach.

The community has done extensive prior work to support asynchronous I/O via result callbacks [19, 18, 20, 23]. Futures runtimes such as Rust's Hyper [16] have adapted this approach by providing I/O libraries whose functions return futures. Rather than duplicate this work, we have integrated preemptible functions with futures so they can leverage it.

```
function PreemptibleFuture(Future fut,
                           Num timeout):
    function adapt():
        // Poll wrapped future in the usual way
        while poll(fut) == NotReady:
            pause()
    fut.linger = launch(adapt, CREATE_ONLY)
    fut.timeout = timeout
    return fut

// Custom polling logic for preemptible futures
function poll(PreemptibleFuture fut):
    resume(fut.linger, fut.timeout);
    if has_finished(fut.linger):
        return Ready
    else
        if called_pause(fut.linger):
            notify_unblocked(fut.subscribers)
        return NotReady
```

Listing 3: Futures adapter type (pseudocode)

4.2 Preemptible futures

For seamless interoperation between preemptible functions and the futures ecosystem, we built a preemptible future adapter that wraps the *libinger* API. Like a normal future, a preemptible future yields when its result is not ready, but it can also time out.

Each language has its own futures interface, so preemptible futures are not language agnostic like the preemptible functions API. Fortunately, they are easy to implement by using `pause()` to propagate cooperative yields across the preemptive function boundary. We give the type construction and polling algorithm in Listing 3; our Rust implementation is only 70 lines.

4.3 Preemptive userland threading

We built the *libturquoise* thread library by modifying the *tokio-threadpool* [13] work-stealing scheduler from the Rust futures ecosystem. Starting from version 0.1.16 of the upstream project, we added 50 lines of code that wrap each incoming task in a preemptible future.

Currently, *libturquoise* assigns each future it launches or resumes the same fixed time budget, although this design could be extended to support multiple job priorities. When a task times out, the scheduler pops it from its worker thread's job queue and pushes it to the incoming queue, offering it to any available worker for rescheduling after all other waiting jobs have had a turn.

5 Shared state: *libgotcha*

We now present one more artifact, *libgotcha*. Despite the name, it is more like a runtime that isolates hidden shared state within an application. Although the rest of the program does not interact directly with *libgotcha*, its

[4] so called because it implements "green threading with a twist"

```c
static bool two;
bool three;

linger_t caller(const char *s, u64 timeout) {
    stdout = NULL;
    two = true;
    three = true;
    return launch(timed, timeout, s);
}

void timed(void *s) {
    assert(stdout); // (1)
    assert(two); // (2)
    assert(three); // (3)
}
```

Listing 4: Demo of isolated (1) **vs. shared** (2&3) **state**

presence has a global effect: once loaded into the process image, it employs a technique we call **selective relinking** to dynamically intercept and reroute many of the program's function calls and global variable accesses.

The goal of *libgotcha* is to establish around every preemptible function a memory isolation boundary encompassing whatever third-party libraries that function interacts with (Section 3.1). The result is that the only state shared across the boundary is that explicitly passed via arguments, return value, or closure—the same state the application programmer is responsible for protecting from concurrency violations (Section 3.2). Listing 4 shows the impact on an example program, and Figure 1 classifies libraries by how *libgotcha* supports them.

Note that *libgotcha* operates at runtime; this constrains its visibility into the program, and therefore the granularity of its operation, to shared libraries. It therefore assumes that the programmer will dynamically link all third-party libraries, since otherwise there is no way to tell them apart from the rest of the program at runtime. We feel this restriction is reasonable because a programmer wishing to use *libinger* or *libgotcha* must already have control over their project's build in order to add the dependency.

Before introducing the *libgotcha* API and explaining selective relinking, we now briefly motivate the need for *libgotcha* by demonstrating how existing system interfaces fail to provide the required type of isolation.

5.1 Library copying: namespaces

Expanding a preemptible function's isolation boundary to include libraries requires providing it with private copies of those libraries. POSIX has long provided a `dlopen()` interface to the dynamic linker for loading shared objects at runtime; however, opening an already-loaded library just increments a reference count, and this function is therefore of no use for making copies.

```c
typedef long libset_t;

bool libset_thread_set_next(libset_t);
libset_t libset_thread_get_next(void);
bool libset_reinit(libset_t);
```

Listing 5: *libgotcha* C interface

Fortunately, the GNU dynamic linker (`ld-linux.so`) also supports Solaris-style **namespaces**, or isolated sets of loaded libraries. For each namespace, `ld-linux.so` maintains a separate set of loaded libraries whose dependency graph and reference counts are tracked independently from the rest of the program [9].

It may seem like namespaces provide the isolation we need: whenever we `launch(`*F*`)`, we can initialize a namespace with a copy of the whole application and transfer control into that namespace's copy of *F*, rather than the original. The problem with this approach is that it breaks the lexical scoping of static variables. For example, Listing 4 would fail assertion (2).

5.2 Library copying: libsets

We just saw that namespaces provide too much isolation for our needs: because of their completely independent dependency graphs, they never encounter any state from another namespace, even according to normal scoping rules. However, we can use namespaces to build the abstraction we need, which we term a **libset**. A libset is like a namespace, except that the program can decide whether symbols referenced within a libset resolve to the same libset or a different one. Control libraries such as *libinger* configure such **libset switches** via *libgotcha*'s private control API, shown in Listing 5.

This abstraction serves our needs: when a `launch(`*F*`)` happens, *libinger* assigns an available `libset_t` exclusively to that preemptible function. Just before calling *F*, it informs *libgotcha* by calling `libset_thread_set_next()` to set the thread's **next libset**: any dynamic symbols used by the preemptible function will resolve to this libset. The thread's **current libset** remains unchanged, however, so the preemptible function itself executes from the same libset as its caller and the two share access to the same global variables.

One scoping issue remains, though. Because dynamic symbols can resolve back to a definition in the same executable or shared object that used them, Listing 5 would fail assertion (3) under the described rules. We want global variables defined in *F*'s object file to have the same scoping semantics regardless of whether they are declared `static`, so *libgotcha* only performs a namespace switch when the use of a dynamic symbol occurs in a different executable or shared library than that symbol's definition.

5.3 Managing libsets

At program start, *libgotcha* initializes a pool of libsets, each with a full complement of the program's loaded object files. Throughout the program's run *libinger* tracks the libset assigned to each preemptible function that has started running but not yet reached successful completion. When a preemptible function completes, *libinger* assumes it has not corrupted its libset and returns it to the pool of available ones. However, if a preemptible function is canceled rather than being allowed to return, *libinger* must assume that its libset's shared state could be corrupted. It unloads and reloads all objects in such a libset by calling `libset_reinit()`.

While *libinger* in principle runs on top of an unmodified `ld-linux.so`, in practice initializing more than one namespace tends to exhaust the statically-allocated thread-local storage area. As a workaround, we build glibc with an increased `TLS_STATIC_SURPLUS`. It is useful to also raise the maximum number of namespaces by increasing `DL_NNS`.

5.4 Selective relinking

Most of the complexity of *libgotcha* lies in the implementation of selective relinking, the mechanism underlying libset switches.

Whenever a program uses a dynamic symbol, it looks up its address in a data structure called the global offset table (GOT). As it loads the program, `ld-linux.so` eagerly resolves the addresses of all global variables and some functions and stores them in the GOT.

Selective relinking works by shadowing the GOT.[5] As soon as `ld-linux.so` finishes populating the GOT, *libgotcha* replaces every entry that should trigger a libset switch with a fake address, storing the original one in its shadow GOT, which is organized by the libset that houses the definition. The fake address used depends upon the type of symbol:

Functions' addresses are replaced by the address of a special function, `procedure_linkage_override()`. Whenever the program tries to call one of the affected functions, this intermediary checks the thread's next libset, looks up the address of the appropriate definition in the shadow GOT, and jumps to it. Because `procedure_linkage_override()` runs between the caller's `call` instruction and the real function, it is written in assembly to avoid clobbering registers. Instead of being linked to their symbol definitions at load time, some function calls resolve lazily the first time they are called: their GOT entries initially point to a special lookup function in the dynamic linker that rewrites the GOT entry when invoked. Such memoization would remove our intermediary, so we alter the ELF relocation entries of affected symbols to trick the dynamic linker into updating our shadow GOT instead.

Global variables' addresses are replaced with a unique address within a mapped but inaccessible page. When the program tries to read or write such an address, a segmentation fault occurs; *libgotcha* handles the fault, disassembles the faulting instruction to determine the base address register of its address calculation,[6] loads the address from this register, computes the location of the shadow GOT entry based on the fake address, checks the thread's next libset, and replaces the register's contents with the appropriate resolved address. It then returns, causing the faulting instruction to be reexecuted with the valid address this time.[7]

5.5 Uninterruptible code: uncopyable

The library-copying approach to memory isolation works for the common case, and allows us to handle most third-party libraries with no configuration. However, in rare cases it is not appropriate. The main example is the `malloc()` family of functions: in Section 1, we observed that not sharing a common heap complicates ownership transfer of objects allocated from inside a preemptible function. To support dynamic memory allocation and a few other special cases, *libgotcha* has an internal whitelist of **uncopyable** symbols.

From *libgotcha*'s perspective, uncopyable symbols differ only in what happens on a libset switch. If code executing in any libset other than the application's **starting libset** calls an uncopyable symbol, a libset switch still occurs, but it returns to the starting libset instead of the next libset; thus, all calls to an uncopyable symbol are routed to a single, globally-shared definition. When the function call that caused one of these special libset switches returns, the next libset is restored to its prior value. The *libgotcha* control API provides one more function, `libset_register_interruptible_callback()`, that allows others to request a notification when one of these libset restorations occurs.

Because it is never safe to preempt while executing in the starting libset, the first thing the *libinger* preemption handler described in Section 3.4 does is check whether the thread's next libset is set to the starting one; if so, it disables preemption interrupts and immediately returns. However, *libinger* registers an interruptible call-

[5] Hence the name *lib**got**cha*.

[6] Although it is possible to generate code sequences that are incompatible with this approach (e.g., because they perform in-place pointer arithmetic on a register rather than using displacement-mode addressing with a base address), we employ a few heuristics based on the context of the instruction and fault; in our experience, these cover the common cases.

[7] This does not break applications with existing segfault handlers: we intercept their calls to `sigaction()`, and forward the signal along to their handler when we are unable to resolve an address ourselves.

back that it uses to reenable preemption as soon as any uncopyable function returns.

5.6 Limitations

The current version of *libgotcha* includes partial support for thread-local storage (TLS). Like other globals, TLS variables are copied along with the libset; this behavior is correct because a thread might call into the same library from multiple preemptible functions. However, we do not yet support migrating TLS variables between threads along with their preemptible function. This restriction is not fundamental: the TLS models we support (general dynamic and local dynamic) use a support function called `__tls_get_addr()` to resolve addresses [10], and *libgotcha* could substitute its own implementation that remapped the running thread's TLS accesses to that of the preemptible function's initial thread when executing outside the starting libset.

While selective relinking supports the ordinary `GLOB_DAT` (eager) and `JUMP_SLOT` (lazy) ELF dynamic relocation types, it is incompatible with the optimized `COPY` class of dynamic variable relocations. The `COPY` model works by allocating space for all libraries' globals in the executable, enabling static linking from the program's code (but not its dynamic libraries'). This transformation defeats selective relinking for two reasons: the use of static linking prevents identifying symbol uses in the executable, and the cross-module migration causes breakages such as failing assertion (3) from Listing 4. When building a program that depends on *libgotcha*, programmers must instruct their compiler to disable `COPY` relocations, as with the `-fpic` switch to GCC and Clang. If *libgotcha* encounters any `COPY` relocations in the executable, it prints a load-time warning.

Forsaking `COPY` relocations does incur a small performance penalty, but exported global variables are rare now that thread safety is a pervasive concern in system design. Even the POSIX-specified `errno` global is gone: the Linux Standard Base specifies that its address is resolved via a call to the `__errno_location()` helper function [21].

5.7 Case study: auto async-signal safety

We have now described the role of *libgotcha*, and how *libinger* uses it to handle nonreentrancy. Before concluding our discussion, however, we note that *libgotcha* has other interesting uses in its own right.

As an example, we have used it to implement a small library, *libas-safe*, that transparently allows an application's signal handlers to call functions that are not async-signal safe, which is forbidden by POSIX because it is normally unsafe.

Written in 127 lines of C, *libas-safe* works by injecting code before `main()` to switch the program away from its starting libset. It shadows the system's `sigaction()`, providing an implementation that:

- Provides copy-based library isolation for signal handlers by switching the thread's next libset to the starting libset while a signal handler is running.
- Allows use of uncopyable code such as `malloc()` from a signal handler by deferring signal arrival whenever the thread is already executing in the starting libset, then delivering the deferred signal when the interruptible callback fires.

In addition to making signal handlers a lot easier to write, *libas-safe* can be used to automatically "fix" deadlocks and other misbehaviors in misbehaved signal-handling programs just by loading it via `LD_PRELOAD`.

We can imagine extending *libgotcha* to support other use cases, such as simultaneously using different versions or build configurations of the same library from a single application.

Operation	Duration (μs)
`launch()`	4.6 ± 0.05
`resume()`	4.4 ± 0.02
`cancel()`	4767.7 ± 1168.7
`fork()`	207.5 ± 79.3
`pthread_create()`	32.5 ± 8.0

Table 2: Latency of preemptible function interface

6 Evaluation

We now evaluate preemptible function performance, presenting several microbenchmarks and two examples of their application to improve existing systems' resilience to malicious or otherwise long-running requests. All experiments were run on an Intel Xeon E5-2683 v4 (Broadwell) server running Linux 4.12.6, rustc 1.36.0, gcc 9.2.1, and glibc 2.29.

6.1 Microbenchmarks

Table 2 shows the overhead of *libinger*'s core functions. Each test uses hundreds of preemptible functions, each with its own stack and continuation, but sharing an implementation; the goal is to measure invocation time, so the function body immediately calls `pause()`. For comparison, we also measured the cost of calling `fork()` then `exit()`, and of calling `pthread_create()` with an empty function, while the parent thread waits using `waitpid()` or `pthread_join()`, respectively.

The results show that, as long as preemptible functions are eventually allowed to run to completion, they are an order of magnitude faster than spawning a thread and two orders of magnitude faster than forking a process. Although cancellation takes milliseconds in the benchmark application, this operation need not lie on the critical path unless the application is cancelling tasks frequently enough to exhaust its supply of libsets.

Recall that linking an application against *libgotcha* imposes additional overhead on most dynamic symbol accesses; we report these overheads in Table 3a. Eager function calls account for almost all of a modern program's dynamic symbol accesses: lazy resolution only occurs the first time a module calls a particular function (Section 5.4) and globals are becoming rare (Section 5.6).

Table 3b shows that the *libgotcha* eager function call overhead of 14 ns is on par with the cost of a trivial C library function (`gettimeofday()`) and one-third that of a simple system call (`getpid()`). This overhead affects the entire program, regardless of the current libset at the time of the call. Additionally, calls to uncopyable functions from within a preemptible function incur several extra nanoseconds of latency to switch back to the main namespace as described in Section 5; Table 3c breaks this overhead down to show the cost of notification callbacks at the conclusion of such a call (always required by *libinger*).

6.2 Web server

To test whether our thread library could combat head-of-line blocking in a large system, we benchmarked *hyper*, the highest-performing Web server in TechEmpower's plaintext benchmark as of July 2019 [16]. The server uses *tokio-threadpool* for scheduling; because the changes described in Section 4 are transparent, making *hyper* preemptive was as easy as building against *libturquoise* instead. In fact, we did not even check out the *hyper* codebase. We configured *libturquoise* with a task timeout of 2 ms, give or take a 100-μs *libinger* preemption interval, and configured it to serve responses only after spinning in a busy loop for a number of iterations specified in each request. For our client, we modified version 4.1.0 of the *wrk* [14] closed-loop HTTP load generator to separately record the latency distributions of two different request classes.

Our testbed consisted of two machines connected by a direct 10-GbE link. We pinned *hyper* to the 16 physical cores on the NIC's NUMA node of our Broadwell server. Our client machine, a Intel Xeon E5-2697 v3 (Haswell) running Linux 4.10.0, ran a separate *wrk* process pinned to each of the 14 logical cores on the NIC's NUMA node. Each client core maintained two concurrent pipelined HTTP connections.

We used loop lengths of approximately 500 μs and 50 ms for short and long requests, respectively, viewing the latter requests as possible DoS attacks on the system. We varied the percentage of long requests from 0% to 2% and measured the round-trip median and tail latencies of short requests and the throughput of all requests. Figure 4 plots the results for three server configurations: `baseline` is cooperative scheduling via *tokio-threadpool*, `baseline+libgotcha` is the same but with *libgotcha* loaded to assess the impact of slower dynamic function calls, and `baseline+libturquoise` is preemptive scheduling via *libturquoise*. A 2% long request mix was enough to reduce the throughput of the *libgotcha* server enough to impact the median short request latency. The experiment shows that preemptible functions keep the tail latency of short requests scaling linearly at the cost of a modest 4.5% median latency overhead when not under attack.

6.3 Image decompression

The Web benchmark showed preemptive scheduling at scale, but did not exercise preemptible function cancellation. To demonstrate this feature, we consider decompression bombs, files that expand exponentially when decoded, consuming enormous computation time in addition to their large memory footprint. PNG files are vulnerable to such an attack, and although *libpng* now supports some mitigations [24], one cannot always expect (or trust) such functionality from third-party code.

We benchmarked the use of *libpng*'s "simple API" to decode an in-memory PNG file. We then compared against synchronous isolation using preemptible functions, as well as the naïve alternative mitigations proposed in Section 1. For preemptible functions, we wrapped all uses of *libpng* in a call to `launch()` and used a dedicated (but blocking) reaper thread to remove the cost of cancellation from the critical path; for threads, we used `pthread_create()` followed by `pthread_timedjoin_np()` and, conditionally, `pthread_cancel()` and `pthread_join()`; and for processes, we used `fork()` followed by `sigtimedwait()`, a conditional `kill()`, then a `waitpid()` to reap the child. We ran `pthread_cancel()` both with and without asynchronous cancelability enabled, but the former always deadlocked. The timeout was 10 ms in all cases.

Running on the benign RGB image `mirjam_meijer_mirjam_mei.png` from version `1:0.18+dfsg-15` of Debian's `openclipart-png` package showed `launch()` to be both faster and lower-variance than the other approaches, adding 355 μs or 5.2% over the baseline (Figure 5a). The results for `fork()` represent a best-case scenario for that technique, as we did not implement a shared memory mechanism for sharing the buffer, and the cost of the system call will increase with the number pages mapped by the process (which was small in this case).

Next, we tried a similarly-sized RGB decompression bomb from revision `b726584` of `https://bomb.codes` (Figure 5b). Without asynchronous cancelability, the pthreads approach was unable to interrupt the thread. Here, `launch()` exceeded the deadline by just 100 μs, a

Symbol resolution scheme	Time without *libgotcha* (*ns*)	Time with *libgotcha* (*ns*)
eager (load time)	2 ± 0	14 ± 0
lazy (runtime)	100 ± 1	125 ± 0
global variable	0 ± 0	3438 ± 13

(a) Generic symbols, without and with *libgotcha*

Baseline	Time without *libgotcha* (*ns*)
`gettimeofday()`	19 ± 0
`getpid()`	44 ± 0

(b) Library functions and syscalls without *libgotcha*

Trigger	Time with *libgotcha* (*ns*)
Uncopyable call	21 ± 0
Uncopyable call + callback	25 ± 0

(c) Uncopyable calls triggering a libset switch

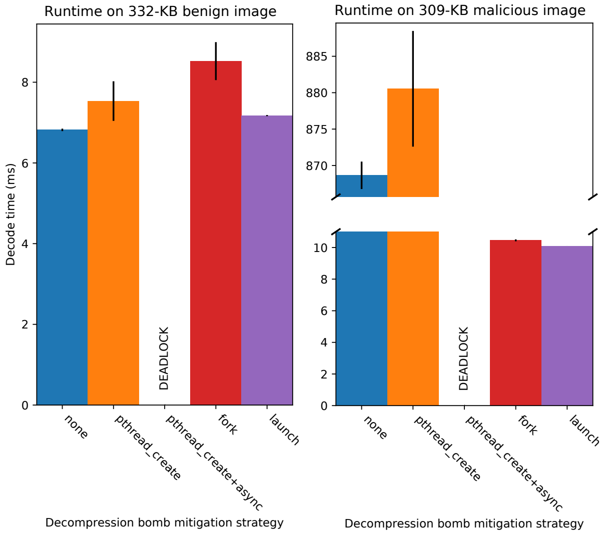
(a) Median latency

(b) 90% tail latency

(c) 99% tail latency

(d) Overall throughput

Figure 4: *hyper* Web server with 500-μs (short) and 50-ms (long) requests



(a) Benign image **(b) Malicious image**

Figure 5: *libpng* in-memory image decode times

figure that includes deviation due to the 100-μs preemption interval in addition to *libinger*'s own overhead. It again had the lowest variance.

Applying preemptible functions proved easy: the `launch()`/`cancel()` approach took just 20 lines of Rust, including the implementation of a reaper thread to move libset reinitialization off the critical path. In comparison, the `fork()`/`sigtimedwait()` approach required 25 lines of Rust. Note that both benchmarks include unsafe Rust (e.g., to use the *libpng* C library and zero-copy buffers).

7 Future work

One of our contributions is asynchronous cancellation, something rarely supported by the state of the art. In Section 3.5, we noted our lack of support for automated resource cleanup; however, we outlined a possible approach for languages such as Rust, which we intend to investigate further. Cancellation is currently our most expensive operation because of the libset reinitialization described in Section 5.3, but we plan to improve this by restoring only the writeable regions of each module.

Another area for improvement is signal-handling performance optimization: whereas *Shinjuku* is able to preempt every 5 μs with a 10% throughput penalty [17], we have observed a similar throughput drop while only preempting every 20 μs via our technique [6]. We have not yet heavily optimized *libinger*, and have reason to believe that doing so will allow our design to achieve a preemption granularity midway between those figures for the same throughput cost. Because *Shinjuku* executes in privilege ring 0, they preempt by issuing interprocessor interrupts (IPIs) directly rather than using Linux signals. Their microbenchmarks reveal an IPI:signal latency ratio of roughly 1:2.5 (1,993 vs. 4,950 CPU cycles), indicating that we are not achieving peak performance. Furthermore, a key design difference between our systems suggests that this ratio probably understates the performance we could achieve. In their benchmark, roughly 42% of cycles are spent sending each signal, a cost we can amortize because our design uses recurring timer signals to counter warmup effects. A further 6.9% of benchmarked cycles are spent propagating the signal between cores, which should not affect our system because we request the timer signals on the same core that will receive them rather than using a central watchdog thread to preempt all workers. Context switching is likely responsible for most of our unexpected latency: by writing our signal handler very carefully, we should be able to adopt the same optimizations they describe (skipping signal mask and floating-point register swaps).

The selective relinking technique that underlies our interface allows safe pausing and cancellation in the presence of shared state, *independent of preemption mechanism*. In lieu of a timeout, control transfer might result from another scheduling consideration, such as real-time computing or task priority.

8 Conclusion

We presented the lightweight preemptible function, a new composable abstraction for invoking a function with a timeout. This enabled us to build a first-in-class preemptive userland thread library by implementing preemption atop a cooperative scheduler, rather than the other way around. Our evaluation shows that lightweight preemptible functions have overheads of a few percent (lower than similar OS primitives), yet enable new functionality.

We believe the lightweight preemptible function abstraction naturally supports common features of large-scale systems. For example: In support of graceful degradation, a system might use a preemptible function to abort the rendering of a video frame in order to ensure SLA adherance. An RPC server might preserve work by processing each request in a preemptible function and memoizing the continuations; if a request timed out but was later retried by the client, the server could resume executing from where it left off.

coIOMMU: A Virtual IOMMU with Cooperative DMA Buffer Tracking for Efficient Memory Management in Direct I/O

Kun Tian, Yu Zhang, Luwei Kang, Yan Zhao, Yaozu Dong
Intel Corporation

Abstract

Direct assignment of I/O devices (Direct I/O) is the best performant I/O virtualization method. However, it requires the hypervisor to statically pin the entire guest memory, thereby hindering the efficiency of memory management. This problem can be fixed by presenting a virtual IOMMU (vIOMMU). Emulation of its DMA remapping capability carries sufficient information about guest DMA buffers, allowing the hypervisor to do fine-grained pinning of guest memory. However, established vIOMMUs are not widely used by commodity guests due to the emulation cost, thus cannot reliably eliminate static pinning in direct I/O.

We propose and implement *coIOMMU*, a new vIOMMU architecture for efficient memory management with a cooperative DMA buffer tracking mechanism. The new mechanism provides a dedicated interface for hypervisor and guest to exchange DMA buffer information over a shared DMA tracking table (DTT), orthogonal to the costly DMA remapping interface. We also explore two techniques: smart pinning and lazy unpinning, to minimize the impact on the performance of direct I/O. Our evaluation results show that coIOMMU dramatically improves the efficiency of memory management in wide direct I/O usages with negligible cost. Moreover, the desired semantics of DMA remapping can be sustained when cooperative tracking is enabled alongside. Overall, we believe that coIOMMU can serve as a reliable solution for efficient memory management in direct I/O.

1. Introduction

Direct I/O [1, 21, 29, 31, 37, 39, 48, 49, 50] is the best performant I/O virtualization method and a cornerstone capability in data centers and clouds. It allows the guest to directly interact with I/O devices without the intervention from software intermediary. An I/O memory management unit (IOMMU) [3, 14, 16] helps prevent Direct Memory Access (DMA) attacks in direct I/O by providing the capability of *DMA remapping*. Each assigned device is associated with an IOMMU page table (IOPT), configured by the hypervisor in a way that only the memory of the guest that owns the device is mapped. The IOMMU walks the IOPTs to validate and translate DMA requests, achieving inter-guest protection among directly assigned devices.

Most devices do not tolerate DMA faults, implying that guest buffers must be pinned in host memory and mapped in the IOPT before they are accessed by DMAs. However, the hypervisor does not know which pages are mapped by the guest when it is eliminated from the direct I/O path. Consequently, it has to pin the entire guest memory upfront, a.k.a *static pinning* [7, 44]. This heavily hinders the efficiency of memory management and worsens memory utilization, as pinned pages cannot be reclaimed for other purposes.

Presenting a virtual IOMMU (vIOMMU) [8, 23, 29, 52, 60] to the guest allows *fine-grained pinning* of guest memory for efficient memory management, although its primary purpose is to help the guest protect itself against buggy drivers. The hypervisor emulates the DMA remapping interface by: 1) walking the virtual IOPT (vIOPT) to identify the affected buffers; 2) pinning and unpinning the buffers in the host memory; and 3) mapping and unmapping them in the physical IOMMU to enforce protection as desired by the guest. Naturally, the emulation leads to a fine-grained pinning scheme, if the guest always uses the vIOMMU to remap its DMA buffers.

Unfortunately, established vIOMMUs are not applicable as a reliable solution for *fine-grained pinning*. Their virtual DMA remapping capabilities are disabled by most guests [8, 24, 30, 38, 51] in typical usages such as public cloud, because significant emulation cost may be incurred due to frequent mapping operations in the guest. Such cost could be alleviated through side-core emulation [8] or para-virtualized extension [23, 52]. However, the side-core emulation requires an additional CPU core to perform the emulation; and can only achieve optimal performance with deferred IOTLB invalidation, leading to compromised security. Para-virtualized extension reduces the virtualization overhead with optimized interfaces, but it still involves large number of VM-exits at the time of guest DMA mappings/unmappings, hence limiting the performance. Therefore, they did not change the fact that established vIOMMUs are used only in limited circumstances, e.g. when intra-guest protection is valued over the overhead of DMA remapping.

We argue that mixing the requirements of protection and pinning, through the same costly DMA remapping interface, is needlessly constraining. Protection is a guest requirement, while pinning is for host memory management. The two do not always match, thus favoring one may easily break the other. Instead, we aim to provide a reliable solution for fine-grained pinning by decoupling it from protection.

We propose and implement a new vIOMMU architecture called coIOMMU, which helps the hypervisor achieve efficient memory management in direct I/O. It introduces a dedicated mechanism for cooperative DMA buffer tracking, orthogonal to the costly DMA remapping interface. coIOMMU allows the hypervisor and guest to communicate over a DMA tracking table (DTT) located in a shared memory region. The guest records the mapping status of its DMA buffers in the DTT and the hypervisor walks the DTT to identify the corresponding pinning requirement. coIOMMU further minimizes the number of notifications from the guest, with two optimizations: (1) *smart pinning*, which heuristically pins frequently used pages and timely shares its pinning status with the guest, to enable precise notification in guest-mapping operations; and (2) *lazy unpinning*, which asynchronously unpins guest pages to eliminate notifications in guest-unmapping operations. On the other hand, the new mechanism does not affect the desired semantics of DMA remapping. It can be enabled with or without DMA remapping, as a reliable and standard interface to achieve fine-grained pinning in direct I/O.

We implement coIOMMU by extending KVM/QEMU vIOMMU and Linux guest. The concept and implementation can be easily ported to other hypervisors, vIOMMUs and guest OSes. Overall, the main contributions of this paper are:

- Observing that established vIOMMUs cannot reliably fix the problem of static pinning in direct I/O, due to the costly DMA remapping interface.
- Proposing and implementing coIOMMU, the first vIOMMU that introduces a dedicated DMA buffer tracking mechanism for fine-grained pinning.
- Introducing smart pinning and lazy unpinning to dramatically reduce the tracking overhead in fine-grained pinning.
- Conducting comprehensive evaluations under different Linux protection policies, with benchmarks in direct networking, storage, and GPU.
- Demonstrating that coIOMMU not only dramatically improves the efficiency of memory management in wide direct I/O usages with negligible cost, but also sustains the desired security as required in specific protection policies.

The rest of the paper is organized as follows. The background and motivation are first provided in section 2. We present the design of coIOMMU in section 3 and its implementation in section 4. Finally, the evaluation results are shown and discussed in section 5, with future work and conclusion drawn in section 6.

2. Motivation

2.1. The Problem

Direct I/O is the best performant I/O virtualization method by enabling direct communication between the guest and the I/O devices. Removal of the software intermediary not only provides much better performance than other I/O virtualization approaches, but also allows faster time-to-market for virtualizing new I/O acceleration capabilities. Direct I/O proliferates via device-side virtualization. Single-Root I/O Virtualization (SR-IOV) [1, 13] allows the device to multiplex its resource into virtual functions, each independently assignable to a guest. Cloud service providers even offload para-virtualized backend drivers into directly assigned devices [11, 12]. With these hardware trends, direct I/O has gained mainstream support in commodity hypervisors and is becoming a cornerstone capability in data centers and clouds.

IOMMUs [3, 14, 16] are introduced by hardware vendors to prevent assigned devices from touching arbitrary memory locations. Use of the IOMMU leads to the static pinning problem due to two factors: (1) most I/O devices do not tolerate DMA faults, and (2) the hypervisor does not know how guest memory is used for DMA. The hypervisor has to pin the entire guest memory upfront, assuming that every guest page might be a DMA page. This heavily hinders the efficiency of memory management and worsens memory utilization, as pinned pages cannot be reclaimed for other purposes.

2.2. Existing Solutions

Previous studies generally tackle this problem in two directions: making the device support DMA page faults or exposing the DMA buffer information to the hypervisor through software approaches.

DMA page faults allow all kinds of memory optimizations that CPU page faults provide. The PCI-SIG standardizes the support of DMA page faults with Address Translation Service (ATS) and Page Request Service (PRS) [2]. It was originally introduced to simplify the programming model on GPUs [27, 41, 42] and now also starts to find its way into NICs [6] and FPGA [9]. However, the latency of handling DMA page faults is 3x-80x higher than that of handling CPU faults [6, 40]. Such long latency, up to hundreds of microseconds, demands a larger on-device buffer to hold in-flight requests and incurs higher device cost. Handling such long latency in all critical paths further complicates the device. Therefore, most commodity devices do not support DMA page faults, or partially support it only for selective workloads. With time, it may become a preferable way for fine-grained pinning, but not anytime soon.

Alternatively, researchers also look at software approaches to expose enlightened guest DMA information to the hypervisor. Knowing when a guest page is mapped or unmapped allows the hypervisor to pin or unpin it dynamically. Willmann et al. [44] evaluates several mapping strategies, revealing that a big performance penalty is incurred when blindly doing hypercalls to notify the hypervisor of every guest mapping/unmapping operation. Yassour et al. [7] dramatically reduces such notifications with a guest-side pin-down cache. However, it puts a complex eviction policy in the guest and provides no intra-guest protection.

Presenting a vIOMMU [23, 29, 60] also provides sufficient information for fine-grained pinning, as a result of emulating its DMA remapping capability for intra-guest protection. However, such emulation may incur significant cost, especially when frequent mapping operations are requested by the guest. To trade off performance and protection, modern OSes typically implement different policies about DMA remapping. For example, Linux [8, 24, 30, 38, 51] implements *strict*, *lazy* and *passthrough* policies. Although DMA remapping is used in *strict* and *lazy* policies, the *passthrough* policy simply disables it to gain best performance. Obviously, the guest cannot provide any DMA buffer information to the hypervisor when the *passthrough* policy is selected. Unfortunately, major guest Linux distributions choose *passthrough* as default and even allow different policies across devices.

Recent studies focus on reducing the cost of emulating DMA remapping in vIOMMU. Tang et al. [52] reduces the remapping overhead by reusing old mappings and delaying their removal, however, at the cost of compromised security. Side-core emulation [8] achieves 100% of 10Gbps line rate with a fully emulated vIOMMU, but with relaxed protection and increased total cost. The overhead of DMA remapping is also tackled on bare metal [24, 30, 38]. While these works generally apply to the guest OS as well, most of them have not been adopted by commodity OSes due to its intrusiveness. In a nutshell, the cost of DMA remapping is still notable in the guest today, leaving the capability disabled or even not exposed in most cloud and data center usages.

2.3. DMA Tracking vs. DMA Remapping

We prefer the vIOMMU approach for two reasons: 1) it supports both intra-guest protection and fine-grained pinning; and 2) DMA page faults are not widely supported by commodity devices. However, we want to go a different direction from previous studies – to enable fine-grained pinning without being encumbered by the intrinsic cost of DMA remapping.

We argue that mixing the requirements of protection and pinning, through the same costly DMA remapping interface, is needlessly constraining. Protection is a guest requirement and relies on the DMA remapping capability, while pinning is for host memory management and needs the capability of tracking guest DMA buffers. The two do not always match, thus favoring one may just break the other, if both are enabled through the same interface. For example, the hypervisor either must fall back to static pinning by assuming that most guests disable protection, or, adopt fine-grained pinning by forcing all guests to enable protection and bear with added cost.

What about inventing a separate DMA buffer tracking mechanism to the vIOMMU, without relying on any semantics of DMA remapping? Separating DMA tracking from DMA remapping allows us to tackle the pinning and protection problems in parallel. If the new tracking mechanism incurs negligible cost, we can expect most guests to always enable it and reliably provide necessary information for fine-grained pinning. If feasible, such an approach would make the vIOMMU as the portal of efficient memory management in future data centers and clouds.

3. Design

We propose coIOMMU, a new vIOMMU architecture that helps the hypervisor achieve efficient memory management in direct I/O. coIOMMU provides a dedicated DMA buffer tracking mechanism that adopts a shared memory interface for efficient communication between host and guest. The guest records the mapping status of its DMA buffers through a shared DMA tracking table (DTT), for the hypervisor to decide its pinning strategy. coIOMMU also introduces two optimizations: smart pinning and lazy unpinning, to dramatically reduce the performance impact when achieving fine-grained pinning.

3.1. Goals

We want the new DMA buffer tracking mechanism to meet these goals:

Orthogonal to DMA Remapping - Our solution should allow DMA buffer tracking and DMA remapping independently configured by the guest. The new tracking mechanism, once enabled, should consistently supply sufficient information for fine-grained pinning, regardless of how DMA remapping is configured to protect guest. Enabling of DMA buffer tracking should not affect the desired protection semantics of DMA remapping.

Low Cost - DMA buffer tracking should incur negligible cost. Otherwise, it faces the same challenge as in DMA remapping: if significant cost is observed, why would one enable it by default? We focus on the efficiency of DMA buffer tracking itself and have no intention to further optimize DMA remapping in this work. The original performance expectation under each guest protection policy is set as the baseline for comparing the cost of DMA buffer tracking in our evaluations.

Non-intrusiveness - We want our solution to minimize the changes in the guest software stack, as a primary factor to gain mainstream support in commodity OSes. Commodity OSes provide a generic DMA API layer [25, 43] to route

DMA mapping requests from device drivers to underlying DMA driver. DMA buffers can be tracked either in the DMA API layer or specific DMA driver. We did not choose DMA API because any change in such common framework usually takes a long time to be adopted by commodity OSes.

Wide Applicability - We prefer a solution that works with all kinds of I/O devices rather than requiring additional changes in hardware or device drivers. We also expect such a solution to make no assumption on any vendor specific characteristics, so it can be easily ported to different vIOMMUs, either emulated or para-virtualized.

Extensibility - The solution should be extensible to help address other limitations in memory management. For example, another challenge in direct I/O is about lively migrating the guest with assigned devices, which requires the ability of tracking the pages that are dirtied by DMAs [20, 26, 28, 35]. We expect our solution can play as a portal of tracking all kinds of DMA buffer status for efficient memory management.

3.2. Architecture

The coIOMMU architecture is illustrated in Figure 1, composed of coIOMMU backend in hypervisor and coIOMMU driver inside the guest. The coIOMMU backend includes three main components: (1) DMA remapping engine (*remapEngine*), the same functionality for intra-guest protection as in established vIOMMUs, over a set of per-device vIOMMU page tables (vIOPTs); (2) DMA tracking engine (*trackEngine*), a new function dedicated for tracking guest DMA buffers over a global DMA tracking table (DTT); and (3) Page-pinning manager (*pManager*), which uses the information gathered by trackEngine to intelligently manage the pinning requirements of guest memory. The remapEngine and trackEngine are independently enumerated and managed by the coIOMMU driver, while pManager is hidden and activated automatically when trackEngine is enabled.

In our prototype, we build coIOMMU by extending an existing vIOMMU, which emulates the Intel VT-d hardware [3]. This allows us to focus on the new trackEngine and pManager, while inheriting the established DMA remapping logic as remapEngine. However, we make no assumption on the specific hardware or vIOMMU type. The design of trackEngine and pManager can be easily ported to any emulated or para-virtualized vIOMMU.

The trackEngine holds the base address of the DTT, which is allocated and registered by the coIOMMU driver. The format of the DTT is a hierarchical page table, containing the mapping information required by fine-grained pinning. trackEngine also includes a doorbell register to notify the hypervisor if necessary. Within the coIOMMU backend, trackEngine provides interfaces for pManager to access the DTT and also notifies pManager when the doorbell is rung. With this design, trackEngine acts as a standard interface solely for conveying the DMA information, while pManager actually uses the information to achieve fine-grained pinning. The separation between these two components allows coIOMMU to be easily extended for other purposes, e.g. by introducing another agent to track dirty pages, alongside pManager, while reusing the same trackEngine interface.

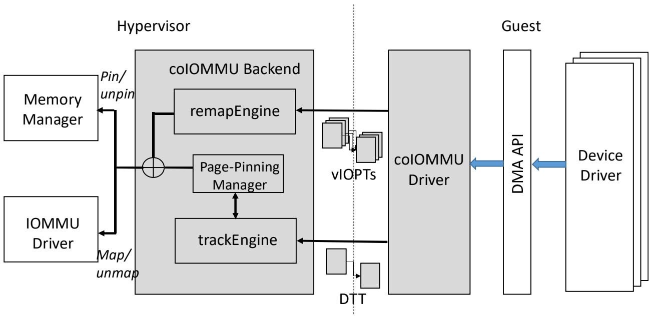

Figure 1: The architecture of coIOMMU

The coIOMMU driver intercepts the DMA API operations in the guest and updates the DTT accordingly. Modern OSes all implement a generic DMA API layer [25, 43], connecting device drivers to the underlying DMA driver to prepare their DMA buffers. The coIOMMU driver registers itself as a DMA driver to capture the latest mapping status of guest DMA buffers. This driver also enforces the desired protection semantics, as other vIOMMU drivers normally do today. In this way, DMA tracking is enabled without any change to the DMA API layer or specific device drivers of the guest.

The pManager contains hypervisor-specific policies for fine-grained pinning. A specific implementation may even include multiple policies and let the hypervisor dynamically choose a policy at runtime. We demonstrate two optimizations in §3.4: smart pinning and lazy unpinning, to minimize the notification overhead. When required, pManager talks to the memory manager for pinning or unpinning a set of guest pages and request the IOMMU driver for mapping or unmapping them in the physical IOPT. When both remapEngine and pManager are enabled, their pinning decisions are ORed together to favor the stricter requirement. Once a guest page is unpinned and unmapped, it can be reclaimed under whatever policy applied by the memory manager.

3.3. DMA Tracking Table (DTT)

The DTT records the mapping status of guest DMA buffers. It is shared by all assigned devices because the hypervisor only wants to know the DMA buffers of the entire guest. It is not necessary to track DMA buffers for virtual devices, assuming their DMAs are emulated by and already known to the hypervisor. The DTT is allocated by the guest, starting as empty and then filled dynamically according to intercepted DMA operations. We choose to track two categories of guest pages in the DTT: 1) the pages that are currently mapped by the guest and 2) the pages that have been unmapped but still pinned by the hypervisor. The latter category is necessary for lazy unpinning introduced in the next section.

One may argue why inventing a new table instead of reusing the vIOPTs, when the latter also carry the information of guest DMA buffers. We considered this approach but gave up for several reasons. First, the vIOPT is designed for intra-guest protection which disallows pinning a page after it is unmapped thus also negates lazy unpinning. Second, the table is indexed by guest I/O Virtual Address (IOVA) for the remapping purpose. The hypervisor has to walk every vIOPT to find out whether a guest page is mapped, which is too costly. Last but not the least, the format of vIOPT is typically vendor-specific, so extending it may not lead to good portability.

The DTT is a 4-level page table in 4KB pages, as shown in Figure 2. The 4KB leaf page consists of 512 DTT PTEs (DTEs) and each 8-bytes DTE is further split into 8 tracking units (TU). Each TU corresponds to one 4KB guest page. In total, the DTT can support up to 51-bits (9+9+9+9+3+12=51) guest physical address width, big enough for prevalent virtualization usages. Such design leaves 8-bits available in each TU. coIOMMU currently uses 3 bits for fine-grained pinning, with the other 5-bits reserved for future extension:

- 'M (mapped)', indicating a page currently mapped by guest for DMA. It is set and cleared by the guest before and after the corresponding DMA and is read-only to the hypervisor. This bit conveys the primary information used by fine-grained pinning.
- 'P (pinned)', marking a page currently pinned by the hypervisor. It is updated by the hypervisor to reflect the pinning status and is read-only to the guest, necessary for smart pinning.
- 'A (accessed)', telling whether a page has ever been used for DMA. The guest sets this bit alongside the setting of M-bit ('mapped' bit). Then it stays sticky until the hypervisor clears it in lazy unpinning.

An entry with both M and P bits cleared marks the page as invalid. If every entry of a DTT page is invalid, the guest may choose to free this page to save space.

3.4. Fine-grained Pinning

Two techniques are introduced in coIOMMU: *smart pinning* and *lazy unpinning*, to minimize the notification overhead of fine-grained pinning. We focus on the scenario where the DMA remapping capability of coIOMMU is disabled by the guest. In this case, there is no intra-guest protection requirement thus the hypervisor can pin more pages than what guest actually maps.

3.4.1. Smart Pinning

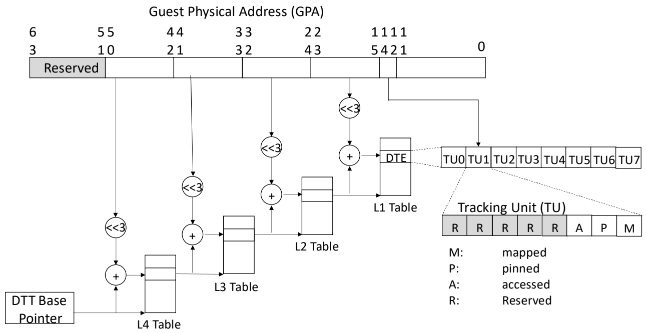

Figure 2: the format of the DTT

coIOMMU manages the pinning of guest pages in three ways: (1) *instantly pinning*: the guest instantly notifies the hypervisor to pin pages when they are being mapped, for correctness; (2) *precise notification*: the guest notifies the hypervisor if and only if the to-be-mapped pages are not pinned, to minimize the notification overhead; and (3) *speculatively pinning*: pManager heuristically pins the frequently used pages for performance.

First, pinning must be *instantly* done before any mapped page is used for DMA, because most devices do not tolerate DMA faults, as aforementioned. In such circumstance, the hypervisor must be notified by the guest to complete the pinning action in a timely manner, if the page has not yet been pinned.

Second, coIOMMU exposes the pinning status to the guest through the P-bit ('pinned' bit) in the DTT, for *precise notification*. If the P-bit is cleared by the hypervisor, the guest must notify the hypervisor instantly when mapping a page. Otherwise, no notification is needed at all. This optimization allows the guest to skip most notifications in its mapping operations.

Last, pManager *speculatively* selects and pins frequently used pages by leveraging the guest DMA locality, which has been identified in both previous studies [7, 44, 51] and our evaluation. The DTT includes an A-bit ('accessed' bit) to mark a page ever used for DMA. The guest sets the A-bit when mapping a page and leaves it set until the hypervisor clears it. pManager determines the ages of unmapped pages by periodically scanning the A-bits (and clears it after a scan). Young pages (with A-bit set) are candidates of frequently used pages and might be accessed soon again. So pManager heuristically pins them to avoid the overhead of another pinning notification in the near future.

Our evaluation shows that precise notification and speculative pinning can dramatically reduce the notification overhead in instant pinning by up to 99.9992% (from 1.5M to 11 notifications, per second), when running memcached with a 40Gbps NIC connection. One notification takes ~2000-4000 cycles in our evaluation, so 1.5M notifications per second may eat up 1-2 CPU cores without such optimization.

3.4.2. Lazy Unpinning

The pManager *lazily* unpins guest pages to completely eliminate the notification overhead in guest unmapping operations. It asynchronously scans the DTT to find out the pages that are unmapped but still pinned, and then unpins them in a batch. In our prototype, we process *lazy unpinning* and *speculative pinning* together in the same thread. Unpinned pages are reclaimable by the memory manager to increase overall memory utilization. In the same example of memcached, lazy unpinning eliminates another 1.5M notifications per second for guest unmapping operations, which means saving another 1-2 CPU cores, with the cost of pinning additional ~1% memory (0.32MB) than the total size of mapped pages (34.68MB), in average.

3.5. Intra-Guest Protection

The DMA remapping engine (remapEngine) can achieve fine-grained pinning as well, as it is required to precisely map and pin DMA buffers per guest protection requirements. However, one cannot solely rely on DMA remapping because the guest may selectively turn it off for certain devices according to its protection strategy. We describe two examples as below.

First, the guest may dynamically enable/disable DMA remapping for an assigned device, leaving the hypervisor to switch back and forth between static pinning and fine-grained pinning. For example, guest Linux typically enables DMA remapping when assigning a device to its user space and then disables remapping when returning the device back to its kernel space [45]. The switch between static and fine-grained pinning may lead to intermittent out-of-memory errors in a budget system. Moreover, the hypervisor needs to unpin all the guest pages when switching away from and then re-pin them when switching back to static pinning, leading to increased overhead.

Second, if the guest enables DMA remapping only for selected devices, DMA remapping cannot provide full DMA buffer information for fine-grained pinning. For example, most Linux distributions enable DMA remapping only for untrusted devices, based on physical characteristics of the device [61, 62]. Such flexible configuration is possible because DMA remapping is typically enabled per device. However, fine-grained pinning needs to know DMA buffers used by all assigned devices in the guest, even for the ones that are not protected with DMA remapping. In such case, the hypervisor must fall back to static pinning with reduced memory utilization.

In both of these examples, DMA buffer tracking of coIOMMU allows reliably providing full DMA buffer information to enable fine-grained pinning. When tracking and remapping are both enabled, it is possible for the two to make different pinning decision for the same page. In such case, the decision from the DMA remapping interface takes precedence, because we must not break any protection semantics desired by the guest.

4. Implementation

We implement coIOMMU by extending the virtual Intel VT-d, which is an emulated vIOMMU in QEMU [58] (the device model of KVM hypervisor [10]), and the intel-iommu driver in the guest Linux. In QEMU, the original DMA remapping logic of the virtual VT-d is reused as remapEngine, while trackEngine and pManager are developed from scratch. Guest-side changes are all contained in the intel-iommu driver and hidden behind the Linux DMA API layer. There is no change required in guest device drivers. Currently, coIOMMU adds ~700 LOC in QEMU and ~1000 LOC in guest.

coIOMMU driver - coIOMMU driver extends guest intel-iommu driver to manage the trackEngine when the capability is detected. The intel-iommu driver registers callbacks to the Linux DMA API layer for mapping and unmapping DMA pages in different forms, e.g. for single page or scatter-gathered page list, for pre-allocated pages or newly allocated pages, etc. We extend the driver by extracting the DMA buffer information from those callbacks and updating the corresponding tracking units (TUs) in DTT. The DTT is allocated in the guest memory, which is always accessible by the commodity KVM hypervisor. If such direct access is prohibited in some specific security related usage cases [55, 56], the DTT should be allocated in a shared memory region. Last, the coIOMMU driver conditionally notifies the hypervisor based on the DTT status.

trackEngine - We extend the virtual VT-d with several changes: (1) a capability bit for enumerating the presence of trackEngine, (2) an enabling bit for activating trackEngine, (3) a register holding the base address of the DTT, (4) a register as the doorbell interface for triggering notification to pManager, and (5) a register pointing to the base address of the notification structure. The notification structure is designed to allow batching requests of multiple pages into one notification, in case of those pages are mapped together. trackEngine also provides function calls for pManager to scan and update the DTT.

pManager – The implementation of pManager can be split into two parts. First, it provides direct function calls for trackEngine to complete instant pinning. The functions are invoked synchronously in the vCPU threads when QEMU emulates the guest write to the doorbell register. Second, pManager also launches a thread for lazy unpinning and speculative pinning, woken up every one second. This thread scans the DTT to find out all the pages that are unmapped but still pinned and speculatively unpin them based on their A-bits. When a pinning decision is made, pManager invokes the VFIO API

[45] to pin/unpin selected pages and map/unmap them in the IOMMU.

Sub-Page Mappings - Multiple DMA buffers may co-locate in the same 4KB guest page, e.g. as widely observed when handling network packets. Sub-page mappings imply that one page might be mapped and unmapped multiple times. In such case, coIOMMU driver tracks the mapping count of each mapped page and clears the "M-bit" of the corresponding entry only when its count reaches zero. We choose to leverage the 5 reserved bits in each TU as the mapping count, holding up to 31 sub-page mappings. Doing so simplifies the implementation and works well in our evaluations. Other implementations may choose different structures for such tracking purpose.

Concurrency - coIOMMU must properly handle concurrent pinning/unpinning requests between multiple vCPU threads and the unpinning thread, as shown in Figure 3.

First, multiple vCPUs may try to map and pin the same DMA page simultaneously, e.g. in sub-page mapping scenario. We employ different locking mechanisms in guest and host for race avoidance. Within the guest kernel, spinlock is required for atomically setting the 'mapped' flag and checking the 'pinned' status of a target page. It is necessary as DMA mappings may happen in the guest interrupt context. On the other hand, a mutex is introduced in QEMU for atomically completing the actual pinning actions: 1) rechecking the 'pinned' status; 2) pinning the page; and 3) updating the 'pinned' flag.

Second, race condition may happen between concurrent pinning requests (from the vCPU threads) and unpinning requests (from the unpinning thread). For example, it is possible seeing an unpinning operation starts before, yet completes after, an in-flight pinning request. Such race may lead to the pinning request completing successfully but with the target page actually unpinned. We introduce two mechanisms to solve this problem. For one, the unpinning thread needs to check the 'mapped' flag before and after clearing the 'pinned' status. We call this special sequence as double-detection, necessary to catch in-flight change of the mapping status in the guest side. For two, the unpinning thread also needs to acquire the aforementioned QEMU mutex for completing its unpinning actions. In particular, the second check of the 'mapped' flag must be done with the mutex acquired and before conducting the unpinning action. If the 'mapped' status becomes true, indicating that a pinning action is in progress for the target page, the unpinning thread should cancel the unpinning operation immediately.

4.1. Discussion

Applicability - coIOMMU applies to all kinds of directly assigned devices, without the need of ad-hoc changes in hardware or software. Porting our Linux implementation to a new guest OS is straightforward, as long as the OS implements a generic DMA API layer which, obviously, is already a common feature in commodity OSes today. On the other hand, the implementation of trackEngine and pManager is vendor-neutral and self-contained. The separation between DMA tracking and DMA remapping allow coIOMMU implementation to be easily portable to other vIOMMUs, regardless of whether remapEngine is emulated or para-virtualized.

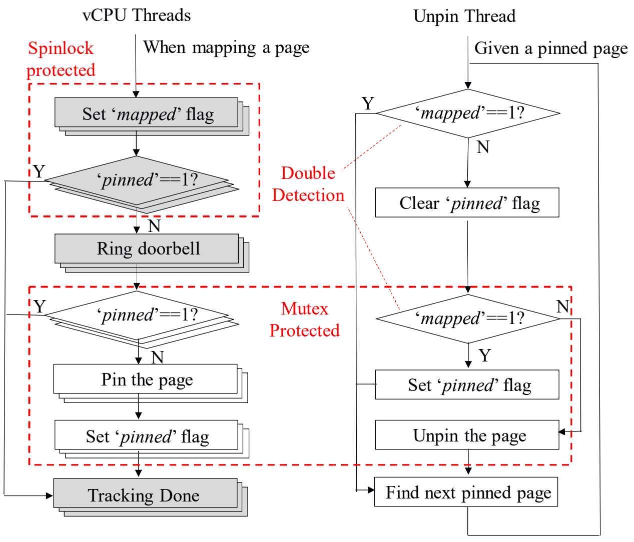

Figure 3: Race avoidance between concurrent pinning and unpinning operations. Gray boxes are guest actions, and white are host.

Extensibility - The page table format of the DTT can be extended to address other limitations in memory management. For example, introducing a "D (dirty)" bit in the TU provides a generic solution for tracking dirty pages when lively migrating VMs in direct I/O. Similarly, using a "W (writable)" bit to indicate read-only page enables the hypervisor to implement copy-on-write features. Ideally, a specific implementation may extend the DTT to include the same set of permission or status bits as available in a CPU page table.

Currently the DTT tracks DMA buffers in 4KB granularity. It is sufficient for most direct I/O usages, as DMA buffers are typically allocated in scattered 4KB pages. When large DMA buffer is used, we rely on pManager to merge batched pinning requests on continuous DMA pages into 2MB-based requests. We observed such optimization leads to ~4.5% FPS improvement in direct GPU benchmark, as illustrated in 5.1. Alternatively, one may also directly extend the DTT format to support 2MB-granular tracking entries.

Kernel Bypassing - coIOMMU also applies to various kernel bypassing techniques [32, 33, 45], which allow applications to directly manage DMA buffers in user space. Applications are untrusted, so they must first register a trunk of memory to the kernel and then manage within that trunk. The registration goes through proper kernel interfaces, e.g. AF_XDP [33] or VFIO [45] in Linux, which finally call into the coIOMMU driver for actual mappings and unmappings thereby are still tracked in the DTT. Kernel bypassing may increase the memory footprint because applications usually register a one-off big buffer pool to avoid calling into the kernel frequently. We leave optimizing such workloads as future work.

DMA Page Faults – For devices which do support DMA page faults, on-demand memory allocation/reclaim can happen at any time thus one could implement fine-grained pinning without using coIOMMU. However, coIOMMU may still provide two benefits in such circumstance. First, the overhead of handling DMA page faults might be non-negligible in hot data paths. coIOMMU allows the guest to reduce the number of faults by proactively requesting pre-pinning of hot pages, based on the knowledge that is easily extracted from DTT, yet invisible or difficult to acquire in legacy host. Second, some devices may allow DMA page faults only in selective data paths. Hypervisor could enable coIOMMU alongside the fault-based pinning scheme, to track DMA pages which are touched in non-faultable data paths in such devices.

Guest Cooperation - coIOMMU is a para-virtualized approach thus requires guest cooperation. We plan to submit our work to Linux and QEMU community, so coIOMMU could be enabled by default in most Linux distributions in the future. However, it is possible that a selfish guest may deliberately report fake DMA pages or simply disable coIOMMU driver to get more pages pinned than a cooperative guest. When required, one may choose to build a quota mechanism alongside the new tracking interface of coIOMMU. For example, the memory ballooning mechanism [57] can be extended to convey the quota information of both total memory and DMA memory, based on the service level agreement of the guest. Afterward, pManager could reject new pinning requests from any guest after its quota is exceeded.

5. Evaluation

Our evaluation aims to answer several questions. How does the overhead imposed by coIOMMU compare to that of established vIOMMUs? How many pages are pinned in various direct I/O usages when using coIOMMU to enable fine-grained pinning? Does coIOMMU sustain the desired performance and security under different intra-guest protection policies? We answer these questions by planning our evaluation to focus on four aspects: footprint, overhead, security and applicability.

Evaluated Modes - We evaluate six modes as shown in Table 1. The guest intel-iommu driver supports three protection policies: 1) *passthrough*, the default policy that disables DMA remapping for performance; 2) *strict*, using DMA remapping to gain full protection; and 3) *lazy*, trading off some security for performance when using DMA remapping (e.g. by deferring and batching IOTLB invalidations). We study the three policies for coIOMMU and a state-of-the-art vIOMMU, respectively, thus leading to six modes in total. In our prototype, coIOMMU inherits the DMA remapping logic of the virtual VT-d, so we choose this emulated vIOMMU solution to represent state-of-the-art vIOMMUs for fair comparison. We use {*PT-O*, *ST-O, LA-O*} to indicate the three protection policies with virtual VT-d and {*PT-N*, *ST-N*, *LA-N*} for the policies with coIOMMU. 'O' stands for the 'old' emulated VT-d while 'N' represents the 'new' coIOMMU.

mode	abbr.	DMA remapping	DMA buffer tracking	pinning model	protection
passthrough (virtual VT-d)	*PT-O*	unused	n/a	static	no
passthrough (coIOMMU)	*PT-N*	unused	used	fine-grained	no
strict (virtual VT-d)	*ST-O*	used	n/a	fine-grained	full
strict (coIOMMU)	*ST-N*	used	used	fine-grained	full
lazy (virtual VT-d)	*LA-O*	used	n/a	fine-grained	relaxed
lazy (coIOMMU)	*LA-N*	used	used	fine-grained	relaxed

Table 1: Evaluated modes in coIOMMU and virtual VT-d

Experimental Setup - Our setup consists of three machines, all running Ubuntu 16.04 with kernel 5.0.0. The primary machine, used for networking and storage tests, is equipped with a 16-core Intel Xeon Cascade Lake CPU at 2.7GHz, one 64GB DDR4 DIMM, an Intel XL710 40Gbps NIC, and two Intel 760P series 1TB NVMe SSDs. The 2nd machine acts as the network traffic generator, with another XL710 NIC connected to the primary machine back-to-back. It includes dual Intel Xeon Gold 6140 CPUs, each with 18 cores at 2.30GHz and 64GB DDR4 memory. The last machine is used for GPU evaluation, equipped with Intel Core i7-7567U CPU with four cores at 3.50GHz, 32GB DDR4 memory, a 256GB Intel 520 series SSD, and an Intel® Iris® Plus graphics 650 GPU.

The VM of the first machine is based on RHEL7.2 with kernel 5.1.0-rc3+, configured with 16 vCPUs, 32GB memory, and a directly assigned device – either a XL710 NIC or a 760P SSD, according to whether direct-networking or direct-storage is under evaluation. The two assigned devices are enabled independently, to avoid mutual interference from section 5.1 to section 5.5. In section 5.6, we evaluated their performance running combined workloads with both devices assigned. The VM for direct GPU includes Ubuntu 18.04 with kernel 5.1.0-rc3+, 4 vCPUs, 4GB memory, and a directly assigned Intel® Iris® Plus graphics 650 GPU. The vCPUs of both VMs are 1:1 pinned to the physical cores for stable results.

Benchmarks - We choose both micro-benchmarks and macro-benchmarks for evaluating the six modes in direct networking, direct storage and direct GPU:

- *Netperf* [63] is a standard micro-benchmark to measure networking throughput. We perform Netperf stream receive (RX) and transmit (TX) tests, using 64KB message size with 16 Netperf client/server instances (one per core) in the guest. Aggregated throughput is reported.

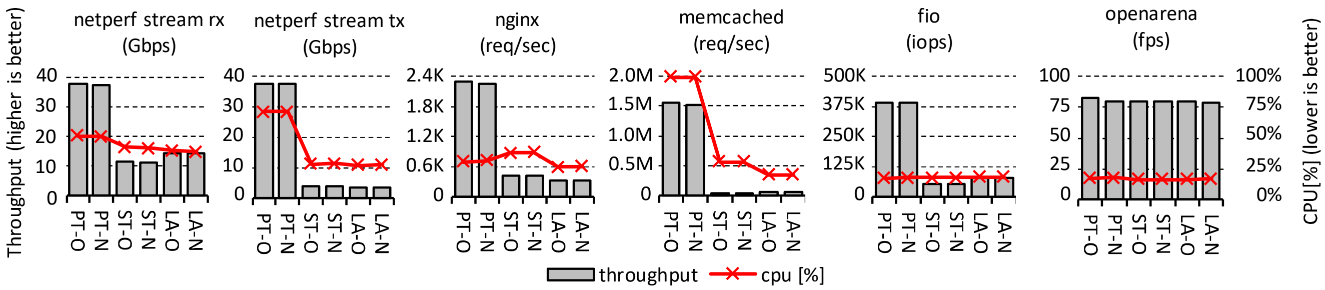

Figure 4: Performance of the six modes (100% CPU is 4 cores in openarena, and 16 cores in all other benchmarks)

mode	netperf stream rx		netperf stream tx		nginx		memcached		fio		openarena	
	dma_ops	VM-exits	dma_ops	VM-exits	dma_ops	VM-exits	dma_ops	VM-exits	dma_ops	VM-exits	dma_ops	VM-exits
PT-O	352,224	0	577,037	0	525,974	0	3,110,716	0	781,055	0	44	0
PT-N	348,335	2,379	572,136	415	525,849	115	3,039,414	11	780,186	9	44	22
ST-O	109,403	109,403	64,448	64,448	72,239	72,239	104,354	104,354	109,864	109,198	44	44
ST-N	108,607	108,607	64,352	64,352	71,682	71,682	103,984	103,984	107,948	107,948	44	44
LA-O	141,844	71,013	59,645	29,896	63,230	31,702	145,309	72,744	163,085	81,655	44	23
LA-N	141,572	70,883	58,398	29,273	62,569	31,370	144,690	72,434	162,417	81,322	44	23

Table 2: The average number of completed DMA operations vs. incurred VM exits, per second.

- *Nginx* [64] is a high-performance HTTP web server. We use ApacheBench [69] to measure the number of concurrent requests that Nginx server can serve. We run ApacheBench to issue 16 concurrent requests of a static 1MB file, through the Nginx server installed in the guest.
- *Memcached* [65] is a popular in-memory key-value store, usually benchmarked using memaslap [70]. We use the default memaslap configuration with 64-byte keys, 1KB values, and 90%/10% GET/SET operations. In the VM, we launch 16 memcached instances driven by 16 memaslap threads each issuing 8 concurrent requests.
- *fio* [66] is a standard micro-benchmark to measure disk performance for wide range of storage types. We configure 16 fio threads, each performing asynchronous direct random reads from the assigned SSD, in 512-byte blocks and 128 in-flight requests.
- *OpenArena* [67] is a 3D first-person shooter game, used to benchmark direct GPU. The throughput is reported in frame-per-second (fps).

In addition, we also selectively run sysbench [68] as a memory benchmark and DPDK [32] for user-space networking stack, for specific evaluation purposes.

5.1. Overhead

We record the performance of aforementioned benchmarks in each evaluation mode, as shown in Figure 4. CPU utilization is aggregated over all cores, i.e. one core at 100% CPU would be reported as 100%/4=25% CPU utilization with 4 cores (for OpenArena) or 100%/16=6.25% CPU utilization with 16 cores (for all other benchmarks). In addition, we also capture the per-second number of completed DMA operations and associated VM-exits when running those benchmarks, in Table 2. All benchmarks run 30 seconds, except OpenArena, which must run to end in around 42 seconds. Next, we compare coIOMMU to virtual VT-d under the three Linux protection policies, respectively.

Passthrough - All networking benchmarks (left four in Figure 4) exhibit consistent results under the passthrough policy: coIOMMU (*PT-N*) retains the performance comparable to that of the virtual VT-d (*PT-O*), with less than 3% throughput degradation and negligible variation in CPU utilization. Such low cost is further explained in Table 2 – although hundreds of thousands of DMA operations are tracked per second, the majority of them do not trigger any VM-exit to notify the hypervisor, due to the optimization of *smart pinning* and *lazy unpinning*. For example, the lowest VM-exit number is observed in memcached, with only 11 VM-exits incurred by ~3M DMA operations.

The overhead of coIOMMU is unrecognizable in FIO but incurs 4.5% FPS drop in OpenArena. We found that OpenArena maps a big buffer (~240MB) in a batch at its launch time, with many pages adjacent to each other. In such case, pinning the buffer in 2MB size is more efficient than pinning in 4KB size, due to increased IOTLB efficiency. Unfortunately, 2MB pinning is not supported in our initial coIOMMU implementation, while it is the preferred option when KVM statically pins the entire guest memory in *PT-O*. After coIOMMU was extended to also conduct 2MB pinning for OpenArena, it then reaches the same performance as the virtual VT-d (not shown in the figure). We do not enable huge page pinning in other benchmarks, because they are observed with frequent mapping operations on many scattered 4KB pages. Blindly doing

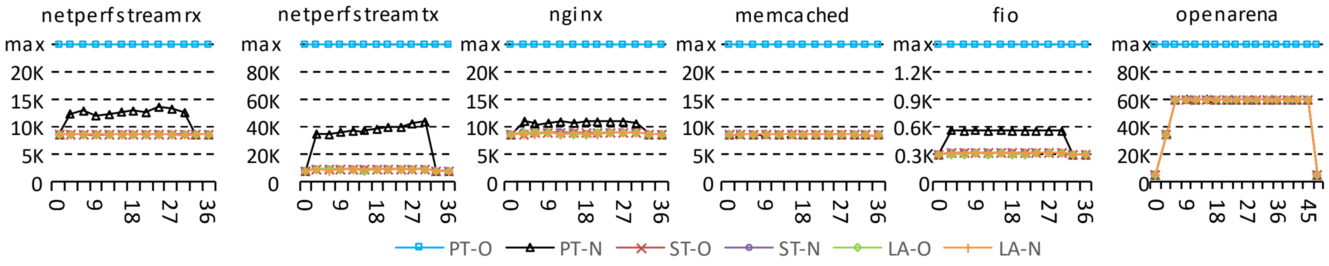

Figure 5: The number of pinned pages sampled in 3 second interval, taken from the beginning of the benchmarks to 6 seconds after their completion. 'max' indicates the total pages of guest memory.

huge page pinning simply adds more cost and footprint in those circumstances.

Strict and Lazy - We did not observe recognizable difference between coIOMMU (*ST-N* and *LA-N*) and virtual VT-d (*ST-O* and *LA-O*) in all benchmarks, regarding to both throughput and CPU utilization. There are much fewer DMA operations completed in the *strict* and *lazy* policy than that in the *passthrough* policy, due to the emulation cost of DMA remapping. As shown in Table 2, the reduction is between 2.46x (in Netperf RX) to 29.8x (in memcached) in all evaluated benchmarks. The tracking overhead in coIOMMU is negligible when comparing to the overhead of DMA remapping.

We also explore an interesting finding between *lazy* and *strict* in Figure 4, although not directly related to coIOMMU. It is a common learning that batching IOTLB invalidations generally brings better performance than strictly invalidating the IOTLB one-by-one. However, it is not always the case in virtualization – we observed 11% and 23% lower throughput when comparing *lazy* to *strict* in Netperf TX and Nginx. We find the batching interface of the virtual VT-d is the root cause. Its emulation requires walking the entire vIOPT to identify every valid mapping. If the walking cost exceeds the cycles of saved invalidations, the performance of *lazy* is instead worse than that of *strict*. We leave studying more efficient batching interface and policy for another research.

5.2. Memory Footprint

We sample the number of pinned pages every 3 seconds, from the beginning of the benchmarks to 6 seconds after its completion, in Figure 5. The extra 6 seconds are used to evaluate the elasticity of the six modes, against transitional system business. One note – the '*max*' mark in the Y-axis indicates the total number of guest pages, representing the case of static pinning. It is 8M (for 32GB memory) in most benchmarks and 1M (for 4GB memory) in OpenArena.

All six modes exhibit the same pattern in all benchmarks, except *PT-N*. First, *PT-O* is tied to static pinning, thereby always sitting in the top 'max' location. Second, all four modes with DMA remapping enabled (*ST-O*, *ST-N*, *LA-O*, and *LA-N*) pin the least number of pages, because they need strictly follow the desired protection semantics. As such, their lines completely overlap in each diagram in Figure 5. The line of *PT-N* (coIOMMU in the passthrough policy) fluctuates in the middle due to smart pinning, which heuristically pins guest pages for balancing performance and footprint. So, it is the focus of our following analysis.

Networking - All four networking benchmarks (left four in Figure 5) start and end with the same number of pinned pages (~8800 pages) in *PT-N*. Those always-pinned pages come from Intel i40e NIC driver, which pre-maps 512 pages per vCPU as the receive buffer pool when the NIC is enabled. The number sums up to 8192 pages with 16 vCPUs in our configuration.

The largest footprint is observed in Netperf stream TX, with up to 44530 pinned pages (174MB). It is ~4.4x of the pages that are actually mapped for DMA at that time. The additionally pinned 34158 pages reflect the DMA temporal locality, occupying only 0.4% of the total 32GB guest memory. coIOMMU recognizes such locality thus sustains the performance of static pinning when keeping a small memory footprint. Netperf stream RX pins fewer pages (up to ~18000) than TX, due to better DMA temporal locality – Intel i40e NIC driver prefers to use the pre-mapped 8192 pages for incoming packets. On the other hand, Nginx and Memcached are less throughput sensitive than Netperf TX/RX, yielding a transfer rate of 2.3Gbps and 1.34 Gbps respectively. Accordingly, there are fewer pages used for DMA in the two benchmarks, leading to smaller footprint in coIOMMU.

Storage - We configure fio to perform asynchronous direct random reads from the assigned SSD, to avoid page cache and readahead optimization in guest Linux. 16 fio threads are launched to read the disk with a 512-byte block size and 128 in-flight requests per I/O queue, summing up to 256 pages for potential DMAs. The guest storage driver pre-maps 302 pages at boot time. Therefore, up to 558 pages may be mapped for DMA simultaneously, at any time. Obviously, coIOMMU precisely captures such temporal locality and constantly pins 558 pages in our test.

GPU - There is no recognizable difference between the line of *PT-N* and the bottom four lines, in OpenArena. The reason is

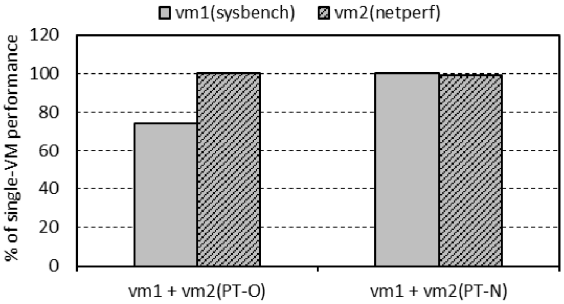

Figure 6: The impact of memory overcommitment: static pinning (*PT-O*) vs. fine-grained pinning (*PT-N*)

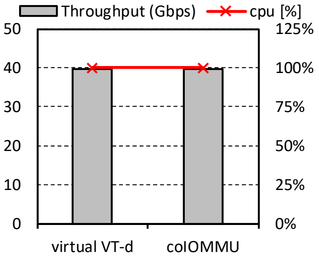

Spent Cycles

	virtual VT-d	coIOMMU	ratio
Create VM	7554ms	407ms	18x
Assign NIC	183ms	2ms	91x
Deassign NIC	815ms	2ms	407x

Pinned Pages

	virtual VT-d	coIOMMU	ratio
Before DPDK	8388608	548	15307x
In DPDK	186368	186368	1x
After DPDK	8838608	548	15307x

Figure 7: Running DPDK with virtual VT-d and coIOMMU

simple, as explained in §5.1, that OpenArena maps most of its DMA pages (~240MB) one-off at launch time and then unmaps them only at exit. In such circumstance, smart pinning and lazy unpinning have no effect at all. Therefore, all five fine-grained pinning modes pin the similar number of guest pages, with only static pinning staying in the top.

5.3. Memory Overcommitment

Overcommitment allows the aggregated size of all VMs to exceed the physical memory, thus improving memory utilization. We explore this configuration in both coIOMMU (*PT-N*) and the virtual VT-d (*PT-O*), to demonstrate the value of fine-grained pinning.

We create two VMs in the test machine with 64GB physical memory. VM1 has no assigned device and is configured with 32GB memory. It runs sysbench to randomly access a 16GB memory region. On the other hand, VM2 is assigned with an Intel i40e NIC and is configured with 48GB memory. It runs Netperf to send packets through the assigned NIC. The total memory size of the two VMs (80GB) exceeds the physical memory limitation.

We compare the performance of running them together to that of running each alone, in Figure 6. With the virtual VT-d, Netperf sustains the single-VM performance while sysbench suffers 25% performance drop. The drop is caused by frequent page swaps due to insufficient host memory. There is only 8.8GB left after statically pinning 48GB memory for VM2. The situation gets worse with random errors reported in VM1, when increasing the memory intensity of sysbench. Conversely, both VMs achieve their desired performance with coIOMMU, with 49GB free memory available even when two benchmarks are both running.

5.4. Guest User Space Driver

The guest kernel may directly assign a device to its user space for improved performance. However, kernel bypassing imposes the risk of DMA attacks from the user space. In such case, the guest kernel typically turns on DMA remapping of vIOMMU when the device is being assigned to the user space and then turns off remapping after the device is assigned backed to the kernel. In such circumstance, coIOMMU can help the hypervisor maintain fine-grained pinning reliably, while state-of-the-art vIOMMUs suffer from increased overhead by switching back and forth between static pinning and fine-grained pinning. We demonstrate such an example using DPDK pktgen, which offloads TCP packet processing from the guest user space to the assigned NIC. We run DPDK with coIOMMU and with the virtual VT-d respectively and show the comparison in Figure 7.

coIOMMU dramatically reduces the latency in several stages, compared with the virtual VT-d: (1) 18x reduction when the VM is created (407ms vs. 7554ms); (2) 91x reduction when the guest kernel assigns the NIC to user space DPDK (2ms vs. 183ms); and (3) 407x reduction when the NIC is assigned back to the guest kernel (2ms vs. 815ms). The cost of the emulated VT-d is mostly caused by pinning or unpinning the entire guest memory when switching to or away from static pinning. The VM creation phase suffers most because every guest page needs to be allocated and cleared in static pinning. In the meantime, coIOMMU pins no more than 186K pages, while the virtual VT-d pins many more pages varying between 186K and 8M.

5.5. DMA Temporal Locality

Good temporal locality on DMA buffers is crucial for high performance I/O processing, both in virtualization and on bare metal. Commercial OSes are optimized toward this goal, as observed in our evaluation and also reported by previous studies [7, 44, 51]. On the other hand, Markuze et al. [30] observes that many pages may be used to hold DMA buffers, over time, in stock Linux. Hence, we studied the DMA temporal locality of the networking stack in a similar configuration, by running 16 Netperf TX instances for 15 minutes, shown in Figure 8. We also run a Linux 'dd' command alongside Netperf, reading the raw virtual disk into /dev/zero. The 'dd' command constantly causes ~20K page cache misses per second, leading to ~20K new page allocated and heavily contending with the networking stack. The experiment is conducted in *PT-N* mode, i.e. under the passthrough policy.

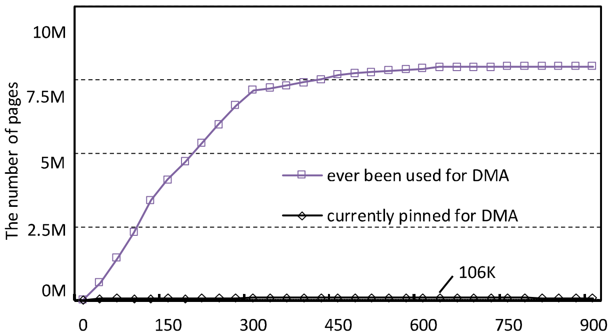

Figure 8: DMA temporal locality when running Netperf with 'dd'

Our data echoes the previous finding [30] – almost the entire guest memory (~7.9M pages, 98.7% of total memory) has ever been used for sending packets, over time. However, the number of pinned pages almost stays flat when coIOMMU is enabled. The peak number is ~106K (424MB), 2.4x of that when running Netperf TX alone and just 1.3% of the total guest memory. The result implies that the DMA locality in a short period is still good in such stress case, allowing the hypervisor to intelligently pin the guest pages with coIOMMU.

5.6. Mixed Workloads

We run Netperf TX and fio together to check how coIOMMU performs in mixed I/O workloads. The tested VM is configured with 16 vCPUs and 32GB memory as previous tests. It is directly assigned two devices: a XL710 NIC and a 760P SSD. We launch 16 netperf instances and 16 fio threads simultaneously in the VM, with each vCPU holding one netperf instance and one fio thread. Here we just compare *PT-O* vs. *PT-N* under the passthrough policy, as the two modes can best demonstrate the coIOMMU benefits according to the baseline data.

The result is promising. First, there is no observable performance difference when comparing Netperf and fio to their baseline performance of running alone. The deviations are less than 1% and within the error bar. Second, the peak number of pinned pages in mixed workloads is 45200 (176.5MB), close to the sum of pinned pages of running Netperf (174MB) and fio (2.2MB) alone. This result proves that coIOMMU can effectively reduce the memory footprint with negligible overhead, even when running mixed direct I/O usages together.

6. Conclusions and Future Work

Established vIOMMUs cannot reliably eliminate static pinning in direct I/O, due to the emulation cost of their DMA remapping interfaces. We instead propose coIOMMU, a new vIOMMU architecture for efficient memory management. coIOMMU introduces a cooperative DMA buffer tracking mechanism for fine-grained pinning, orthogonal to the costly DMA remapping interface. The new mechanism uses a shared DMA tracking table (DTT) for hypervisor and guest to exchange the DMA buffer information, without incurring excessive notifications from the guest, due to smart pinning and lazy unpinning. We demonstrate that coIOMMU not only dramatically improves the efficiency of memory management in wide direct I/O usages with negligible cost, but also sustains the desired security as required in specific protection policies. Last but not the least, although we implement coIOMMU by extending an emulated vIOMMU - the virtual Intel VT-d, this design can be easily ported to other vIOMMUs.

As for future work, we will focus on several areas. First, new IOMMU trends [53, 54] begin to support two-level address translations, allowing the guest to skip certain virtual IOTLB invalidations for improved performance. coIOMMU should provide efficient DMA buffer tracking in two-level translation and maintain its performance benefit. Second, some devices (e.g. GPUs) partially support DMA page faults, e.g. only for selective pages such as those used by applications. We want to study a hybrid approach for fine-grained pinning, by leveraging DMA page faults for faultable pages and using coIOMMU for other non-faultable pages. Last, kernel bypassing usually needs to pre-map a big trunk of memory for the application to manage. We want to extend the coIOMMU concept from the boundary between hypervisor and guest to the boundary between kernel space and user space, to enable finer-grained memory management in such usage.

Abstract

Cross-silo federated learning (FL) enables organizations (e.g., financial or medical) to collaboratively train a machine learning model by aggregating local gradient updates from each client without sharing privacy-sensitive data. To ensure no update is revealed during aggregation, industrial FL frameworks allow clients to mask local gradient updates using *additively homomorphic encryption* (HE). However, this results in significant cost in *computation* and *communication*. In our characterization, HE operations dominate the training time, while inflating the data transfer amount by two orders of magnitude. In this paper, we present BatchCrypt, a system solution for cross-silo FL that substantially reduces the encryption and communication overhead caused by HE. Instead of encrypting individual gradients with full precision, we *encode a batch of quantized gradients* into a long integer and encrypt it in one go. To allow *gradient-wise aggregation* to be performed on *ciphertexts* of the encoded batches, we develop new quantization and encoding schemes along with a novel gradient clipping technique. We implemented BatchCrypt as a plug-in module in FATE, an industrial cross-silo FL framework. Evaluations with EC2 clients in geo-distributed datacenters show that BatchCrypt achieves 23×-93× training speedup while reducing the communication overhead by 66×-101×. The accuracy loss due to quantization errors is less than 1%.

1 Introduction

Building high-quality machine learning (ML) models requires collecting a massive amount of training data from diverse sources. However, in many industries, data is dispersed and locked in multiple organizations (e.g., banks, hospitals, and institutes), where data sharing is strictly forbidden due to the growing concerns about data privacy and confidentiality as well as violating the government regulations [12, 17, 45]. Cross-silo federated learning (FL) [27, 61] offers an appealing solution to break "data silos" among organizations, where participating clients *collaboratively learn* a global model by uploading their *local gradient updates* to a central server for aggregation, without sharing privacy-sensitive data.

To ensure that no client reveals its update during aggregation, many approaches have been proposed [9, 37, 47, 48, 52]. Among them *additively homomorphic encryption* (HE), notably the Paillier crytosystem [46], is particularly attractive in the cross-silo setting [37, 48, 61], as it provides a strong privacy guarantee at no expense of learning accuracy loss (§2). With HE, gradient aggregation can be performed on *ciphertexts* without decrypting them in advance. HE has been adopted in many cross-silo FL applications [13, 23, 37, 38, 44], and can be easily plugged into the existing FL frameworks to augment the popular parameter server architecture [33]. Before the training begins, an HE key-pair is synchronized across all clients through a secure channel. During training, each client encrypts its gradient updates using the public key and uploads the ciphertexts to a central server. The server aggregates the encrypted gradients from all clients and dispatches the result to each of them. A client decrypts the aggregated gradients using the private key, updates its local model, and proceeds to the next iteration. As clients only upload the encrypted updates, no information can be learned by the server or an external party during data transfer and aggregation.

Although HE provides a strong privacy guarantee for cross-silo FL, it performs complex cryptographic operations (e.g., modular multiplications and exponentiations) that are extremely expensive to compute. Our testbed characterization (§3) shows that more than 80% of the training iteration time is spent on encryption/decryption. To make matters worse, encryption yields substantially larger ciphertexts, inflating the amount of data transfer by over 150× than plaintext learning. The significant overhead of HE in *encryption* and *communication* has become a major roadblock to facilitating cross-silo FL. According to our contacts at WeBank [57], most of their FL applications cannot afford to use the encrypted gradients and are limited to scenarios with less stringent privacy requirements (e.g., FL across departments or trustworthy partners).

In this paper, we tackle the encryption and communication bottlenecks created by HE with a simple *batch encryption* technique. That is, a client first *quantizes* its gradient values into low-bit integer representations. It then *encodes* a batch of quantized values to a long integer and encrypts it in one go.

Compared with encrypting individual gradient values of full precision, batch encryption significantly reduces the encryption overhead and data transfer amount. Although this idea has been briefly mentioned in the previous work [37,48], the treatment is rather informal without a viable implementation. In fact, to enable batch encryption in cross-silo FL, there are two key technical challenges that must be addressed, which, to our knowledge, remains open.

First, a feasible batch encryption scheme should allow us to directly sum up the ciphertexts of two batches, and the result, when decrypted, matches that of performing *gradient-wise aggregation* on the two batches in the clear. We show that although it is viable to tweak the generic quantization scheme to meet such need, it has many limitations as it is not designed for aggregation. Instead, we design a customized quantization scheme that quantizes gradient values to *signed integers* uniformly distributed in a *symmetric* range. Moreover, to support gradient-wise aggregation in a simple additive form, and that the addition does not cause overflow to corrupt the encoded gradients, we develop a new batch encoding scheme that adopts *two's compliment representation* with *two sign bits* for quantized values. We also use *padding* and *advance scaling* to avoid overflow in addition. All these techniques allow gradient aggregation to be performed on ciphertexts of the encoded batches, without decryption first.

Second, as gradients values are *unbounded*, they need to be *clipped* before quantization, which critically determines the learning performance [5,41]. However, it remains unclear how to choose the clipping thresholds in the cross-silo setting. We propose an efficient analytical model dACIQ by extending ACIQ [5], a state-of-the-art clipping technique for ML over centralized data, to cross-silo FL over decentralized data. dACIQ allows us to choose optimal clipping thresholds with the minimum cumulative error.

We have implemented our solution BatchCrypt in FATE [18], a secure computing framework released by WeBank [57] to facilitate FL among organizations. Our implementation can be easily extended to support other optimization schemes for distributed ML such as local-update SGD [22, 35, 56], model averaging [40], and relaxed synchronization [24, 34, 62], all of which can benefit from BatchCrypt when applied to cross-silo FL. We evaluate BatchCrypt with nine participating clients geo-distributed in five AWS EC2 datacenters across three continents. These clients collaboratively learn three ML models of various sizes: a 3-layer fully-connected neural network with FMNIST dataset [60], AlexNet [32] with CIFAR10 dataset [31], and a text-generative LSTM model [25] with Shakespeare dataset [55]. Compared with the stock implementation of FATE, BatchCrypt accelerates the training of the three models by 23×, 71×, and 93×, respectively, where more salient speedup can be achieved for more complex models. In the meantime, the communication overhead is reduced by 66×, 71×, and 101×, respectively. The significant benefits of BatchCrypt come at no cost of model quality, with a negligible accuracy loss less than 1%. BatchCrypt[1] offers the first efficient implementation that enables HE in a cross-silo FL framework with low encryption and communication cost.

2 Background and Related Work

In this section, we highlight the stringent privacy requirements posed by cross-silo federated learning. We survey existing techniques for meeting these requirements.

2.1 Cross-Silo Federated Learning

According to a recent survey [27], federated learning (FL) is a scenario where multiple clients collaboratively train a machine learning (ML) model with the help of a central server; each client transfers local updates to the server for immediate aggregation, without having its raw data leaving the local storage. Depending on the application scenarios, federated learning can be broadly categorized into *cross-device* FL and *cross-silo* FL. In the cross-device setting, the clients are a large number of mobile or IoT devices with limited computing power and unreliable communications [27,30,39]. In contrast, the clients in the cross-silo setting are a small number of organizations (e.g., financial and medical) with reliable communications and abundant computing resources in datacenters [27,61]. We focus on cross-silo FL in this paper.

Compared with the cross-device setting, cross-silo FL has significantly more stringent requirements on privacy and learning performance [27,61]. *First*, the final trained model should be *exclusively released* to those participating organizations—no external party, including the central server, can have access to the trained model. *Second*, the strong privacy guarantee should not be achieved at a cost of learning accuracy. *Third*, as an emerging paradigm, cross-silo FL is undergoing fast innovations in both algorithms and systems. A desirable privacy solution should impose *minimum constraints* on the underlying system architecture, training mode (e.g., synchronous and asynchronous), and learning algorithms.

2.2 Privacy Solutions in Federated Learning

Many strategies have been proposed to protect the privacy of clients for federated learning. We briefly examine these solutions and comment on their suitability to cross-silo FL.

Secure Multi-Party Computation (MPC) allows multiple parties to collaboratively compute an agreed-upon function with private data in a way that each party knows nothing except its input and output (i.e., zero-knowledge guarantee). MPC utilizes carefully designed computation and synchronization protocols between clients. Such protocols have strong privacy guarantees, but are difficult to implement efficiently

[1] BatchCrypt is open-sourced and can be found at https://github.com/marcoszh/BatchCrypt

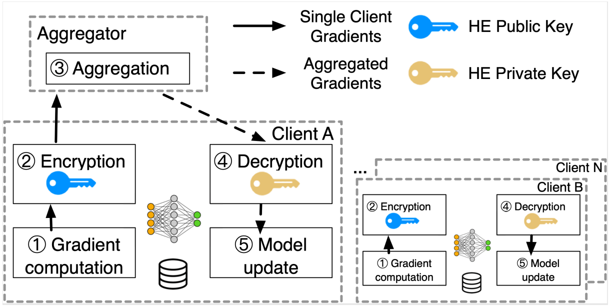

Figure 1: The architecture of cross-silo FL system, where HE is implemented as a pluggable module on the clients.

in a geo-distributed scenario like cross-silo FL [61]. Developers have to carefully engineer the ML algorithms and divide the computation among parties to fit the MPC paradigm, which may lower the privacy guarantees for better performance [16, 42, 43].

Differential Privacy (DP) is another common tool that can be combined with model averaging and SGD to facilitate secure FL [47, 52]. It ensures the privacy of each individual sample in the dataset by injecting noises. A recent work proposes to employ *selective parameter update* [52] atop differential privacy to navigate the tradeoff between data privacy and learning accuracy. Although DP can be efficiently implemented, it exposes plain gradients to the central server during aggregation. Later study shows that one can easily recover the information from gradients [48]. While such privacy breach and the potential accuracy drop might be tolerable for mobile users in cross-device FL, they raise significant concerns for participating organizations in cross-silo FL.

Secure Aggregation [9] is proposed recently to ensure that the server learns no individual updates from any clients but the *aggregated updates* only. While secure aggregation has been successfully deployed in cross-device FL, it falls short in cross-silo FL for two reasons. First, it allows the central server to see the aggregated gradients, based on which the information about the trained model can be learned by an external entity (e.g., public cloud running the central server). Second, in each iteration, clients must synchronize secret keys and *zero-sum masks*, imposing a strong requirement of *synchronous training*.

Homomorphic Encryption (HE) allows certain computation (e.g., addition) to be performed directly on ciphertexts, without decrypting them first. Many recent works [13, 37, 38, 48] advocate the use of additively HE schemes, notably Paillier [46], as the primary means of privacy guarantee in cross-silo FL: each client transfers the encrypted local updates to the server for direct aggregation; the result is then sent back to each client for local decryption. HE meets the three requirements of cross-silo FL. *First*, it protects the trained model from being learned by any external parties including the server as update aggregation is performed on ciphertexts. *Second*, it incurs no learning accuracy loss, as no noise is added to the model updates during the encryption/decryption process. *Third*, HE directly applies to the existing learning systems, requiring no modifications other than encrypting/decrypting updates. It hence imposes no constraints to the synchronization schemes and the learning algorithms. However, as we shall show in §3, HE introduces significant overhead to computation and communication.

Summary To summarize, each of these privacy-preserving techniques has its pros and cons. MPC is able to provide strong privacy guarantees, but requires expert efforts to re-engineer existing ML algorithms. DP can be adopted easily and efficiently, but has the downside of weaker privacy guarantee and potential accuracy loss. Secure aggregation is an effective way to facilitate large-scale cross-device FL, but may not be suitable for cross-silo FL as it exposes the aggregated results to third parties and incurs high synchronization cost. HE can be easily adopted to provide strong privacy guarantees without algorithm modifications or accuracy loss. However, the high computation and communication overheads make it impractical for production deployment at the moment.

2.3 Cross-Silo FL Platform with HE

Fig. 1 depicts a typical cross-silo FL system [27, 37, 61], where HE is implemented as a pluggable module on the clients. The *aggregator* is the server which coordinates the *clients* and aggregates their encrypted gradients. Note that in this work, we assume the aggregator is *honest-but-curious*, a common threat model used in the existing FL literature [9, 38, 52]. The communications between all parties (the clients and the aggregator) are secured by cryptographic protocols such as SSL/TLS, so that no third party can learn the messages being transferred. Before the training starts, the aggregator randomly selects a client as the leader who generates an HE key-pair and synchronizes it to all the other clients. The leader also initializes the ML model and sends the model weights to all the other clients. Upon receiving the HE key-pair and the initial weights, the clients start training. In an iteration, each client computes the local gradient updates (①), encrypts them with the public key (②), and transfers the results to the aggregator. The aggregator waits until the updates from all the clients are received. It then adds them up and dispatches the results to all clients (③). A client then decrypts the aggregated gradients (④) and uses it to update the local model (⑤).

This architecture design follows the classic distributed SGD pattern. So the existing theories and optimizations including flexible synchronization [24, 34, 62] and local update SGD [22, 35, 56] naturally apply. Moreover, as model updating is performed on the client's side using the plaintext gradient aggregation, we can adopt state-of-the-art adaptive optimizers such as Adam [28] for faster convergence—a huge advantage over the existing proposal [48] that applies encrypted gradients directly on the encrypted global model in the server.

3 Characterizing Performance Bottlenecks

In this section, we characterize the performance of cross-silo FL with three real applications driven by deep learning models in a geo-distributed setting. We show that encryption and communication come as two prohibitive bottlenecks that impede the adoption of FL among organizations. We survey possible solutions in the literature and discuss their inefficiency. To our knowledge, we are the first to present a comprehensive characterization for cross-silo FL in a realistic setting.

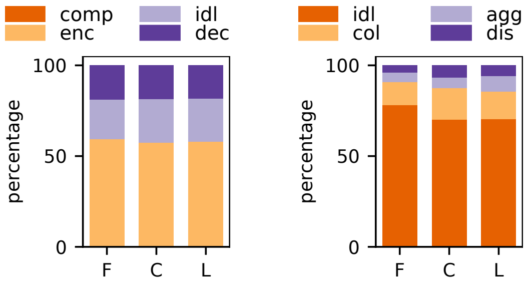
3.1 Characterization Results

Cross-silo FL is usually performed in multiple *geo-distributed* datacenters of participating organizations [27, 61]. Our characterization is carried out in a similar scenario where nine EC2 clients in five geo-distributed datacenters collaboratively training three ML models of various sizes, including FMNIST, CIFAR, and LSTM (Table 3). Unless otherwise specified, we configure *synchronous training*, where no client can proceed to the next iteration until the (encrypted) updates from all clients have been aggregated. We defer the detailed description of the cluster setup and the ML models to §6.1.

We base our study in FATE (Federated AI Technology Enabler) [18], a secure compute framework developed by WeBank [57] to drive its FL applications with the other industry partners. To our knowledge, FATE is the only open-source cross-silo FL framework deployed in production environments. FATE has a built-in support to the Pailler cryptosystem [46] (key size set to 2048 bits by default), arguably the most popular additively HE scheme [50]. Our results also apply to the other partially HE cryptosystems.

Encryption and Communication Overhead We start our characterization by comparing two FL scenarios, with and without HE. We find that the use of HE results in *exceedingly long training time* with *dramatically increased data transfer*. More specifically, when HE is enabled, we measured the average training iteration time 211.9s, 2725.7s, and 8777.7s for FMNIST, CIFAR, and LSTM, respectively. Compared with directly transferring the plaintext updates, the iteration time is extended by 96×, 135×, and 154×, respectively. In the meantime, when HE is (not) in use, we measured 1.1GB (6.98MB), 13.1GB (85.89MB), and 44.1GB (275.93MB) data transfer between clients and aggregator in one iteration on average for FMNIST, CIFAR, and LSTM, respectively. To sum up, the use of HE increases both the training time and the network footprint by two orders of magnitude. Such performance overhead becomes even more significant for complex models with a large number of weights (e.g., LSTM).

Deep Dive To understand the sources of the significant overhead caused by HE, we examine the training process of the three models in detail, where we sample an iteration and depict in Fig. 2 the breakdown of the iteration time spent on different operations on the client's side (left) and on the aggregator's side (right), respectively.



(a) Client: **comp**ute, **enc**rypt, **idl**e, **dec**rypt

(b) Aggregator: **idl**e, **col**lect, **agg**regate, **dis**patch

Figure 2: Iteration time breakdowns of **F**MNIST, **C**IFAR, and **L**STM for a client and the aggregator.

As illustrated in Fig. 2a, on the client's side, HE-related operations dominate the training time in all three applications. In particular, a client spent around 60% of the iteration time on gradient encryption (yellow), 20% on decryption (dark purple), and another 20% on data transfer and idle waiting for the gradient aggregation to be returned[2] (light purple). In comparison, the time spent on the actual work for computing the gradients becomes *negligible* ($< 0.5\%$).

When it comes to the aggregator (Fig. 2b), most of the time ($> 70\%$) is wasted on idle waiting for a client to send in the encrypted gradients (orange). Collecting the gradients from all clients (yellow) and dispatching the aggregated results to each party (dark purple) also take a significant amount of time, as clients are geo-distributed and may not start transferring (or receiving) at the same time. The actual computation time for gradient aggregation (light purple) only accounts for less than 10% of the iteration span. Our deep-dive profiling identifies encryption and decryption as the two dominant sources of the exceedingly long training time.

Why is HE So Expensive? In additively HE cryptosystems such as Paillier [46], encryption and decryption both involve multiple modular multiplications and exponentiation operations with a large exponent and modulus (usually longer than 512 bits) [50], making them extremely expensive to compute. Encryption also yields significantly larger ciphertexts, which, in turn, causes a huge communication overhead for data transfer. In additively HE schemes such as Paillier, a ciphertext takes roughly the same number of bits as the key size, irrespective of the plaintext size. As of 2019, the minimum secure key size for Paillier is 2048 [6], whilst a gradient is typically a 32-bit floating point. This already translates to 64× size inflation after encryption.

We further benchmark the computation overhead and the inflated ciphertexts of Paillier with varying key sizes. We use `python-paillier` [15] to encrypt and then decrypt 900K 32-bit floating points. Table 1 reports the results on

[2] Due to the synchronization barrier, a client needs to wait for all the other clients to finish transferring updates to the aggregator.

Table 1: Benchmarking Paillier HE with various key sizes.

Key size	Plaintext	Ciphertext	Encryption	Decryption
1024	6.87MB	287.64MB	216.87s	68.63s
2048	6.87MB	527.17MB	1152.98s	357.17s
3072	6.87MB	754.62MB	3111.14s	993.80s

a c5.4xlarge instance. As the key size increases (higher security), both the computation overhead and the size of ciphertexts grow linearly. Since Paillier can only encrypt integers, floating point values have to be scaled beforehand, and their exponents information contribute further to data inflation.

Summary The prohibitive computation and communication overhead caused by HE, if not properly addressed, would lead to two serious economic consequences. First, given the dominance of HE operations, accelerating model computation using high-end hardware devices (e.g., GPUs and TPUs) is no longer relevant—a huge waste of the massive infrastructure investments in clients' datacenters. Second, the overwhelming network traffics across geo-distributed datacenters incurs skyrocketing Internet data charges, making cross-silo FL economically unviable. In fact, in WeBank, production FL applications may choose to turn off HE if the security requirement is not so strict.

3.2 Potential Solutions and Their Inefficiency

Hardware-Accelerated HE HE process can be accelerated using software or hardware solutions. However, typical HE cryptosystems including Paillier have limited interleaving independent operations, thus the potential speedup of a single HE operation is quite limited. In fact, it is reported that a specialized FPGA can only accelerate Paillier encryption by 3× [50]. Moreover, simply accelerating the encryption itself does not help reduce the communication overhead.

Reducing Communication Overhead As accelerating HE itself does not clear the barrier of adopting HE in FL, what if we reduce the amount of data to encrypt in the first place? Since data inflation is mainly caused by the mismatch between the lengths of plaintexts and ciphertexts, an intuitive idea would be *batching* as many gradients together as possible to form a *long* plaintext, so that the amount of encryption operations will reduce greatly. However, the challenge remains how to maintain HE's additive property after batching without modifying ML algorithms or hurting the learning accuracy.

While some prior works have explored the idea of joining multiple values together to reduce HE overhead, they give no viable implementation of batch encryption for cross-silo FL. [48] makes a false assumption that quantization is lossless, and uses adaptive optimizer Adam in its simulation even though its design does not support that. With only plain SGD available, [48] requires tedious learning rate scheduling tuning to achieve similar results of advanced optimizers [59]. The naive batching given in [37] cannot be correctly implemented as homomorphic additivity is not retained. In fact, none of these works have systematically studied the impact of batching. Gazelle [26] and SEAL [51] adopt the SIMD (single instruction multiple data) technique to speed up HE. However, such approach only applies to lattice-based HE schemes [11] and is restricted by their unique properties. For instance, it incurs dramatic computational complexity for lattice-based HE schemes to support more levels of multiplication [26]. Besides, these works only accelerate integer cryptographic operations. How to maintain the training accuracy in cross-silo FL context remains an open problem.

4 BatchCrypt

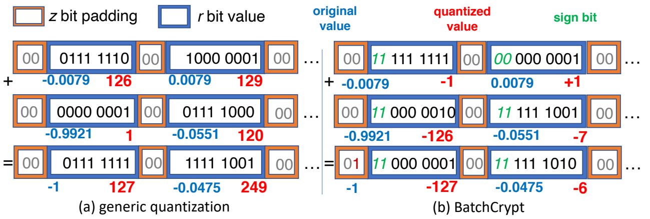
In this section, we describe our solution for gradient batching. We begin with the technical challenges. We first show that gradient quantization is required to enable batching. We then explain that generic quantization scheme lacks flexibility and efficiency to support general ML algorithms, which calls for an appropriately designed encoding and batching scheme; to prevent model quality degradation, an efficient clipping method is also needed. We name our solution BatchCrypt, a method that co-designs quantization, batch encoding, and analytical quantization modeling to boost computation speed and communication efficiency while preserving model quality in cross-silo FL with HE.

4.1 Why is HE Batching for FL a Problem?

On the surface, it seems straightforward to implement gradient batching. In fact, batching has been used to speed up queries over integers in a Paillier-secured database [19]. However, this technique only applies to *non-negative integers* [19]. In order to support floating numbers, the values have to be *reordered and grouped by their exponents* [19]. Such constraints are the key to preserving HE's additivity of batched ciphertexts—that is, the sum of two batched ciphertexts, once decrypted, should match the results of element-wise adding plaintext values in the two groups. Gazelle and SEAL [26, 51] employ SIMD technique to meet this requirement, but the approach is limited to lattice-based cryptosystems. We aspire to propose a universal batching method for all additively homomorphic cryptosystems.

Why Quantization is Needed? Gradients are *signed floating values* and must be ordered by their corresponding model weights, for which we cannot simply rearrange them by exponents. The only practical approach is to use integer representations of gradients in the batch, which requires quantization.

Existing Quantization Schemes ML algorithms are resilient to update noise and able to converge with gradients of limited precision [10]. Fig. 3a illustrates how generic gradient quantization scheme can be used in HE batching. Notably, since there is no bit-wise mapping between a ciphertext and its plaintext, permutation within ciphertexts is not allowed—only plain bit-by-bit addition between batched integers is available. Assume a gradient g in $[-1, 1]$ is quantized into an



(a) generic quantization

(b) BatchCrypt

Figure 3: An illustration of a generic quantization scheme and BatchCrypt. The latter preserves additivity during batching, with the sign bits highlighted within values.

8-bit unsigned integer. Let $[\cdot]$ denote the standard rounding function. The quantized value of g is

$$Q(g) = [255 * (g - min)/(max - min)],$$

where $max = 1$ and $min = -1$. Suppose n quantized gradients are summed up. The result, denoted by q_n, is dequantized as

$$Q^{-1}(q_n) = q_n * (max - min)/255 + n * min.$$

Referring to Fig. 3a, gradients of a client (floating numbers in blue) are first quantized and then batch joined into a large integer. To aggregate the gradients of two clients, we simply sum up the two batched integers, locate the added gradients at the same bit positions as in the two batches (8-bit integers in red), and dequantize them to obtain the aggregated results.

Such a generic quantization scheme, though simple to implement, does not support aggregation well and has many ***limitations*** when applied to batched gradient aggregation.

(1) It is restrictive. In order to dequantize the results, it must know how many values are aggregated. This poses extra barriers to flexible synchronization, where the number of updates is constantly changing, sometimes even unavailable.

(2) It overflows easily in aggregation. As values are quantized into positive integers, aggregating them is bound to overflow quickly as the sum grows larger. To prevent overflow, batched ciphertexts have to be decrypted after a few additions and encrypted again in prior work [48].

(3) It does not differentiate *positive* overflows from *negative*. Once overflow occurs, the computation has to restart. Should we be able to tell them apart, a saturated value could have been used instead of discarding the results.

4.2 HE Batching for Gradients

Unsatisfied with the generic quantization technique, we aspire to devise a batching solution tailored to gradient aggregation. Our scheme should have the following desirable properties: (1) it preserves the additivity of HE; (2) it is more resilient to overflows and can distinguish positive overflows from negative ones; (3) it is generally applicable to existing ML algorithms and optimization techniques; (4) it is flexible enough that one can dequantize values directly without additional information, such as the number of values aggregated.

Gradient Quantization Existing works use gradient compression techniques to reduce network traffic in distributed training [1,29,36,58]. These quantization methods are mainly used to compress values for transmission [58] or accelerate inference where only multiplication is needed [5]. However, they are not designed for gradient aggregation, and we cannot perform computations over the compressed gradients efficiently, making them inadequate for FL. We scrutinize the constraints posed by our design objectives, and summarize the stemed requirements for quantization as follows:

- **Signed Integers:** Gradients should be quantized into *signed* integers. In this way, positive and negative values can cancel each other out in gradient aggregation, making it less prone to overflowing than quantizing gradients into unsigned integers.
- **Symmetric Range:** To make values with opposite signs cancel each other out, the quantized range must be symmetrical. Violating this requirement may lead to an incorrect aggregation result. For example, if we map $[-1,1]$ to $[-128,127]$, then $-1+1$ would become $-128+127 = -1$ after quantization.
- **Uniform Quantization:** Literature shows that non-uniform quantization schemes have better compression rates as gradients have non-uniform distribution [1, 7]. However, we are unable to exploit the property as additions over quantized values are required.

BatchCrypt We now propose an efficient quantization scheme BatchCrypt that meets all the requirements above. Assume that we quantize a gradient in $[-\alpha, \alpha]$ into an r-bit integer. Instead of mapping the whole range all together, we *uniformly map* $[-\alpha, 0]$ and $[0, \alpha]$ to $[-(2^r - 1), 0]$ and $[0, 2^r - 1]$, respectively. Note that the value 0 ends up with two codes in our design. Prior work shows that 16-bit quantization ($r = 16$) is sufficient to achieve near lossless gradient quantization [21]. We will show in §6 that such a moderate quantization width is sufficient to enable efficient batching in FL setting.

With quantization figured out, the challenge remains how to encode the quantized values so that signed additively arithmetic is correctly enabled—once the batched long integer is encrypted, we cannot distinguish the sign bits from the value bits during aggregation. Inspired by how modern CPUs handle signed integer computations, we use *two's complement representation* in our encoding. By doing so, the sign bits can engage in the addition just like the value bits. We further use the *two sign bits* to differentiate between the positive and negative overflows. We illustrate an example of BatchCrypt in Fig. 3b. By adding the two batched long integers, BatchCrypt gets the correct aggregation results for $-1 + (-126)$ and $+1 + (-7)$, respectively.

BatchCrypt achieves our requirements by co-designing quantization and encoding: no additional information is needed to dequantize the aggregated results besides the batch itself; positive and negative values are able to offset each other; the signs of overflow can be identified. Compared

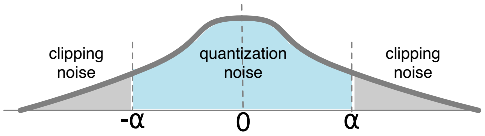


Figure 4: A typical layer gradient distribution. α is the clipping threshold.

with the batching methods in [26, 51], BatchCrypt's batching scheme is generally applicable to all additively HE cryptosystems' and fully HE cryptosystems' additive operations.

4.3 dACIQ: Analytical Clipping for FL

Our previous discussion has assumed gradients in a bounded range (§4.2). In practice, however, gradients may go unbounded and need to be *clipped* before quantization. Also, gradients from different layers have different distributions [58]. We thus need to quantize layers individually [1, 58]. Moreover, prior works show that gradients from the same layer have a bell-shaped distribution which is near Gaussian [2, 7, 53]. Such property can be exploited for efficient gradient compression [1, 58]. Finally, gradients require *stochastic rounding* during quantization [21, 36, 58], as it stochastically preserves diminishing information compared to *round-to-nearest*.

Layer-wise quantization and stochastic rounding can be easily applied, yet it remains unclear how to find the optimal clipping thresholds in the FL setting. As shown in Fig. 4, clipping is the process of saturating the outlaying gradients beyond a threshold α. If α is set too large, the quantization resolution becomes too low. On the other hand, if α gets too small, most of the range information from outlaying gradients has to be discarded.

In general, there are two ways to set the clipping threshold, *profiling-based* methods and *analytical modeling*. Profiling-based clipping selects a sample dataset to obtain a sample gradient distribution. Thresholds are then assessed with metrics such as KL divergence [41] and convergence rate [58]. However, such approach is impractical in FL for three reasons. First, finding a representative dataset in FL can be difficult, as clients usually have non-i.i.d. data, plus it breaks the data silo. Second, the gradient range narrows slowly as the training progresses [14], so clipping needs to be calibrated constantly, raising serious overhead concerns. Third, the profiling results are specific to the training models and datasets. Once the models or the datasets change, new profiling is needed. For both practicality and cost considerations, BatchCrypt instead adopts analytical modeling.

As shown in Fig. 4, the accumulated noise comes from two sources. *Quantization noise* refers to the error induced by rounding within the clipping range (the light blue area), while *clipping noise* refers to the saturated range beyond the clipping threshold (the gray area). To model the accumulated noise from both quantization and clipping, state-of-the-art clipping technique ACIQ [5] assumes that they follow a Gaussian distribution. However, ACIQ cannot be directly applied to BatchCrypt for two reasons. First, it employs a generic asymmetric quantization, which is not the case in BatchCrypt; second, in FL, gradients are not available at one place in plaintext to conduct distribution fitting.

We address these problems by extending ACIQ clipping to the distributed FL setting, which we call dACIQ. In particular, we adopt stochastic rounding with an r-bit quantization width. Assume that gradients follow Gaussian distribution $X \sim N(0, \sigma^2)$. Let q_i be the i-th quantization level. We compute the accumulated error in BatchCrypt as follows:

$$\begin{aligned} E[(X-Q(X))^2] &= \int_{-\infty}^{-\alpha} f(x)\cdot(x+\alpha)^2 dx + \int_{\alpha}^{\infty} f(x)\cdot(x-\alpha)^2 dx \\ &+ \sum_{i=0}^{2^r-3} \int_{q_i}^{q_{i+1}} f(x) \cdot [\, (x-q_i)^2 \cdot (\frac{q_{i+1}-x}{\triangle}) + (x-q_{i+1})^2 \cdot (\frac{x-q_i}{\triangle})\,] dx \\ &\approx \frac{\alpha^2+\sigma^2}{2} \cdot [1 - erf(\frac{\alpha}{\sqrt{2}\sigma})] - \frac{\alpha\cdot\sigma\cdot e^{-\frac{\alpha^2}{2\cdot\sigma^2}}}{\sqrt{2\pi}} + \frac{2\alpha^2\cdot(2^r-2)}{3\cdot 2^{3r}}, \end{aligned} \tag{1}$$

where the first and the second terms account for the clipping noise, and the third the rounding noise. As long as we know σ, we can then derive the optimal threshold α from Eq. (1). We omit the detailed derivations in the interest of space.

Gaussian Fitting Now that we have Eq. (1), we still need to figure out how to fit gradients into a Gaussian distribution in the FL setting. Traditionally, to fit Gaussian parameters μ and σ, Maximum Likelihood Estimation and Bayesian Inference can be used. They require information including the size of observation set, its sum, and its sum of squares. As an ML model may have up to millions of parameters, calculating these components as well as transferring them over Internet is prohibitively expensive. As a result, dACIQ adopts a simple, yet effective Gaussian fitting method proposed in [4]. The method only requires the size of observation set and its max and min, with the minimum computational and communication overhead. We later show that such light-weight fitting does not affect model accuracy in §6.

Advance Scaling With multiple clients in FL, it is essential to prevent overflows from happening. Thanks to clipping, the gradient range is predetermined before encryption. Let m be the number of clients. If m is available, we could employ *advance scaling* by setting the quantization range to m times of the clipping range, so that the sum of gradients from all clients will not overflow.

4.4 BatchCrypt: Putting It All Together

Putting it all together, we summarize the workflow of BatchCrypt in Algorithm 1.

Initialization The aggregator randomly selects one client as the leader. The leader client generates the HE key-pair and initializes the model weights. The key-pair and model weights are then synchronized with the other client workers.

Training After initialization, there is no differentiation between the leader and the other workers. Clients compute gra-

function StartsTraining
    for epoch $e = 0, 1, 2, ..., E$ do
        Issue WorkerStartsEpoch($e$) to all clients
        for all training batch $t = 0, 1, 2, \cdots, T$ do
            Collect gradients range and size
            Return clipping values $\alpha$ calculated by dACIQ
            Collect, sum up all $g_i^{(e,t)}$ into $g^{(e,t)}$, and dispatch it

Client Worker: $i = 1, 2, \ldots, m$
    – $r$: quantization bit width, $bs$: BatchCrypt batch size
function InitializeLeader
    Generate HE key-pair pub_key and pri_key
    Initialize the model to train w
    Send pub_key, pri_key, and w to other clients
function InitializeOther
    Receive HE key-pair pub_key and pri_key
    Receive the initial model weights w
function WorkerStartsEpoch($e$)
    for all training batch $t = 0, 1, 2, \cdots, T$ do
        Compute gradients $g_i^{(e,t)}$ based on $w$
        Send per-layer range and size of $g_i^{(e,t)}$ to aggregator
        Receive the layer-wise clipping values $\alpha$'s
        Clip $g_i^{(e,t)}$ with corresponding $\alpha$, quantize $g_i^{(e,t)}$ into $r$ bits, with
    quantization range setting to $m\alpha$                ▷ Advance scaling
        Batch $g_i^{(e,t)}$ with $bs$ layer by layer
        Encrypt batched $g_i^{(e,t)}$ with pri_key
        Send encrypted $g_i^{(e,t)}$ to aggregator
        Collect $g^{(e,t)}$ from aggregator, and decrypt with pub_key
        Apply decrypted $g^{(e,t)}$ to $w$
```

dients and send the per-layer gradient range and size to the aggregator. The aggregator estimates the Gaussian parameters first and then calculates the layer-wise clipping thresholds as described in § 4.3. Clients then quantize the gradients with range scaled by the number of clients, and encrypt the quantized values using BatchCrypt. Note that advanced scaling utilizing the number of clients is used to completely avoid overflowing. However, Algorithm 1 is still viable even without that information, as BatchCrypt supports overflow detection. The encrypted gradients are gathered at the aggregator and summed up before returning to the clients.

5 Implementation

We have implemented BatchCrypt atop FATE (v1.1) [18]. While we base our implementation on FATE, nothing precludes it from being extended to the other frameworks such as TensorFlow Federated [20] and PySyft [49].

Overview Our implementation follows the paradigm described in Algorithm 1, as most of the efforts are made on the client side. Fig. 5 gives an overview of the client architecture.

BatchCrypt consists of dACIQ, Quantizer, two's Compliments Codec, and Batch Manager. dACIQ is responsible for Gaussian fitting and clipping threshold calculation. Quantizer takes the thresholds and scales them to quantize the clipped values into signed integers. Quantizer also performs dequantization. Two's Compliments Codec translates between a quantized value's true form and two's compliment form with two sign bits. Given the large volume of data to encode, we adopt Numba to enable faster machine codes and massive parallelism. Finally, Batch Manager is in charge of batching and unbatching gradients in their two's compliment form, it remembers data's original shape before batching and restores it during unbatching. Batch Manager utilizes joblib to exploit computing resources by multiprocessing. FATE is used as an infrastructure to conduct FL, in which all the underlying ML computations are written with TensorFlow v1.14 optimized for our machines shipped with AWS DLAMI [3]. FATE adopts the open-sourced python-paillier as the Paillier HE implementation. We again employ joblib to parallel the operations here. FATE's Communication Manager conducts the SSL/TLS secured communication with gRPC. During our characterizations and evaluations, the CPUs are always fully utilized during Paillier operations and BatchCrypt process.

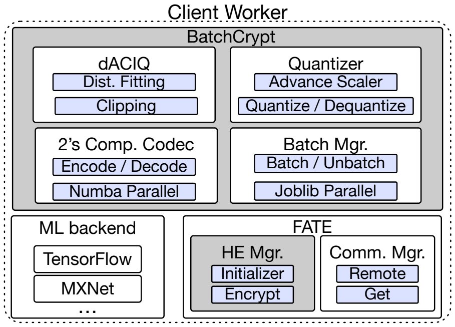

Figure 5: The architecture of a client worker in BatchCrypt.

Model Placement In the typical parameter server architecture, model weights are placed on the server side, while we purposely place weights on the worker side in BatchCrypt. Prior work [48] employs the traditional setup: clients encrypt the initialized weights with HE and send them to the aggregator first; the aggregator applies the received encrypted gradients to the weights encrypted with the same HE key. Such placement has two major drawbacks. First, keeping weights on the aggregator requires *re-encryption*. Since new gradients are constantly applied to weights, the model has to be sent back to the clients to decrypt and re-encrypt to avoid overflows from time to time, resulting in a huge overhead. Second, applying encrypted gradients prevents the use of sophisticated ML optimizers. State-of-the-art ML models are usually trained with adaptive optimizers [28] that scale the learning rates according to the gradient itself. By keeping the model weights on the client side, BatchCrypt can examine the aggregated plaintext gradients, enabling the use of advanced optimizers like Adam, whereas on the aggregator side, one can only adopt plain SGD.

Table 2: Network bandwidth (Mbit/sec) between aggregator and clients in different regions.

Region	Ore.	TYO.	N.VA.	LDN	HK
Uplink (Mbps)	9841	116	165	97	81
Downlink (Mbps)	9841	122	151	84	84

6 Evaluation

In this section, we evaluate the performance of BatchCrypt with real ML models trained in geo-distributed datacenters. We first examine the learning accuracy loss caused by our quantization scheme (§6.2). We then evaluate the computation and communication benefits BatchCrypt brings as well as how its performance compares to the ideal plaintext learning (§6.3). We then assess how BatchCrypt's speedup may change with various batch sizes (§6.4). Finally, we demonstrate the significant cost savings achieved by BatchCrypt (§6.5).

6.1 Methodology

Setting We consider a geo-distributed FL scenario where nine clients collaboratively train an ML model in five AWS EC2 datacenters located in Tokyo, Hong Kong, London, N. Virginia, and Oregon, respectively. We launched two compute-optimized `c5.4xlarge` instances (16 vCPUs and 32 GB memory) as two clients in each datacenter except that in Oregon, where we ran only one client. Note that we opt to not use GPU instances because computation is not a bottleneck. We ran one aggregator in the Oregon datacenter using a memory-optimized `r5.4xlarge` instance (16 vCPUs and 128 GB memory) in view of the large memory footprint incurred during aggregation. To better outline the network heterogeneity caused by geo-locations, we profiled the network bandwidth between the aggregator and the client instances. Our profiling results are summarized in Table 2. We adopt Pailler cryptosystem in our evaluation as it is widely adopted in FL [50], plus batching over it is not supported by Gazelle or SEAL [26, 51]. We expect our results also apply to other cryptosystems as BatchCrypt offers a generic solution.

Benchmarking Models As there is no standard benchmarking suites for cross-silo FL, we implemented three representative ML applications in FATE v1.1. Our first application is a 3-layer fully-connected neural network trained over FMNIST dataset [60], where we set the training batch size to 128 and adopt Adam optimizer. In the second application, we train AlexNet [32] using CIFAR10 dataset [31], with batch size 128 and RMSprop optimizer with 10^{-6} decay. The third application is an LSTM model [25] with Shakespeare dataset [55], where we set the batch size to 64 and adopt Adam optimizer. Other LSTM models that are easier to validate have significantly more weights. Training them to convergence is beyond our cloud budget. As summarized in Table 3, all three applications are backed by deep learning models of various sizes and cover common learning tasks such as image classification and text generation. For each application, we randomly partition its training dataset across nine clients. We configure synchronous training unless otherwise specified.

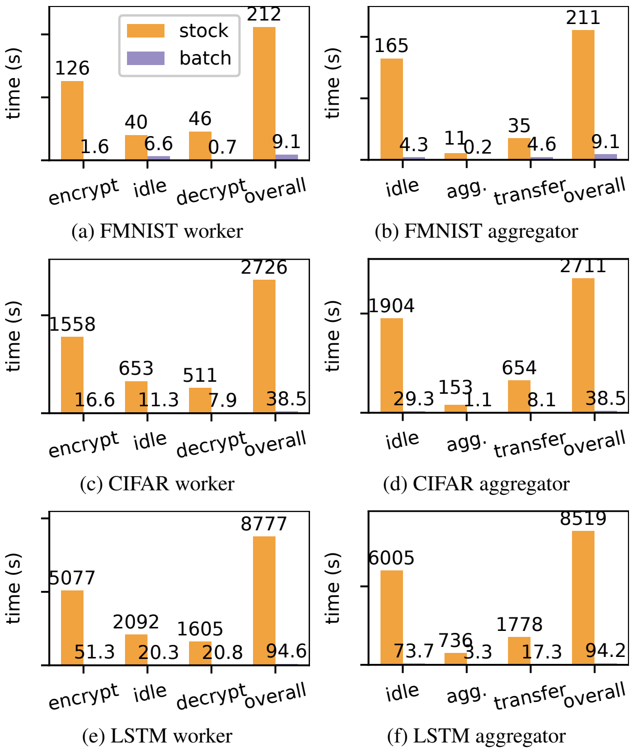
(c) LSTM train loss

Figure 6: The quality of trained model with different quantization bit widths in BatchCrypt.

6.2 Impact of BatchCrypt's Quantization

We first evaluate the impact of our quantization scheme, and see how quantization bit width could affect the model quality. We report the test accuracy for FMNIST and CIFAR workloads to see how BatchCrypt's quantization affects the classification top-1 accuracy. Training loss is used for LSTM as the dataset is unlabelled and has no test set. We simulated the training with nine clients using BatchCrypt's quantization scheme including dACIQ clipping. The simulation scripts are also open-sourced for public access. We set the quantization bit width to 8, 16, and 32, respectively, and compare the results against plain training (no encryption) as the baseline. We ran the experiments until convergence, which is achieved when the accuracy or loss does not reach a new record for three consecutive epochs.

Fig. 6 depicts the results. For FMNIST, plain baseline reaches peak accuracy 88.62% at the 40th epoch, while the 8-bit, 16-bit, and 32-bit quantized training reach 88.67%, 88.37%, and 88.58% at the 122nd, 68th, and 32nd epoch, respectively. For CIFAR, plain baseline reaches peak accuracy 73.97% at the 285th epoch, while the 8-bit, 16-bit, and 32-bit quantized training reach 71.47%, 74.04%, and 73.91% at the 234th, 279th, and 280th epoch, respectively. Finally, for LSTM, plain baseline reaches bottom loss 0.0357 at the 20th epoch, while the 8-bit, 16-bit, and 32-bit quantized training reach 0.1359, 0.0335, and 0.0386 at the 29th, 23rd, and 22nd epoch, respectively. We hence conclude that, with appropriate quantization bit width, BatchCrypt's quantization has negligible negative impact on the trained model quality. Even in



(a) FMNIST worker

(b) FMNIST aggregator

(c) CIFAR worker

(d) CIFAR aggregator

(e) LSTM worker

(f) LSTM aggregator

Figure 7: Breakdown of training iteration time under stock FATE and BatchCrypt, where "idle" measures the idle waiting time of a worker and "agg." measures the gradient aggregation time on the aggregator. Note that model computation is left out here as it contributes little to the iteration time.

the case where the quantized version requires more epochs to converge, we later show that such overhead can be more than compensated by the speedup from BatchCrypt.

Although 8-bit quantization performs poorly for CIFAR and LSTM, it is worth notice that, longer bit width does not necessarily lead to higher model quality. In fact, quantized training sometimes achieves better results. Prior quantization work has observed similar phenomenon [63], where the stochasticity introduced by quantization can work as a regularizer to reduce overfitting, similar to a dropout layer [54]. Just like the dropout rate, quantization bit width acts as a trade-off knob for how much information is retained and how much stochasticity is introduced.

In summary, with apt bit width, our gradient quantization scheme does not adversely affect the trained model quality. In contrast, existing batching scheme introduces 5% of quality drop [37]. Thus, quantization-induced error is not a concern for the adoption of BatchCrypt.

6.3 Effectiveness of BatchCrypt

BatchCrypt vs. FATE We next evaluate the effectiveness of BatchCrypt in real deployment. We set the quantization bit width to 16 as it achieves a good performance (§6.2). The batch size is set to 100, in which we pad two zeros between the two adjacent values. We report two metrics: the iteration time breakdown together with the network traffic. We ran the experiments for 50 iterations, and present the averaged results against those measured with the stock FATE implementation in Figs. 7 and 8. We see in Fig. 2 that BatchCrypt significantly speeds up a training iteration: 23.3× for FMNIST, 70.8× for CIFAR, and 92.8× for LSTM. Iteration time breakdown further shows that our implementation reduces the cost of HE related operations by close to 100×, while the communication time is substantially reduced as well ("idle" in worker and "transfer" in aggregator).

We next refer to Fig. 8, where we see that BatchCrypt reduces the network footprint by up to 66×, 71×, and 101× for FMNIST, CIFAR, and LSTM, respectively. Note that FATE adopts `grpc` as the communication vehicle whose limit on payload forces segmenting encrypted weights into small chunks before transmission. By reducing the size of data to transfer, BatchCrypt alleviates the segmenting induced overhead (metadata, checksum, etc.), so it is possible to observe a reduction greater than the batch size.

Our experiments also show that BatchCrypt achieves more salient improvements for larger models. First, encryption related operations take up more time in larger models, leaving more potential space for BatchCrypt. Second, since layers are batched separately, larger layers have higher chances forming long batches. BatchCrypt's speedup can be up to two orders of magnitude, which easily offset the extra epochs needed for convergence caused by quantization (§6.2).

	plain	20	0.0357	12.3	10.4

footprint under the two implementations. While encryption remains the major bottleneck, BatchCrypt successfully reduces the overhead by an order of magnitude, making it practical to achieve the same training results as the plain distributed setting. Note that encrypted numbers in FATE each carries redundant information such as public keys, thus causing the communication inflation compared with the plain version. Such inflation can be reduced if FATE employs some optimized implementation.

Training to Convergence Our previous studies mainly focus on a single iteration. Compared with stock FATE and plain distributed learning, BatchCrypt requires a different number of iterations to converge. We hence evaluate their end-to-end performance by training ML models till convergence. As this would take exceedingly long time and high cost if performed in real deployment, we instead utilize our simulation in §6.2 and iteration profiling results to project the total time and network traffic needed for convergence.

Table 4 lists our projection results of the three solutions. Compared with the stock implementation in FATE, BatchCrypt dramatically reduces the training time towards convergence by 13.76×, 72.32×, and 80.65× for FMNIST, CIFAR, and LSTM, respectively. In the meantime, the network footprints shrink by 37.96×, 72.01×, 87.23×, respectively. We stress that these performance improvements are achieved without degrading the trained model quality. On the other hand, BatchCrypt only slows down the overall training time by 1.78×, 2.84×, and 7.55× for the three models compared with plain learning—which requires no encryption and hence achieves the fastest possible training convergence. In summary, BatchCrypt significantly reduces both the computation and communication overhead caused by HE, enabling efficient HE for cross-silo FL in production environments.

(c) Aggregator traffic

Figure 10: Breakdown of iteration time and communication traffic of BatchCrypt with LSTM model with various quantization bit widths in one iteration. The corresponding batch sizes for bit width 8, 16, and 32 are 200, 100, and 50, respectively.

6.4 Batching Efficiency

We have shown in §6.2 that ML applications have different levels of sensitivity towards gradient quantization. It is hence essential that BatchCrypt can efficiently batch quantized values irrespective of the chosen quantization bit width. Given an HE key, the longest plaintext it can encrypt is determined by the key size, so the shorter the quantization width is, the larger the batch size is, and the higher the potential speedup could be. We therefore look into how our BatchCrypt implementation can exploit such batching speedup.

We evaluate BatchCrypt by varying the batch size. In particular, we train the LSTM model on the geo-distributed clients with different quantization widths 8, 16, and 32. The corresponding batch sizes are set respectively to 200, 100, and 50. We ran the experiments for 50 iterations, and illustrate the average statistics in Fig. 10. Figs. 10a and 10b show the time breakdown in the three experiments. It is clear that employing a shorter quantization bit width enables a larger batch size, thus leading to a shorter training time. Note that the speedup going from 8-bit to 16-bit is smaller compared with that from 16-bit to 32-bit, because HE operations become less of a bottleneck with larger batch size. Fig. 10c depicts the

Figure 11: Total cost until convergence between FATE's stock implementation and BatchCrypt, **ins**tance and **net**work costs are highlighted separately.

accumulated network traffic incurred in one iteration, which follows a similar trend as that of the iteration time. In conclusion, BatchCrypt can efficiently exploit batching thanks to its optimized quantization. Similar to [26, 51], BatchCrypt's batching scheme reduces both the computation and communication cost linearly as the batch size increases. In fact, if lattice-based HE algorithms are adopted, one can replace BatchCrypt's batching scheme with that of [26, 51], and still benefit from BatchCrypt's accuracy-preserving quantization.

6.5 Cost Benefits

The reduced computation and communication overheads enable significant cost savings: sustained high CPU usage leads to high power consumption, while ISPs charge for bulk data transfer over the Internet. As our evaluations were conducted in EC2, which provides a runtime environment similar to the organization's own datacenters, we perform cost analysis under the AWS pricing scheme. The hourly rate of our cluster is \$8.758, while the network is charged based on outbound traffic for \$0.042, \$0.050, \$0.042, \$0.048, \$0.055 per GB for the regions listed in Table 2.

We calculate the total cost for training until convergence in Table 4 and depict the results in Fig. 11. As both computation and communication are reduced substantially, BatchCrypt achieves huge cost savings over FATE. While the instance cost reduction is the same as the overall speedup in Table 4, BatchCrypt lowers the network cost by 97.4%, 98.6% and 98.8% for FMNIST, CIFAR, and LSTM, respectively.

7 Discussion

Local-update SGD & Model Averaging Local-update SGD & model averaging is another common approach to reducing the communication overhead for FL [22, 40], where the aggregator collects and averages model weights before propagating them back to clients. Since there are only addition operations involved, BatchCrypt can be easily adopted.

Split Model Inference In many FL scenarios with restrictive privacy requirement, a trained model is split across clients, and model inference involves coordination of all those clients [23, 61]. BatchCrypt can be used to accelerate the encryption and transmission of the intermediate inference results.

Flexible Synchronization There have been many efforts in amortizing the communication overhead in distributed SGD by removing the synchronization barriers [24, 34, 62]. Although we only evaluate BatchCrypt's performance in synchronous SGD, our design allows it to take advantage of the flexible synchronization schemes proposed in the literature. This is not possible with Secure Aggregation [9].

Potential on Large Models Recent research and our evaluations show that more sophisticated ML models are more resilient to quantization noise. In fact, certain models are able to converge even with 1- or 2-bit quantization [8, 58]. The phenomenon promises remarkable improvement with BatchCrypt, which we will explore in our future work.

Applicability in Vertical FL Vertical FL requires complicated operations like multiplying ciphertext matrices [38, 61]. Batching over such computation is beyond BatchCrypt's current capability. We will leave it as a future work.

8 Concluding Remark

In this paper, we have systematically studied utilizing HE to implement secure cross-silo FL. We have shown that HE related operations create severe bottlenecks on computation and communication. To address this problem, we have presented BatchCrypt, a system solution that judiciously quantizes gradients, encodes a batch of them into long integers, and performs batch encryption to dramatically reduce the encryption overhead and the total volume of ciphertext. We have implemented BatchCrypt in FATE and evaluated its performance with popular machine learning models across geo-distributed datacenters. Compared with the stock FATE, BatchCrypt accelerates the training convergence by up to 81× and reduces the overall traffic by 101×, saving up to 99% cost when deployed in cloud environments.

A Deep Dive into DNS Query Failures

Donghui Yang[†] [§], Zhenyu Li[†] [§] [‡], Gareth Tyson[♭]
[†]*ICT-CAS,* [§]*University of Chinese Academy of Sciences,* [‡] *Purple Mountain Laboratories,* [♭]*QMUL*

Abstract

The Domain Name System (DNS) is fundamental to the operation of the Internet. Failures within DNS can have a dramatic impact on the wider Internet, most notably preventing access to any services dependent on domain names (*e.g.* web, mobile apps). Although there have been several studies into DNS utilization, we argue that greater focus should be placed on understanding *how* and *why* DNS queries fail in-the-wild. In this paper, we perform the largest ever study into DNS activity, covering 3B queries. We find that 13.5% of DNS queries fail, and this leads us to explore the root causes. We observe significant differences between IPv4 and IPv6 lookups. A handful of domains that have high failure rates attract a huge volume of queries, and thus dominate the failures. This is particularly the case for domains that are classified as malicious. The success rates also vary greatly across resolvers due to the differences in the domains that they serve and the infrastructure reliability.

1 Introduction

The Domain Name System (DNS) is organized as a distributed system that provides mappings between human-readable domain names (*e.g.* foo.com) and their associated DNS records [17–20]. These include A type records for IPv4 addresses, AAAA for IPv6 addresses, MX for SMTP mail exchanges, NS for name servers, PTR for pointers of reverse DNS lookups and CNAME for domain name aliases. Nearly all Internet-connected applications depend on DNS. As such, it is a critical dependency, whose failure has the potential to create global Internet outages. For example, in 2016, Dyn (a DNS operator) suffered a major Denial of Service attack against its infrastructure. This meant that DNS queries for popular domains such as Netflix and Visa began to fail, crippling access to these services (even though those services were still online).

Although there is a significant body of research into DNS behavior, we argue that *DNS failures* specifically require further investigation. Root DNS server behavior was examined in [5, 8], where negative DNS answers were analyzed including NXDOMAIN responses. Callahan *et al.* [4] also examined the DNS behavior from the perspectives of performance and response message. We differ in that our focus is on failures not caused by NXDOMAINs. In addition, we note that DNS has evolved significantly since these studies, *e.g.* the rise of new gTLDs and IDNs. Although there have been a number of studies of new gTLDs and IDNs [9, 13, 15], they mainly focus on domain registration behavior and cyber attacks, while we complement these studies with DNS query failure analysis. Other work [12, 22, 25] has leveraged NXDOMAIN responses to detect botnets or DGAs. Again, our work focuses on failures caused by DNS infrastructures instead of NXDOMAINs.

With the above in-mind, we present a large-scale analysis of DNS query failures in-the-wild. To achieve this, we gather a unique dataset containing 3B DNS queries (Section 2). We find that failed queries are, indeed, common place with 13.5% of all queries not successfully resolved. This motivates us to inspect which factors correlate most closely with failed queries (Section 3). We observe a highly skewed distribution, whereby a small number of domains are responsible for the majority of failures. AAAA queries (IPv6) are particularly unreliable, with only 1/3 of queries successfully resolved. This is perhaps understandable given the use of protocols such as Happy Eyeballs [24], although we also find that many domains lack AAAA support. We further inspect the relationship between failures and the DNS resolver used, to find a vast array of resolvers, with 13.5% of queries in our dataset being issued to public resolvers, *e.g.* OpenDNS. We observe diverse failure rates across the resolvers, confirming that they do have an impact on failures. We also note differences among the Top Level Domains (TLDs) with, for example, the new wave of generic-TLDs having higher failure rates than more traditional TLDs. Finally, we propose system implications based on our findings. To sum up, we make the following key findings:

- In spite of the promotion of IPv6 over recent years [7, 21, 26], the majority (86.2%) of DNS queries are still for A records, while only 10.4% are for AAAA records (comparable to the proportion in 2012 [8]). The failure rate for A lookups is 6.9%, yet, to our surprise, the failure rate for AAAA queries is as high as 64.2%, almost 3 times of that in 2012 [8]. We observe that approximately 60% of domains do not support AAAA queries.

- We explore a number of factors to explore the causes of failures. We observe a heavy-tailed distribution of failures across domains, indicating that a handful of domains contribute to most of the failures. 20% of local resolvers in our dataset have never successfully resolved AAAA queries, implying they are not ready for IPv6. The use of public resolvers may also impact query failures as they show diverse failure rates, in-part due to the distinct domain sets that each serves and the differences in infrastructure reliability.
- The success rates for new gTLD domains and IDNs are 10% lower than that of well established domains. This is largely because of the prevalence of malicious domains. Certain ASes are prevalent for hosting malicious new gTLD domains, and these new gTLD domains contribute to 73.7% of the all new gTLD queries. The malicious domains are, however, volatile and change frequently. In fact, *none* are resolvable today. The malicious new gTLD domains in these ASes are of various types and have distinct network footprints.

2 Dataset

Dataset Oveview. Our dataset consists of passive DNS logs that are generated by Deep Packet Inspection (DPI) appliances in 3 ISPs in China. Each DPI appliance parses the DNS response messages from recursive resolvers to end users, and generates a log for each response. A log includes the end user's anonymized IP address, BGP prefix,[1] the ASN (Autonomous System Number), the recursive resolver's IP address, the DNS query type, all the resource records, the timestamp (in seconds) and an indicator about whether the resolver and the end user's original IP address share a common /24 prefix. In cases of CNAME responses, we follow the redirection to the final record. The dataset contains 14 samples that were collected every other day in February 2018. Each sample consists of 10-minute logs generated by all the DPI appliances of the 3 ISPs. In total, we obtain 3,085,998,589 logs. It is noteworthy that while there were IPv6 addresses in the response IP list of AAAA queries, no IPv6 addresses were seen in end users' IP addresses and recursive DNS resolvers.

Identification of Failed Queries. We next extract the set of failed queries for the four most popular types of records (A, AAAA, PTR, MX), because they constitute 99.5% of all queries. For each response, we extract the requested domain (the QNAME) from the Question portion, and check if the response contains a valid answer (*e.g.* for an A query, at least one RR in the response is an A record of the requested domain). In this paper, we are interested in failures caused by DNS infrastructures instead of NXDOMAINs (*e.g.* typos). However, we do not have the response code (*e.g.* 'NOERROR', 'NXDOMAIN' or other status) in our dataset. Therefore, we turn to a heuristic method to filter out logs that are attributed to NXDOMAINs. Specifically, for each domain requested (*i.e.,*QNAME in the log), we check if it has succeeded at least once in our logs. We then remove the logs containing domains that have never succeeded in the whole dataset, as they are likely NXDOMAINs. The subsequent analyses are based on the remaining dataset, which contains 2,811,010,890 logs issued by 37,070,965 unique IP addresses to 246,991 resolvers.

Caveats. It is important to highlight potential limitations in our data. The above heuristic method may leave some domains that were resolvable at a time but then became NXDOMAINs later. Moreover, our dataset does not allow us to inspect failed queries that did not trigger a response (*e.g.* due to packet loss). Naturally, the fact that a DNS response is returned does not necessarily mean that the web server is live and responsive. Therefore, we only inspect if a valid DNS response is returned (not if the IP address is correct). There are many possibilities that lead to incorrect mapping of domains to addresses, such as DNS manipulation [16] and on-path DNS interception [14]. Another related concern pertains to censored domains. Thus, before continuing, we test if a censored domain will return a valid IPv4/IPv6 address for an A/AAAA query. Our tests confirm that, indeed, valid addresses are returned, even when querying censored websites.[2] Another potential limitation is that our data is local to China. Nevertheless, we believe the scale of the Chinese Internet means that these findings can still have a major impact. As DNS is a globally distributed system where China and other countries are all involved, there is not much specific to China from the perspective of the DNS infrastructure. We also note that (to the best of our knowledge) this is by far the largest DNS failure dataset ever studied.

Ethical Issues. The ISPs collect the DNS logs for the purpose of improving their service quality and security. The end users' IP addresses were anonymized and we are unable nor allowed to link queries to users. Users are notified when subscribing that the ISPs may collect this information, and may share it with academics for research. Our study has not triggered the collection of any new data. All data was processed in a secure silo by the first author.

3 Exploring DNS Query Failures

3.1 A Primer on DNS Failures

We begin by simply computing the number and types of failed queries in our dataset. Table 1 shows the percentage of query

[1] IP addresses and BGP prefixes are anonymized with `Crypto-PAn` [2]

[2] Since we focus on DNS query failures, we did not check whether the returned IP address does host the queried domain or not [1].

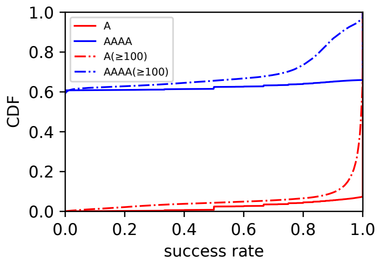

Figure 1: CDFs of success rates of domains for A and AAAA queries.

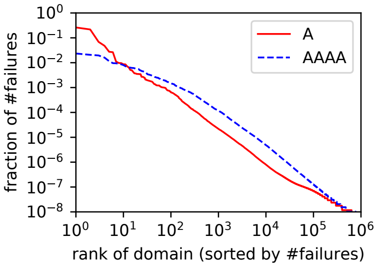

Figure 2: #failures - rank of domains(log-log).

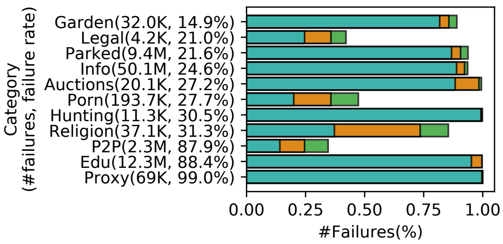

Figure 3: The top 11 domain categories sorted by failure rates with # of failures $>$ 1K.

types, alongside the *overall* success rate, which is 1 minus the ratio of failed queries to all queries of each query type. We present the four most popular query types. The A type queries account for the majority (86.2%), and AAAA queries have a smaller query volume (10.4%).[3] We observe a variety of success rates across the query types. Overall, the A queries are successfully resolved most frequently, while other query types manifest lower success rates. This confirms that a sizeable fraction of queries are *not* successfully resolved; we spend the rest of the section exploring factors influencing this trend.

Table 1: Four popular types of DNS queries: percentages of the number of queries and success rates.

Query Type	A	AAAA	PTR	MX	Others
#queries	86.2%	10.4%	2.8%	0.1%	0.5%
Success Rate	93.1%	35.8%	40.4%	82.9%	-

3.2 Failures Across Domains

We first compute the distribution of failures across domains. Due to their prominence, we focus on A and AAAA queries. Figure 1 presents the CDFs of the success rates across domains encountered within our dataset.

A Queries. A queries exhibit high success rates: overall, 93.7% of domains have a success rate exceeding 95% suggesting high reliability. There are ouliers though; for instance, the bottom 0.1% of domains have success rates below 5%. To eliminate the impact of low-frequency domains on the results, we filter out domains that issue fewer than 100 requests and plot the CDF of success rate of the remaining domains (the red dash-dot line), where 84.9% of remaining domains have a success rate exceeding 95%. Nevertheless, as many as 7% of domains experience a success rate lower than 50%. Given that we have removed the failures caused by NXDOMAINs, the result suggests that problems with the DNS infrastructure do impact users when visiting these domains.

AAAA Queries. For AAAA queries, only 34.3% of domains have a success rate exceeding 95%. When limiting to domains whose query frequency exceeds 100, only 7.8% of domains have a success rate exceeding 95%, while about 60% of domains have never been successfully resolved. Again, given that we only include domains that have been successfully resolved (considering all query types), this suggests that there are infrastructural limitations in how DNS supports IPv6.

Domain Failure Rates The above suggests that the majority of failures are the responsibility of a small set of domains, especially for A queries. To explore this further, Figure 2 presents the number of failures per domain on a log-log plot. We sort the X-axis by the rank of the domain (based on the number of failures). We see that failures are concentrated on a small number of domains. To gain a further understanding of the types of domains that have high failure rates, we utilize the Webroot Brightcloud API[4] to classify the top 50K domains (measured by failure rate). Figure 3 presents the results. The Y-axis shows the top 11 categories sorted by failure rate, where the number of failed queries ($>$ 1K) and the failure rate is shown in the parentheses. For each category, we plot the ratio of the number of failed queries of the top 3 SLDs to the total number of failures. A number of classifications which can be expected to fail frequently are present, *e.g.* proxy, porn and parked domains. This suggests that such domain types are paramount in increasing failure rates. However, it is unexpected to see the Education category is ranked second. Closer inspection reveals that *clock.cuhk.edu.hk*, which is the third most failed domain, contributes the most failures. Another interesting observation is the concentration of failures for each category on a few domains. For 8 out of the 11 categories, over 80% of the failures are attributed to the top 3 SLDs (top 1 SLD in most cases).

3.3 Failures Across Resolvers

Another explanation for failed queries is that the resolvers may not correctly handle queries.

Testing Resolvers. To explore this, we calculate the success rate of queries issued to each DNS resolver (identified by the resolver's IP address). Figure 4 presents the CDF of the success rate for the domains per resolver.[5] The majority of

[3] Note that we follow CNAME redirections, rather than reporting them here as responses.

[4] https://www.brightcloud.com/web-service

[5] We eliminate the resolvers serving fewer than 100 queries in our dataset to avoid bias.

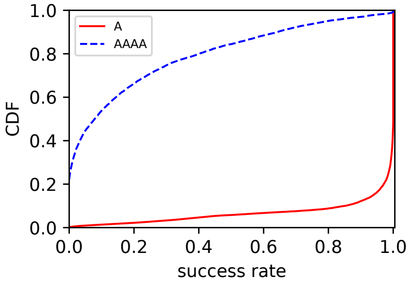

Figure 4: CDF of the success rate for individual resolvers.

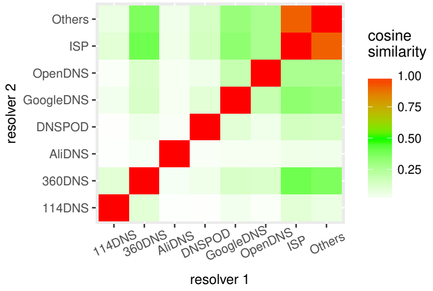

Figure 5: Cosine similarity between each pair of DNS resolver types.

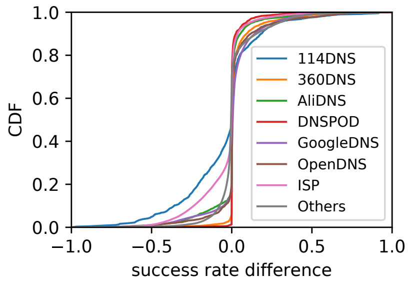

Figure 6: Different success rates of same domains handled by different resolvers.

Table 2: The number of A and AAAA queries and their success rates (shown in the parentheses) handled by each resolver.

	114DNS	360DNS	AlibabaDNS	DNSPOD	GoogleDNS	OpenDNS	ISP	Others
A	296.4K(98.5%)	831.0K(95.9%)	667.8K(94.7%)	352.5K(99.6%)	333.4M(90.7%)	467.6K(86.3%)	48.7M(95.3%)	2.1B(93.5%)
AAAA	75.4K(14.5%)	50.3K(61.8%)	112.9K(52.4%)	15.5K(54.3%)	40.6M(43.4%)	31.0K(49.2%)	9.6M(22.8%)	252.6M(35.0%)

resolvers have very high success rates when serving A queries: about half experience almost no failures. By contrast, 60% of resolvers serving AAAA queries can successfully resolve just 20% of the queries. Surprisingly, about 20% of the resolvers never succeed in resolving AAAA queries. These resolvers may not be IPv6 ready during our observation period.

Testing Public Resolvers. Closer inspection reveals that a notable set of queries are sent to *public resolvers* [3,6,10]. Hence, we also inspect the reliability of these public infrastructures, which include 114 (Chinese) DNS resolvers provided by multiple telecom operators, DNS Pai which belongs to Qihoo 360, AliDNS which belongs to Alibaba, and DNSPOD which belongs to Tencent. We also take into account GoogleDNS and OpenDNS which are widely used throughout the world. We identify these public DNS resolvers by the IP addresses offered on their official websites. Table 2 shows the number of A and AAAA queries handled by each public DNS resolver mentioned above along with their success rates. GoogleDNS dominates the most used public DNS service (even though Google is less well known in China). Others do not show much difference in terms of query volume. We observe various success rates across public DNS resolvers though. For example, DNSPOD succeeds in almost all its A queries, while OpenDNS achieves just 86.3%. There is also notably lower success rate across all resolvers for AAAA queries.

The above confirms that resolvers do seem to have an impact on success rates. A potential reason for this is that the resolvers may simply receive different queries. To explore this, we compute a vector for each resolver, where each element represents a domain, which appears in A or AAAA queries using the resolver, and the query volume of that domain handled by the resolver. Then we calculate the similarity of each pair of DNS resolver using the cosine similarity between their vectors. Figure 5 illustrates the result. The resolvers actually demonstrate a surprisingly low similarity with each other, signalling rather different request patterns. Among these resolvers, 114DNS and AliDNS are the least like the others. Indeed, 114DNS handles many requests for Akamai domains which appear less often in other resolvers, while AliDNS handles many requests of taobao.com and alipay.com which belongs to Alibaba services. This could be the reason for the variance of success rates observed from different resolvers.

Another possible explanation is the differences between resolvers' infrastructures. To explore this, we compare the success rates of the same domains handled by different resolvers. Specifically, for each resolver, we first find the domain intersection of it and each other resolver. Then for each domain in each intersection, we calculate the difference in their success rates on the two resolvers. Finally, for each type of resolver, we plot the CDF of the differences between this type to other types in Figure 6. Note, a difference below 0 indicates a lower success rate of this type of resolver, and a positive value indicates a higher success rate. We can see significant differences for some types of resolvers: domains resolved by 114DNS and ISP are more likely to fail, while DNSPOD and 360DNS have higher success rates. This observation partially explains the results in Table 2.

3.4 Failures Across TLDs

We next inspect if certain TLDs have lower query success rates. Specifically, we explore two camps of TLDs: the new generic Top Level Domains (gTLD),[6] and those that have Internationalized Domain Name (IDNs). Our dataset contains 611,769 new gTLDs and 79,705 IDNs. Table 3 summarizes our results. We see rather different rates of success across the domain and query types. The lower success rate for new gTLDs may be because such gTLDs attract certain types of domain registrant. For example, the .lol domain is well known to attract large volumes of malicious activites [11]. With this in-mind, we find a success rate of just 20.3% for

[6] Based on the list from nTLDStats https://ntldstats.com

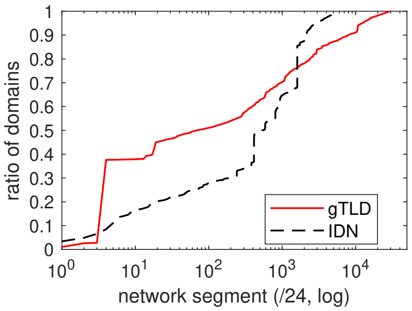

Figure 7: Distri. of new gTLD domains (gTLD in the legend for short) and IDNs seperated by /24 network segments.

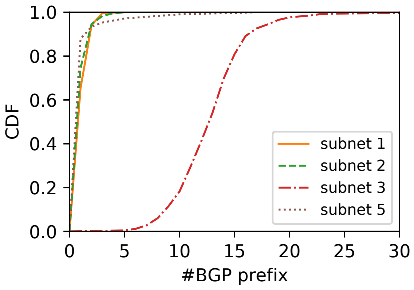

Figure 8: CDF of # BGP prefixes requesting individual malicious SLDs.

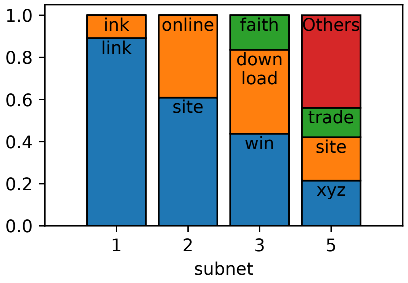

Figure 9: TLDs and their fractions of # malicious SLDs.

.lol, compared to 83.0% of .com. Another reason for failed queries is the presence of malicious domains which are unreliable. To inspect this, we extract all A record queries that were successfully resolved and investigate the network segments hosting them. Overall, we obtain 113,539 (11,729) IP addresses hosting new gTLDs (IDNs) mapping to 29,047 (5,635) /24 network segments, respectively.

Table 3: The number of queries and success rates (shown in the parentheses) of new gTLD domains and IDNs.

	new gTLD	IDN
total	4.0M (79.3%)	0.26M (66.6%)
A	3.4M (88.6%)	0.17M (86.7%)
AAAA	0.6M (25.9%)	0.09M (26.4%)

Figure 7 presents the distribution of the number of new gTLD domains and IDNs per network segment (sorted by #IPs hosting new gTLD domains and IDNs, respectively). Several surges in both lines further arouse our attention: they indicate the existence of some /24 network segments that serve a large number of new gTLD domains or IDNs. This is naturally driven by the presence of large web hosting providers.

Thus, we extract the top 5 surges for both new gTLD domains and IDNs to explore their details. Due to space limitation, we only present the results of new gTLD domains in Table 4, where the last column presents the number of domains that are resolvable on 26 Sept. 2019. Across all of these top ASes we witness an extremely low rate of successful resolutions. In the most extreme case, we observe 201K queries for 195K domains being mapped to Enzu, none of which are resolvable today. In addition, the number of queries is close to the number of FQDNs, suggesting that these domains are short-lived and change frequently. The above trends lead us to hypothesize that some of these domains may be associated with malicious activities. To explore this, we leverage two blacklists from VirusTotal and Qihoo 360 to check the domains. We label a domain as malicious if any of these two blacklists classify it as so. Due to the large volume of domains, we only check SLDs (as opposed to FQDNs). The results are listed in parentheses in Table 4. None of the IDNs are classified as malicious by the two blacklists, however, a *significant* fraction of the new gTLD domains fall into this category. For example, 80% of the SLDs hosted in 23.245.136.0/24 prefix (first row) are classified as malicious. This is common across all of the top new gTLD domains. In total, 73.7% of the queries are for the malicious domains.

Figure 8 presents the distribution of the number of end users' BGP prefixes requesting each malicious SLD in Subnet 1, 2, 3, 5 (shown in Table 4). Except the SLDs hosted in subnet 3, other malicious SLDs affect only 1 or 2 networks. In contrast, malicious SLDs hosted in subnet 3 have a footprint in dozens of networks, implying a larger impact. One possible explanation is that the subnets host different sites. Hence, Figure 9 presents the make-up of the 5 subnets, confirming that they do map to different TLDs.

4 Implications on Systems Design

In this section, we discuss about the implications of our findings on system design, *i.e.,*what systems we could build based on our observations.

Active Measurement System. Our results show that although IPv6 has been promoted in recent years, AAAA queries still fail frequently, and there exist resolvers that do not support AAAA queries. In order to understand which resolvers support AAAA queries, we can build a system to actively measure the IPv6 support of the resolvers. For instance, similar to [23], we can build a single-node measurement system for monitoring IPv6 support of DNS resolvers. The system can distinguish between resolvers that support and do not support AAAA queries by sending DNS queries of popular domains that support AAAA queries. We can also test whether a domain supports AAAA queries by sending requests of this domain to resolvers that are classified as supporting AAAA queries. Considering the differences between resolvers, we could measure the success rates of domains by sending queries to different resolvers, and use the result to help choose the better resolvers.

In addition, we could compare different resolvers from the perspective of localization, *i.e.,*whether the resolver directs

Table 4: new gTLD domains hosted by the top 5 subnets. The number of domains labeled as malicious are within the parentheses.

No.	subnet	AS num.	AS name	#IPs	#queries	#FQDN	#SLD	#resolvable
1	23.245.136.0/24	18978	Enzu Inc	252	201.9K (157.1K)	195.9K (152.2K)	483 (386)	0(0)
2	192.238.167.0/24	395954	Leaseweb	236	17.4K (14.8K)	16.3K (13.9K)	287 (243)	0 (0)
3	172.246.207.0/24	18978	Enzu Inc	236	15.7K (15.4K)	13.2K (13.0K)	443(434)	1 (1)
4	104.217.93.0/24	40676	Psychz Net	253	9.0K (1)	8.8K (1)	923 (1)	9(0)
5	47.89.58.0/24	45102	Alibaba	4	10.9K (469)	8.8K (114)	7.7K (107)	748 (7)

Table 5: The localization performance of resolvers: the proportion of queries directed to servers in the same AS as the end user when possible.

114DNS	360DNS	AlibabaDNS	DNSPOD	GoogleDNS	OpenDNS	ISP	Others
91.2%	98.0%	95.9%	94.3%	64.6%	43.8%	71.7%	69.9%

users to remote servers. This additional function is motivated by our observation presented in Table 5: We calculate for each resolver the fraction of queries that redirect clients to servers in the same AS (when possible). For each domain i, we count all its response IP addresses in the entire dataset and these IP addresses form a set S_i. Then for each log whose QNAME equals i, if at least one IP address in S_i is in the same AS as the end user, we label this query as "possible to be served locally"; if at least one IP address in the response IP addresses of this log is in the same AS as the end user, we label this query as "served locally". These two labels are independent and a log can have both labels, one of the labels, or no label. We aggregate the logs according to the resolvers, and calculate the ratio of *the number of logs labeled as served locally* to *the number of logs labeled as possible to be served locally* for each resolver. We observe that the obtained ratio differs significantly across the resolvers, which indicates that users can choose appropriate resolvers for better network performance. Therefore, it is useful to develop a system for end users to measure the localization performance of different resolvers.

Such an active measurement system is useful for content publishers, ISPs and end users. Many CDNs are being upgraded for better IPv6 support, however, if AAAA queries frequently fail, then the content publisher should be careful to use such CDN IPv6 service. Therefore, it is useful for publishers to locate their content if they can understand in advance which resolvers do not support AAAA queries. In addition, ISPs could also benefit when considering IPv6 network expansion, because understanding which domains support AAAA queries is useful for estimating the IPv6 traffic. For users, the measurement of different resolvers can help them to choose more suitable resolvers considering both IPv6 support and localization performance.

Malicious New gTLD Domain Detection System. We have found that malicious SLDs (of new gTLD domains) hosted by particular ASes contribute to higher failure rates. Manual inspection further reveals that the length of the SLDs tend to be short. Table 6 presents the fraction of malicious SLDs of different length. In more traditional TLDs, malicious domains are usually long because registering a short domain name would cost too much for an attacker. However, registering short new gTLD domains is much easier. Therefore, extracting features from domain names may not work well for detecting malicious new gTLD domains. We could use features like DNS query frequency, the number of FQDNs of an SLD, the resolved IP addresses and the corresponding ASes to build a system for detecting malicious SLDs of new gTLD domains.

Table 6: Fraction of malicious SLDs of different lengths.

Length	3	4	5	≥6
% of SLDs	0.1%	93.0%	6.1%	0.8%

5 Conclusion

The paper has presented a deep dive into DNS query failures using over 3B queries. We have identified high failure rates: 6.9% of A and 64.2% of AAAA queries. IPv6 is far from ready as over half of the domains and 20% of local resolvers do not support AAAA queries. Upgrading these resolvers and popular domains for IPv6 is the first step towards the wider usage of IPv6. Internet users, on the other hand, should be aware of the impact of using public resolvers, from both the perspectives of query failures and mapping inaccuracy [6]. We also found that the volatility of malicious domains (particularly new gTLD domains and IDNs) contributes to higher failure rates because they change frequently and accesses to them results in failures. The corresponding SLDs of malicious new gTLD domains and IDNs, however, are limited, and they are likely hosted by particular ASes. We finally proposed two potential systems that could build on our findings.

Guang Yang†, Wei Xu, Fan Long‡†, Andrew Chi-Chih Yao
Tsinghua University †*Conflux Foundation* ‡*University of Toronto*

Abstract

This paper presents Conflux, a scalable and decentralized blockchain system with high throughput and fast confirmation. Conflux operates with a novel consensus protocol which optimistically processes concurrent blocks without discarding any as forks and adaptively assigns weights to blocks based on their topologies in the Conflux ledger structure (called Tree-Graph). The adaptive weight mechanism enables Conflux to detect and thwart liveness attack by automatically switching between an optimistic strategy for fast confirmation in normal scenarios and a conservative strategy to ensure consensus progress during liveness attacks.

We evaluated Conflux on Amazon EC2 clusters with up to 12k full nodes. The consensus protocol of Conflux achieves a block throughput of 9.6Mbps with 20Mbps network bandwidth limit per node. On a combined workload of payment transactions and Ethereum history transactions, the end-to-end system of Conflux achieves the throughput of up to 3480 transactions per second while confirming transactions under one minute.

1 Introduction

Following the success of cryptocurrencies [2, 23], blockchain has evolved into a technology powering secure, decentralized, and consistent transaction ledgers at Internet-scale. Newer blockchain platforms such as Ethereum [2, 35] support customized transaction rules as smart contracts, which greatly extend the capability of blockchain ledgers beyond value transfers.

Blockchain platforms like Bitcoin [23] use *Nakamoto consensus*. It organizes transactions into an ordered list of blocks, each of which contains multiple transactions and a link to its predecessor. Participants (miners) solves *proof-of-work* (PoW) puzzles to compete for the right of generating the next block. To prevent an attacker from reverting previous transactions, honest participants agree on the longest chain of blocks as the correct history. Each new block is appended at the end of the longest chain to make the chain longer and therefore harder to revert.

However, the performance remains one of the most critical issues of blockchains. Nakamoto consensus is bottlenecked by its slow block generation rate. For example, Bitcoin generates one 1MB block every 10 minutes and can therefore only process 7 transactions per second. Users have to wait for typically one hour (i.e., six blocks) to obtain high confidence on the finality of a transaction.

An ideal blockchain has the following four desirable properties, *security*, *decentralization*, *high throughput*, and *fast confirmation*. The key challenge of building such a blockchain system is the threat of security attacks. To obtain high performance, the system typically has to operate with a fast block generation rate. Because block propagation takes time, the system may therefore generate many concurrent blocks (i.e., forks). In Nakamoto consensus, concurrent blocks waste PoW computation because they do not contribute to the finality of the longest chain. They make the system vulnerable to *double spending attacks* that attempt to revert history transactions.

Moreover, a high block generation rate can make several recently proposed protocols vulnerable to *liveness attacks* [17, 31, 32]. An attacker can simultaneously generate blocks at two competing branches and strategically withhold/release these blocks to maintain the balance of the two branches. The attacker with little PoW computation power can stall the consensus progress [36].

Conflux: We present Conflux, the first blockchain system that achieves all of the four desirable properties. Conflux can process thousands of transactions per second while confirming each transaction with within one minute on average. With its novel consensus protocol, the consensus layer of Conflux is no longer the performance bottleneck, i.e., the throughput saturates its underlying gossip network bandwidth and the confirmation speed is within the same order of magnitude as the gossip network propa-

*The first two authors contributed equally.

gation delay. Conflux is provably secure (see our formal proof in [19]). It is also as decentralized and permissionless as Bitcoin — participants can join and leave the consensus process at any time and there is no privileged committee or super-node dictating the process. Conflux also implements a modified version of Ethereum Virtual Machine (EVM) [35] and most smart contracts in Ethereum can be directly ported to Conflux.

To address the security attack challenge, Conflux organizes blocks into a novel Tree-Graph structure, which is a tree embedded inside a direct acyclic graph (DAG). In Tree-Graph, concurrent blocks are not considered harmful and they contribute to the Conflux ledger as well. Their PoW solutions will improve the finality of all of their ancestors and their transactions will be optimistically included into the ledger total order. This secures Conflux against double spending attacks and improves the Conflux throughput. To address liveness attacks, the consensus protocol of Conflux inherently encodes two different block generation strategies: an optimistic strategy that allows fast confirmation and a conservative strategy that ensures the consensus progress. Conflux uses its novel *adaptive weight* mechanism to combine these two strategies into a unified consensus protocol.

Adaptive Weight: Conflux assigns a weight to each block, which indicates the amount of finality that the block contributes to its ancestors. For each new block, Conflux analyzes its topology in the Tree-Graph, decides whether a liveness attack is potentially going on (e.g., whether there are old ancestor blocks that are not finalized yet), and then adaptively assigns weights to blocks in the Tree-Graph to switch between the two strategies. In normal scenarios, the mechanism assigns weights in one way that enables the optimistic strategy to confirm transactions fast. When a liveness attack happens, the mechanism assigns weights in another way that enables the conservative strategy to thwart the attack.

Deferred Execution: The execution order of recently packaged transactions may oscillate temporarily in a system with fast block generation. A naive implementation of the transaction execution engine would have to roll back executions many times and waste computation resources. Conflux addresses this challenge with its *deferred execution* mechanism. Instead of executing transactions in every received block immediately, Conflux waits for several blocks so that the order is relatively stabilized. Our observation is that users need to wait for the stabilization of the total order anyway to confirm a transaction with high confidence. Therefore the deferred execution does not harm the user experience at all.

Link-Cut Tree: An efficient consensus implementation is important to the performance of Conflux. To maintain the Conflux Tree-Graph, a naive implementation has the time cost of $O(n)$ for processing a new block on average, where n is the number of existing blocks. To address this challenge, Conflux uses *link-cut tree* to maintain weight values in Tree-Graph efficiently. It reduces the processing time from $O(n)$ to $O(\log n)$ per block.

Experimental Results: We implemented Conflux and evaluated it with Amazon EC2 machines under the same experimental setup as previous work like Algorand and OHIE [11, 36]. Our experimental results show that with the bandwidth limit of 20Mbps and the simulated real world network latency setting, Conflux achieves a transaction throughput of 9.6Mbps and a confirmation latency of 47.75-51.54 seconds when running 3000-12000 nodes. For a combined workload of payment transactions and Ethereum history transactions, Conflux achieves up to 3480 transactions per second and confirms transactions within one minute with high confidence. Comparing to Algorand [11], Conflux has more than 4x higher throughput and comparable confirmation speed. Comparing to OHIE [36], Conflux has the same throughput and one order of magnitude faster confirmation speed.

Contribution: This paper makes the following contributions: 1) we design and implement Conflux, a decentralized and smart-contract-enabled blockchain system with high throughput and fast confirmation; 2) we present a novel consensus protocol with the adaptive weight mechanism; 3) we present a set of novel and critical optimizations, including deferred execution and link-cut tree.

2 Related Work

Nakamoto Consensus in Bitcoin: Transactions are packed into blocks in Bitcoin. Each block has one predecessor block and all blocks form a tree structure with the genesis block as the root. Participants agree on the longest chain as the valid transaction history. Nakamoto consensus has to use a relatively slow block generation rate to avoid the generation of concurrent blocks, i.e., forks. This is essential for the safety against double spending attacks as shown in Figure 1a. More forks would mean relatively less blocks in the longest chain. In Figure 1a, due to forks, only 20% of blocks are on the longest chain so that an attacker with more than 20% of the network computation power can revert the longest chain to launch double spending attacks.

GHOST: GHOST is a previous proposal to replace the longest chain rule to improve the consensus safety under a fast block generation rate [32]. It is partially implemented in Ethereum [2]. Figure 1b presents an exam-

(a) An attacker with more than 20% of the network computation power can revert the longest chain.

(b) GHOST algorithm iteratively advances to the largest subtree to select the agreed chain.

(c) The attacker can strategically withhold or release his/her blocks to maintain the balance of two subtrees.

(d) If *h* is large enough, two groups will converge eventually.

Figure 1: Double Spending Attack, GHOST, Liveness Attack, and Structured GHOST

ple to illustrate the GHOST algorithm. GHOST starts from the genesis block and iteratively advances to the child block with the largest subtree to select the agreed chain [32]. In Figure 1b, the new block appends to the end of the agreed chain, which is in the subtree of X (containing 6 blocks) not in the subtree Y (containing 5 blocks). The difference between GHOST and the longest chain rule is that all blocks generated by honest participants will contribute to the finality of the agreed chain. Suppose G is an old enough block that is on the agreed chains of all honest participants. Future blocks generated by honest participants will all contribute the finality of G regardless of whether they are concurrent or not, because all of these blocks will be under the subtree of G. Unlike the longest chain rule, an attacker would need more than half of computation power to revert *G* from the agreed chain even with the presence of concurrent blocks [32].

Liveness Attack on GHOST: Unfortunately, GHOST is vulnerable to liveness attacks if the block generation rate is very fast. Figure 1c presents one example of such attacks. The example has the following settings: 1) the total block generation rate of honest participants is λ; 2) honest participants are devided into two groups with equal computation power (group X and group Y in Figure 1c); 3) blocks will transmit instantly inside each group, but the propagation between these two groups has a delay of d. In Figure 1c, each of the two groups extends its own subtree following the GHOST rule. Note that recent generated blocks within the time period of d are in-transit blocks (gray blocks in Figure 1c), which are only visible by the group who generates them. Therefore each group will believe its own subtree is larger until one group generates sufficiently more blocks than the other to overcome the margin caused by the in-transit blocks.

In normal scenarios, one of the two groups will get lucky to enable the blockchain to converge. However, an attacker can mine under two subtrees simultaneously to delay the convergence. The attacker can strategically withhold or release the mined blocks to maintain the balance of the two subtrees as shown in Figure 1c.

Theoretically, if honest participants evenly split due to network delay and the margin caused by in-transit blocks is significant, i.e., $\lambda d > 1$, a small portion of computation power is enough to launch attacks. Previous work [36] includes a simulation shows only 10% will do. In practice, even if honest participants do not have an even partition, the more computation power the attacker controls, the more likely the attacker will succeed. Consider the presence of mining pools, it is not rare to see one miner controlling more than 20% of computation power. Such a miner will be able to launch successful balance attacks without even partition.

DAG-based Structures: To improve the throughput and the confirmation speed, researchers have explored several alternative structures to organize blocks. Inclusive blockchain [17] extends the Nakamoto consensus and GHOST to DAG and specifies a framework to include off-chain transactions. In PHANTOM [31], participating nodes first find an approximate k-cluster solution for its local block DAG to prune potentially malicious blocks. They then obtain a total order via a topological sort of the remaining blocks. Unfortunately, when the block generation rate is high, inclusive blockchain and PHANTOM are all vulnerable to liveness attacks similar to Figure 1c. Therefore, unlike Conflux they cannot achieve both the security and the high performance.

Some protocols attempt to obtain partial orders instead of total orders for payment transactions. SPECTRE [30] produces a non-transitive partial order for all pairs of blocks in the DAG. Avalanche [4] connects raw transactions into a DAG and uses an iterative random sampling algorithm to determine the acceptance of each transaction. Unlike Conflux, it is very difficult to support smart contracts on these protocols without total orders.

Hierarchical and Parallel Chains: Besides DAG, alternative ways to organize blocks include hierarchical chains and parallel chains. For example, in BitcoinNG [9], a macro block is generated every 10 minutes. The miner of such a block becomes the leader to generate micro blocks that contain actual transactions until the next macro block. Similarly, FruitChain [27] packs transactions first into fruits (i.e., micro blocks) and then packs fruits into blocks. OHIE [36] runs multiple parallel chains with the standard Nakamoto consensus and then deterministically sorts blocks to obtain a total order.

The shared property of these protocols is that only a small portion of blocks (e.g., macro blocks in BitcoinNG and FruitChain) influence the total order of the transaction ledger. It mitigates the liveness attack issue in Figure 1c because it reduces the chance of in-transit blocks influencing the total order. But these protocols have slow confirmation speed because they need to wait for more blocks to confirm transactions than other protocols. For example, BitcionNG has the same slow confirmation speed as Bitcoin [9]; OHIE confirms transactions in about 10 minutes on average only under an extremely fast block generation rate of 64 blocks per second [36]. In contrast, Conflux has a much faster confirmation speed in normal circumstances with no ongoing liveness attack.

Prism operates with one proposer chain and many parallel vote chains, each of which casts vote to decide the total order of blocks in the proposer chain [6]. The theoretical simulation in [6] shows that Prism may achieve high throughput and fast confirmation speed similar to our Conflux results in Section 6. But the simulation assumes a block propagation delay of one second, which is too ideal (e.g., the measured block delay is 10-15 seconds in our experiments). It is therefore unclear how fast a blockchain system that implements Prism can confirm transactions when running under practical P2P networks.

Byzantine Fault Tolerance: ByzCoin [14] and Thunderella [28] propose to achieve consensus by combining the Nakamoto consensus with Byzantine fault tolerance (BFT) protocols. Algorand [11], HoneyBadger [22], and Stellar [21] replace the Nakamoto consensus entirely with BFT protocols. In practice, all these proposals run BFT protocols within a confined group of nodes, since BFT protocols only scale up to dozens of nodes. The confined group is often chosen based on their recent PoW computation power [14, 28], their stakes of the system [11], or external hierarchy of trusts [21, 22]. However, these approaches may create undesirable hierarchies among participants and compromise the decentralization of blockchain systems. In contrast, Conflux allows any participant to join and leave the network without permission. In addition, instead of *eagerly* deciding the total order of blocks as in BFT-based approaches, Conflux allows multiple blocks to be generated in parallel and finalizes their orders later, which leads to its higher throughput.

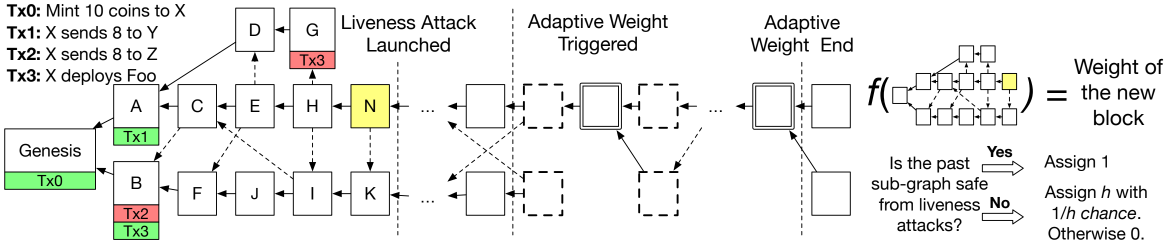
Sharding: Elastico [20], OmniLedger [15], RapidChain [37], and Monoxide [33] split the blockchain state into shards. Instead of having every node to verify all transactions, the systems select a small committee to maintain each shard to improve scalability. Unlike Conflux, such systems sacrifice security for scalability, i.e., the committee configuration can only be changed slowly (like days) due to reconfiguration overhead and therefore a small shard may be vulnerable to powerful attackers who can adaptively corrupt participants. This security issue is so important that Vault [16] chooses to only use sharding to mitigate storage cost with the trade-off of increased network bandwidth cost. Also despite the high combined throughput of all shards, the throughput of inter-shard transactions is still limited.

3 Overview

We will first present an example to illustrate a straw-man algorithm called *structured GHOST* that can defend against liveness attacks but has a sub-optimal confirmation speed. We will then present an overview of the Conflux consensus protocol, which uses the straw-man algorithm as a building block.

Structured GHOST: In our structured GHOST algorithm, only $1/h$ of blocks are weighted blocks that would count in the chain selection process. These blocks are selected randomly based on their PoW solution qualities (e.g., the number of leading zeros of the PoW hash). During the chain selection, the structured GHOST iteratively advances to the subtree with the largest number of weighted blocks, instead of considering all blocks.

Figure 1d shows an example to illustrate how structured GHOST can defend against the liveness attack we described before. With a sufficiently large h value, the expected number of in-transit weighted blocks ($\lambda d/h$) will be very small. As shown in Figure 1d, the generation of a weighted block of one group will very likely to make the two subtrees to converge, unless another group generates a concurrent weighted block. When $\lambda d/h \ll 1$, the chance of such concurrent generation is very unlikely. Without the margin caused by the in-transit blocks, the



(a) Tree-Graph Example. Solid blocks have weight one. Double-line blocks have weight 600. Dotted-line blocks have weight zero.

(b) Adaptive Weight

Figure 2: Examples of Conflux Consensus on Tree-Graph

liveness attack is not possible without significant computation power. Although structured GHOST is secure against liveness attacks, it sacrifices the confirmation speed — a user has to wait for the accumulation of enough weighted blocks to confirm a transaction.

Consensus with Two Strategies: The Conflux consensus protocol operates with two strategies, an optimistic strategy similar to the GHOST algorithm and a conservative strategy similar to the above straw-man algorihtm. Our adaptive weight mechanism enables Conflux to encode these two strategies in a unified framework. In normal scenarios, Conflux would use the optimistic strategy to achieve high performance. If a liveness attack happens, the adaptive weight mechanism enables honest participants of Conflux to cooperatively switch to the conservative strategy to thwart the attack automatically.

Tree-Graph: The Conflux consensus protocol operates on the local Tree-Graph state of each individual node. Figure 2a presents a running example of the local Tree-Graph state of a node in Conflux. We will use this example in the remaining of this section to illustrate the high-level ideas of the Conflux consensus protocol. Each vertex in the Tree-Graph in Figure 2a corresponds to a block. In Figure 2a, Genesis is the predefined genesis block. Only Genesis, A, B, and G are associated with transactions. There are two kinds of edges in the Tree-Graph, parent edges and reference edges:

Parent and Reference Edges: Each block except Genesis has exactly one outgoing parent edge (solid line arrows in Figure 2a). For example, there is a parent edge from C to A. Each block can have multiple outgoing reference edges (dashed line arrows in Figure 2a). A reference edge corresponds to generated-before relationships between blocks. For example, there is an edge from E to D. It indicates that D is generated before E.

Pivot Chain: Note that all parent edges in the Tree-Graph together form a *parental tree* in which the genesis block is the root. In the tree, Conflux selects a chain from the genesis block to one of the leaf blocks as the *pivot chain*. Each block in the Tree-Graph may have a different weight determined by our novel adaptive weight mechanism. Conflux iteratively advances to the subtree with the heaviest total block weight to select the pivot chain. In Figure 2a before the liveness attack, Conflux selects Genesis, A, C, E, and H as the pivot chain to append the new block N. Note that Conflux does not selects the chain of Genesis, B, F, J, I, and K, because the subtree of A has heavier weights than the subtree of B.

Generating New Block: Whenever a node generates a new block, it first computes the pivot chain in its local Tree-Graph state and sets the last block in the chain as the parent of the new block. The node then finds all tip blocks in the Tree-Graph that have no incoming edge and creates reference edges from the new block to each of those tip blocks. For example, in Figure 2a, when generating N, the node chooses H as the parent of N and creates a reference edge from N to K.

Adaptive Weight: Figure 2b illustrates the basic idea of the adaptive weight mechanism. The goal is to assign a different weight to each generated block so that Conflux can adaptively switch between the optimistic strategy with a fast confirmation and the conservative strategy that ensures the consensus progress. Conflux determines the weight of a new block based on its past sub-graph, i.e., all blocks that are reachable via a traversal from the new block. As shown in Figure 2b, if the past sub-graph is safe — every old enough ancestor of the new block in the past sub-graph is secured on the pivot chain with high probability, the weight of the new block will be one. If not, the new block will be assigned an adaptive weight — it gets a weight of h with the chance of $1/h$ (depending on the PoW quality) or zero otherwise. Note that we set $h = 600$ in Conflux. See Section 4.1.

Liveness Attack Resilience: Figure 2a shows how the adaptive weight mechanism stops liveness attacks. Suppose after the generation of N, an attacker launches a liveness attack similar to one described in Figure 1c to balance the subtree of A and B. After a while, all honest participants start to generate blocks with adaptive weights, because they find that the old ancestors of their new generated blocks (e.g., A or B in Figure 2a) are still not secured on the pivot chain with high probability. This essentially enables the consensus protocol to operate in the conservative strategy similar to the structured GHOST algorithm. In Figure 2a, the heavy weight blocks make Conflux to converge to the the subtree of A. After more blocks being generated under A, the past sub-graph of new generated blocks will become safe. Participants therefore assign weight one to the new blocks, automatically swtiching back to the optimistic strategy.

Epoch and Block Order: Parent edges, reference edges, and the pivot chain together enable Conflux to split all blocks in a Tree-Graph into epochs. Every block on the pivot chain corresponds to one epoch. Each epoch contains all blocks 1) that are reachable from the corresponding block in the pivot chain via the combination of parent and reference edges (including the pivot chain block itself) and 2) that are not included in previous epochs. For example, in Figure 2a, J belongs to the epoch of H because J is reachable from H but not reachable from the previous pivot chain blocks.

Conflux then derives a total order of all blocks in the Tree-Graph with the following rules. Conflux first sorts blocks based on their epochs. For blocks within the same epoch, Conflux sorts them based on their topological order. Conflux break ties determinisitcally (e.g., with the PoW quality or the block hash). For example, in Figure 2a, Conflux will obtain the following block total order for all blocks before the liveness attack: Genesis, A, B, C, D, F, E, G, J, I, H, K, and N.

Transaction Order: Conflux first sorts transactions based on the total orders of their enclosing blocks. If two transactions belong to the same block, Conflux sorts the two transactions based on the appearance order in the block. Conflux checks the conflicts of the transactions at the same time when deriving the order. If two transactions are conflicting with each other, Conflux will discard the second one. If one transaction appears in multiple blocks, Conflux will only keep the first appearance and discard all redundant ones. In Figure 2a, the transaction total order is Tx0, Tx1, ~~Tx2~~, Tx3, and ~~Tx3~~. Conflux discards Tx2 because it conflicts with Tx1.

4 Consensus on Tree-Graph

The local state of a node in Conflux is $S = \langle B, g \rangle$, where B is the set of blocks and $g \in B$ is the genesis block. There are several fields associated with a block $b \in B$. $b.\mathsf{parent}$ denotes the parent block of b. $b.\mathsf{pred\_blocks}$ denotes the set of predecessor blocks linked by the reference and parent edges from b. $b.\mathsf{pow\_quality}$ is the quality of the PoW solution — for b to be valid, $b.\mathsf{pow\_quality}$ must no less than the PoW difficulty D. $b.\mathsf{weight}$ is the adaptive weight of b. We use $b.\mathsf{hash}$ to denote the hash of b – all nodes in Conflux share a predefined deterministic hash function that maps each block to a unique id.

$$\mathsf{Child}(B,b) = \{b' \mid b' \in B,\, b'.\mathsf{parent} = b\}$$
$$\mathsf{SubT}(B,b) = (\cup_{i \in \mathsf{Child}(B,b)} \mathsf{SubT}(B,i)) \cup \{b\}$$
$$\mathsf{SubTW}(B,b) = \textstyle\sum_{i \in \mathsf{SubT}(B,b)} i.\mathsf{weight}$$
$$\mathsf{Past}(b) = (\cup_{i \in b.\mathsf{pred\_blocks}} \mathsf{Past}(i)) \cup b.\mathsf{pred\_blocks}$$
$$\mathsf{PastW}(b) = \textstyle\sum_{i \in \mathsf{Past}(b)} i.\mathsf{weight}$$

Figure 3: The definitions of utility functions.

```
Input  : A set of blocks $B$ and a starting block $b$.
Output : The pivot block for the subtree of $b$.
1 if $\mathsf{Child}(B,b) = \emptyset$ then
2     return $b$
3 else
4     $w \leftarrow \max\{\mathsf{SubTW}(B,i) \mid i \in \mathsf{Child}(B,b)\}$
5     $a \leftarrow \operatorname{arg\,min}_{i \in \mathsf{Child}(B,b)} \{i.\mathsf{hash} \mid \mathsf{SubTW}(B,i) = w\}$
6     return $\mathsf{Pivot}(B,a)$
```

Figure 4: The definition of $\mathsf{Pivot}(B,b)$.

Figure 3 defines several utility functions and notations. $\mathsf{Child}()$ returns the set of child blocks of a given block. $\mathsf{SubT}()$ returns the set of blocks in the subtree of a given block in the parental tree. $\mathsf{SubTW}()$ returns the sum of the weights in the subtree. $\mathsf{Past}()$ returns the set of blocks that are generated before a given block. $\mathsf{PastW}()$ returns the sum of the weights of the past block set of a block. Note that $\mathsf{Past}(b)$ and $\mathsf{PastW}(b)$ are determined at the generation time of b and remain constant afterwards. In this section, we use lists to denote chains and serialized orders. "$\circ$" denotes the concatenation of two lists.

4.1 Pivot Chain and Adaptive Weight

Pivot Chain: Figure 4 presents the pivot chain selection algorithm in Conflux. Given a set of blocks B and the starting genesis block g, $\mathsf{Pivot}(B,g)$ returns the leaf block of the selected pivot chain. The algorithm recursively advances to the child block whose corresponding subtree has the largest total weights (lines 4-6). To break ties, the algorithm selects the child block with the smallest unique hash id (line 5). The algorithm terminates until it reaches a leaf block (lines 1-2).

Adaptive Weight: Figure 5 presents how we calculate the weight of a block b. The algorithm first determines whether the block should have adaptive weight or not based on the past block set of b (lines 1-11). If not, the weight of the block will be one (lines 12-13). If so, the algorithm checks the PoW solution quality against a difficulty that is h times higher than the base validation difficulty. The weight of the block will be h if it passes the check and be zero if it fails (lines 14-17).

To determine whether b should have adaptive weight, the algorithm operates at a sub-Tree-Graph that only contains blocks in the past set of b. It inspects every block in

```
Input   : A new block $b$
Output  : The adaptive weight of $b$
1  $B \leftarrow \mathsf{Past}(b)$
2  $a \leftarrow b.\mathsf{parent}$
3  $adaptive \leftarrow$ False
4  Let $f(x) =$
     $2 \cdot \mathsf{SubTW}(B,x) - \mathsf{SubTW}(B,x.\mathsf{parent}) + x.\mathsf{parent.weight}$
5  Let $t(x) = |\mathsf{TimerChain}(b)| - |\mathsf{TimerChain}(x.\mathsf{parent})|$
6  Let $g(x) = |\mathsf{SubT}(B,x.\mathsf{parent})|$
7  while $a.\mathsf{parent} \neq$ Nil do
8      if $f(a) < \alpha$ and $(t(a) > \beta$ or $g(a) > \gamma)$ then
9          $adaptive \leftarrow$ True
10         break
11     $a \leftarrow a.\mathsf{parent}$
12 if not $adaptive$ then
13     return 1
14 else if $b.\mathsf{pow\_quality} \geq h \cdot D$ then
15     return $h$
16 else
17     return 0
```

Figure 5: The definition of $\mathsf{AdaptiveWeight}(b)$

```
Input   : A block $b$.
Output  : The timer chain of the past sub-graph of $b$.
if $b.\mathsf{pred\_blocks} = \emptyset$ then
    return $b$
else
    $a \leftarrow \underset{i \in b.\mathsf{pred\_blocks}}{\arg\max} \{|\mathsf{TimerChain}(i)|\}$
    if $b.\mathsf{pow\_quality} > h_0 \cdot D$ then
        return $\mathsf{TimerChain}(a) \circ b$
    else
        return $\mathsf{TimerChain}(a)$
```

Figure 6: The definition of $\mathsf{TimerChain}(b)$.

the path from the genesis to $b.\mathsf{parent}$. For each inspected block a, it determines 1) whether a is still not secure on the pivot chain with high probability – the subtree weight of a is not significantly larger than the weight of the sibling subtrees of a (i.e., $f(a) < \alpha$) and 2) whether a is old enough – there is an enough amount of timer ticks or an enough number of blocks in the subtree of its parent (i.e., $t(a) > \beta$ or $g(a) > \gamma$). If any inspected block satisfies these two conditions, b should have adaptive weight.

The intuition is that to make progress, for any pivot chain block a' in Tree-Graph, after a certain period of time, one of the child subtree of a' (e.g., the subtree of a) should become dominant. If the attacker attempts to maintain the balance between the subtrees of two (or more) children of a' for a long time, the condition at line 8 will become true for a. Therefore, all honest participants will start to generate blocks with adaptive weights. Conflux will essentially operate with a conservative strategy similar to the structured GHOST algorithm (see Section 3). This will thwart the attack to ensure the progress.

Timer Chain: Because an attacker with enough computation power may influence the subtree sizes of recent pivot chain blocks via strategically withholding mined blocks, only counting the number of blocks under the subtree of a pivot block is not sufficient to detect whether the pivot block is old enough or not. To this end, Conflux uses a timer chain mechanism to obtain an attacker resilient estimation for the generation time of each block.

```
Input   : The local state $S = \langle B, g \rangle$ and a new discovered
          block $b$
1  if $b.\mathsf{pow\_quality} \geq D$ then
2      Wait until $\mathsf{Past}(b) \subseteq B$
3      if $\mathsf{Pivot}(\mathsf{Past}(b), g) = b.\mathsf{parent}$ then
4          $b.\mathsf{weight} \leftarrow \mathsf{AdaptiveWeight}(b)$
5          $S \leftarrow \langle B \cup \{b\}, g \rangle$
```

Figure 7: The block validation procedure.

```
Input   : A block $b$
Output  : An ordered list of all blocks in Past($b$) $\cup \{b\}$
if $b$.parent = Nil then
    return $\emptyset$
$L \leftarrow$ ConfluxOrder($b$.parent)
$B_\Delta \leftarrow$ (Past($b$) $-$ Past($b$.parent) $- \{b$.parent$\}) \cup \{b\}$
while $B_\Delta \neq \emptyset$ do
    $B'_\Delta \leftarrow \{x \mid |x.\mathsf{pred\_blocks} \cap B_\Delta| = 0\}$
    Sort all blocks in $B'_\Delta$ in order as $a_1, a_2, \ldots, a_k$
      such that $\forall 1 \leq i < j \leq k$, $a_i.\mathsf{hash} < a_j.\mathsf{hash}$
    $L \leftarrow L \circ a_1 \circ a_2 \circ \ldots \circ a_k$
    $B_\Delta \leftarrow B_\Delta - B'_\Delta$
return $L$
```

Figure 8: The definition of ConfluxOrder().

Figure 6 presents the definition of $\mathsf{TimerChain}(b)$, which is the longest chain of blocks in the past sub-graph of b whose PoW qualities are h_0 times higher than the normal difficulty. We then use the length of the timer chain as the timer tick of the generation time estimation of each block (i.e., line 5 in Figure 5). When h_0 is large enough respecting the network delay, the attacker cannot stop the growth of the timer chain, because honest participants will contribute to the timer chain almost synchronously. In Conflux we set $h_0 = 360$. See Section 6.1.

4.2 Block Validation and Total Order

Block Validation: Figure 7 presents the validation procedure for a new discovered block. It first checks whether the block has a PoW solution with a sufficient quality (line 1). The procedure will wait for all blocks in its past sub-graph being processed first (line 2). The procedure will then compute the pivot chain in its past sub-Tree-Graph to check whether it selects the right parent (line 3). If so, the procedure computes the weight of the new block and adds it to the local Tree-Graph state (lines 4-5).

Block Order: Figure 8 defines $\mathsf{ConfluxOrder}()$, our block ordering algorithm. Given a block b, $\mathsf{ConfluxOrder}(b)$ returns the total order of all blocks in $\mathsf{Past}(b) \cup \{b\}$. The algorithm sorts the blocks based on their corresponding epochs, i.e., it first recursively orders all blocks in previous epochs. It then computes all blocks in the epoch of b as B_Δ (line 4). It topologically sorts all blocks in B_Δ and appends them to the result list (lines 5-10), and uses the hashes to break ties (lines 7-8).

4.3 Correctness

We next discuss the intuitions behind the correctness of our consensus algorithm. Suppose the network together has a block generation rate of λ. The correctness of Conflux is based on the following assumptions: 1) attackers control at most δ of the total block generation power ($\delta < 0.5$); 2) the network is d-synchronous, i.e., if at time t one honest node broadcast a block via the gossip network, then before time $t+d$, all honest nodes will receive this block and add this block into their local states.

Adversary Model: The attacker can choose arbitrary strategies to disrupt honest nodes. We also assume 1) attackers immediately receive all blocks and transactions from the gossip network, 2) attackers can arbitrarily control the communication of honest nodes as long as the d-synchronous assumption holds. The attacker however does not have the capability to reverse cryptographic functions. Therefore honest nodes can reliably verify the integrity of a block in the presence of the attacker.

Safety: Conflux is safe against double spending attacks because of two facts: 1) to revert a transaction in an epoch, the attacker has to revert the pivot chain block associated with the epoch from the pivot chain; 2) reverting an old pivot chain block that is on the common pivot chain of all honest nodes requires the attacker to compete with all honest nodes together. Although honest nodes may generate blocks that are concurrent with each other, all of these blocks will be under the subtree of the common pivot chain block. As the time passes by, it will be impossible for the attacker to forge an alternative heavier subtree without the pivot chain block.

Liveness: Many previous consensus algorithms based on tree and DAG can only provide liveness guarantees if the block generation rate is significantly slower than the block propagation delay (i.e., $\lambda \cdot d \ll 1$) [13, 26]. In contrast, Conflux is safe against liveness attacks at the protocol level even when the block generation rate is fast, because if the consensus does not make progress for a certain period of time, all honest nodes will start to generate blocks with adaptive weights. In this scenario, only blocks with very high PoW quality will decide the total order and the block generation rate of these blocks is significantly slower than the block propagation delay (i.e., $\frac{\lambda \cdot d}{h} \ll 1$ for a large enough h). Because concurrent generation of such heavy weight blocks is rare, an attacker has to release a large number of previously withheld blocks to balance a new generated heavy block or all honest nodes will make progress and will recognize the heavy block as a common pivot chain block. Because block withholding capability of an attacker is limited by its block generation power, the attacker will eventually run out of blocks to continue the liveness attack. We prove in [19] that when $\delta < 1/2$, once a block in Conflux is seen by an honest node, its order will become irreversible with exception risk ε after $d \cdot O(\log(1/\varepsilon))$ time.

Confirmation Policy: Conflux confirms a block b if for any ancestor block of b, the corresponding subtree total weight is heavier than all of the subtrees of its siblings by a margin. This margin is not a preset value. It depends on the status of blockchain protocol. With the parameter setting used in our experiments, this margin is about 20∼30 in normal scenarios for obtaining the same confidence as waiting six blocks in Bitcoin. Specially, if Conflux is in the conservative mode and is generating blocks with adaptive weights, we need to wait six blocks with heavy weights instead. See [19] for the detailed formulas of the risk in confirming a block.

5 Implementation and Optimizations

We have implemented Conflux in Rust [1].

Difficulty Adjustment: For brevity, our algorithm in Section 4 assumes a constant PoW difficulty. Conflux operates with a difficulty adjustment mechanism tailored for Tree-Graph. Every 5000 epochs, Conflux counts the number of blocks generated in the last 5000 epochs and adjusts the difficulty accordingly to maintain a stable block generation interval. Instead of setting the weight of every normal block to one, Conflux sets the weight to the difficulty of the block. For a block with a heavy adaptive weight, its weight will be its difficulty multiplied by h. The rationale is to allow the block weight to align with the accumulated PoW as the difficulty changes.

Storage: A Conflux full node stores the blockchain account state as Merkle Patricia Trees [35] in a key-value DB. To save storage space, Conflux periodically forms checkpoints at specific epoch heights (e.g., every 200k epoch heights) when the confirmation risk of the pivot chain blocks at these heights become extremely low. After a checkpoint, all history transactions before it can be safely discarded — all full nodes treat the checkpoint block as the new genesis. Note that full nodes still store all block headers to help new nodes bootstrapping.

Bootstrap: To bootstrap a new full node to join the network, it first synchronizes all the block headers in the ledger from the peers and decides the latest confirmed checkpoint block based on the headers. It then fetches the corresponding checkpoint state from the peers and continues the execution from that state.

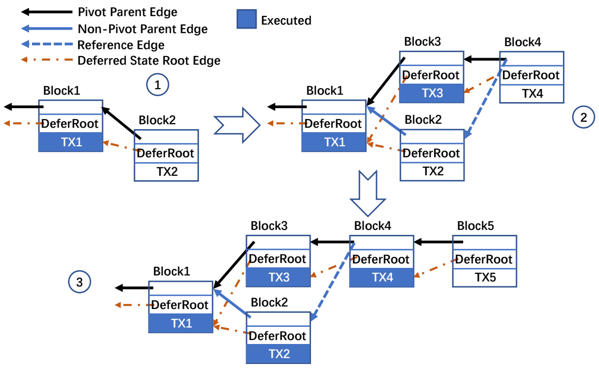


Figure 9: Save Redundant Execution by Deferred Execution

Transaction Relay: For a high performance blockchain like Conflux, it is critical to minimize the redundant transactions that are transferred. Ideally and optimally, each node should only receive each transaction exactly once. In current Bitcoin and Ethereum implementation, transactions are disseminated among nodes via flooding, which may waste network bandwidth resources. Erlay [24] tries to solve this issue of Bitcoin by letting peers exchange sets of unsent transactions that are encoded with PinSketch algorithm [8]. However, this method cannot be applied in Conflux, since it only works well when the difference between the transaction sets of two peers is small. Conflux is not this case because the transaction throughput of Conflux is orders of magnitude higher than Bitcoin. Conflux instead only floods 4-byte short transaction ids and pulls the missed transactions from peers. The short id is built by a SipHash [12] on the SHA-3 hash of the transaction and a peer-specific random nonce to significantly decrease the id conflict rate.

Signature Verification: Signature verification is computation-intensive and may become a bottleneck when the throughput is high. Conflux therefore uses a thread-pool to parallel the signature verification for different transactions to avoid bottlenecking other components.

Incentive Mechanism: For every mined block, Conflux assigns its block generation reward based on how many other blocks that are generated in parallel in Tree-Graph, i.e., blocks that are not in the past and future sets of the mined block. The more blocks are in parallel with the mined block, the smaller the block reward would be. This incentive mechanism penalizes malicious behaviors such as withholding mined blocks and not referencing other blocks. Because every block receives reward regardless of whether they are on the pivot chain or not, this mechanism nullifies selfish mining attack strategies [10, 25, 29]. See [7] for the details of the incentive mechanism.

5.1 Deferred Execution

In Conflux, when a block just enters the Tree-Graph structure, its position in the total order will change frequently. Although such oscillation will stop in a short time, it poses a challenge for the transaction execution engine. In typical blockchain systems, all transactions in a block immediately get executed in a node as soon as it is discovered. Such naive approach may execute transactions in a block many times as the order of the block oscillates. This incurs significant execution overhead. The top part of Figure 9 illustrates this problem. When a full node just gets the $Block_2$, it is on the pivot chain and the total order of transactions is $\{TX_1, TX_2\}$. TX_2 is then executed in this order. But, when the node later gets $Block_3$ and $Block_4$, $Block_2$ does not belong to pivot chain anymore and TX_3 is positioned between TX_1 and TX_2 in the newly decided total order. TX_2 has to be executed again.

Conflux uses a novel *deferred execution* mechanism to address this issue. The insight is that, just like users waiting for a period of time to confirm transactions, Conflux can wait for the total order position of a block to almost stabilize to execute its transactions. Conflux delays the execution by k-epochs. Specifically, unlike Ethereum where the header of each block b contains a merkle state root that corresponds to the execution results after processing all transactions in and before b, the header of b in Conflux contains a deferred root that corresponds to the execution results of the block that are k-hops older than b along its path to the root. We set k to five in Conflux so that Conflux can avoid re-execution of transactions in most cases. Five is also smaller than the typical number of epochs that an user needs to wait to confirm transactions and therefore it does not impact the user experience.

Figure 9 presents an example to illustrate the saving of redundant executions by using deferred execution. For illustration purpose, we set k to be one in this example. Therefore in Figure 9, the $Block_2$ stores the state root based on the execution of TX_1. When the full node gets $Block_3$ and $Block_4$, in order to verify the deferred state root of $Block_4$, the system needs to execute TX_3 but does not need to execute TX_2 because TX_2 is positioned after TX_3 in the decided total order. When getting and verifying $Block_5$, Conflux then needs to produce the state based on the execution of TX_4 which depends on TX_2. In the process, although the pivot chain oscillates between $Block_2$ and $Block_3$, TX_2 only gets executed once.

5.2 Link-cut Tree Optimizations

Maintaining pivot chain in Conflux is not trivial. Adding a new block to the Tree-Graph requires updating the subtree weights of all the blocks from this new block back to the genesis. The naive approach will takes $O(n)$ time to complete, because the Tree-Graph height is usually linear to the number of blocks. To efficiently update the subtree weights, Conflux uses a data structure called *link-cut tree* [3]. Link-cut tree splits a tree structure into one or more paths, and represents each path using a splay tree, a form of balanced binary search tree invented by Tarjan et al. [5]. The link-cut tree is ideal for maintaining values like the subtree weights in the Conflux consensus protocol, because it enables the following operations at an amortized cost of $O(\log n)$: 1) increase or decrease values of all nodes along a path in the tree by a given value; 2) find the minimum or maximum value among values of all nodes along a path; 3) find the least common ancestor (LCA) of two nodes in the tree.

Update Pivot Chain: Conflux tracks the last pivot chain block of the current Tree-Graph state. Conflux uses the link-cut tree to maintain the total subtree weights of each block. When Conflux discovers a new block b, it inserts b into the link-cut tree and increases the total subtree weights of all blocks along the path from b to the root (i.e., genesis) by $b.\mathsf{weight}$. Note that adding b may trigger a pivot chain change — instead of running the chain selection algorithm from the root, Conflux uses the link-cut tree to calculate the LCA of b and the current last pivot block p. If the weight of the subtree p belongs to is still heavier than the one b belongs to, no pivot chain update occurs. Otherwise, Conflux re-runs the selection algorithm from the LCA block. Because long range pivot chain reorganization is extremely rare, rerunning the algorithm from the LCA block is not expensive in practice.

6 Experimental Results

We next present a systematic evaluation of Conflux on its throughput, confirmation speed, and scalability. We also evaluate important design aspects of Conflux, e.g., the adaptive weight mechanism for defending against liveness attacks, the deferred execution for optimizing the transaction execution, as well as link-cut tree for optimizing the Tree-Graph maintainance.

We deployed Conflux on up to 800 Amazon EC2 m5.2xlarge virtual machines (VM), each of which has 8 cores and 1Gbps network throughput. By default, we run one Conflux full node in each VM. To model the network latency, we use the intercity latency measurements [34] and assign each VM to one of 20 major cities. We emulate the intercity delay by inserting artificial delays. For each full node, the gossip network of Conflux connects it to an average of 10 randomly selected peers.

When we measure the confirmation speed of a transaction, we count a transaction as confirmed if we can obtain the same confidence as empirically confirming a transaction in Bitcoin after waiting six Bitcoin blocks. In our experiments, unless otherwise noted, we limit the bandwidth of each full node to 20Mbps and we assign each full node with an equal block generation power.

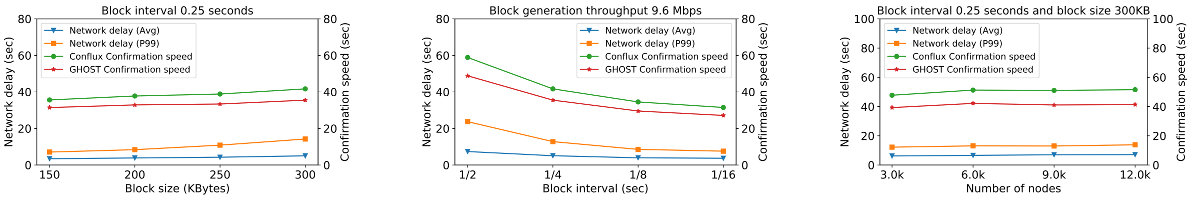
6.1 Protocol Parameter Calibration

To calibrate Conflux consensus protocol parameters, we run a set of experiments with 200 Conflux full nodes on Amazon EC2 with one full node per VM. We run Conflux with a set of different combinations of block size limits and block generation rates to measure the block propagation delays. For each setting, we run Conflux from the genesis for 10 minutes and fill each block to full with randomly generated simple payment transactions.

Figure 10a and 11a presents the experimental results of Conflux where we fix the block generation rate at four blocks per second and change the block size limit. Average network delay corresponds to the number of seconds on average for a generated block to reach more than 50% of participants. Network delay (99%) corresponds the number of seconds for all blocks to reach more than 99% of participants. In our experiments, we use the network delay (99%) number as the network diameter d for calculating parameters. There are often one or two machines lagging behind for some blocks and we can tolerate them as temporary failure nodes.

Conflux achieves the throughput of 9.6Mbps at the setting of 300K $\times$ 4 blocks per second. We find that Conflux almost saturates its underlying gossip network capability, considering that we limit the bandwidth of each full node to 20Mbps, which is only enough to send each block twice on average. With block sizes of 350K and beyond, full nodes start to experience significantly higher delay and may not be able to catch up new blocks.

Figure 10b and 11b presents the experimental results of Conflux where we fix the block generation throughput at 9.6Mbps and change the block generation rate from 2 blocks/s to 16 blocks/s. Our results show that as Conflux operates with faster block generation rate and smaller blocks, the network propagation delay decreases. But the delay no longer decreases much as it approaches the latency limit of the network. Smaller network propagation delay will improve the confirmation speed of transactions, but there are additional costs for using high generation rate. 1) Conflux full nodes have to store all block headers (block content could be pruned away with checkpoint techniques) and the average header size of Conflux is 300$\sim$500 bytes; 2) high block generation rates incur more blocks in parallel and these blocks cannot process transactions with dependencies.

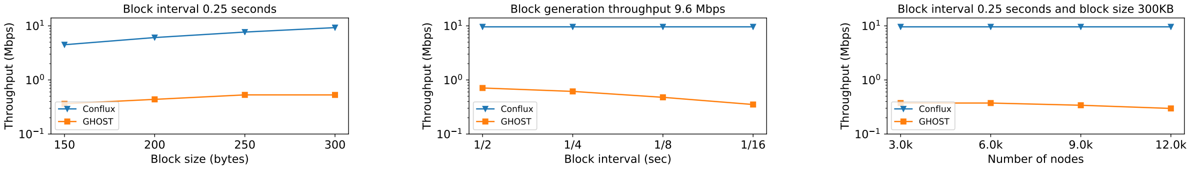


(a) Latency vs. block sizes.

(b) Latency vs. block intervals.

(c) Scalability

Figure 10: Network Delay and Confirmation Speed



(a) Throughput vs. block sizes.

(b) Throughput vs. block intervals.

(c) Scalability

Figure 11: Throughput

Based on the above trade-off, we choose the block generation rate of 4 blocks per second and the block size limit of 300K. With the measured network propagation delay, we determine the adaptive weight algorithm parameters following suggestions in our theory analysis [19]. 1) $h = 600$ is large enough to enable Conflux to tolerate liveness attacks from a powerful attacker that controls 40% of the network computation power; 2) $\beta = 160$ and $\gamma = 10000$ so that the confirmation policy gives a desirable margin; 3) $\alpha = 1800$ since it requires $\alpha \geq 3h$; 4) $h_0 = 360$ so the timer chain will have rare forks. Figure 10 plots the average confirmation speed under this set of parameters.

Compared to GHOST (by only considering pivot blocks as valid), Conflux achieves the similar confirmation latency while provides significantly higher throughput. As Figure 11b shows, the transaction throughput of GHOST decreases with increasing block generation rate since more concurrently generated blocks with smaller size lead to less valid transactions.

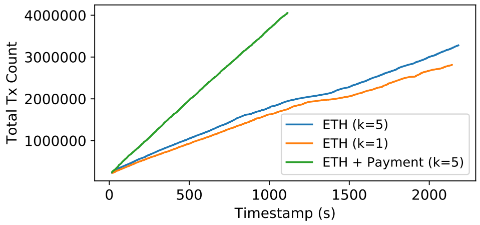


Figure 12: End-to-end Results for ETH Workload

6.2 Performance Results

Consensus Scalability Results: We next evaluate the consensus protocol performance as the number of nodes increases. Due to our resource limitation, we have to run 15 full nodes per VM. Because we are evaluating the consensus protocol only, we turn off signature verification and transaction execution to ensure enough computation resources for 15 full nodes sharing each VM.

Figure 10c presents the network propagation delay and the average transaction confirmation speed when running Conflux with different numbers of full nodes. In all the experiments, Conflux successfully operates with the block throughput of 9.6Mbps (300K × 4 blocks per second). Our results highlight the fast confirmation speed of Conflux, it confirms transactions on average in 47.75-51.54 seconds when running 3000-12000 full nodes. Our results also show that the consensus protocol of Conflux scales well. As the number of nodes increases, the network propagation delay only increases slightly so does the confirmation speed.

Note that our experimental setup is as same as the Algorand and OHIE papers [11, 36], therefore we can directly compare our results with their results. Compared to Algorand [11], Conflux achieves more than 4x throughput and similar confirmation latency. Compared to OHIE [36], Conflux achieves similar throughput but one order of magnitude faster confirmation.

End-to-end Results: With the calibrated parameters, we run Conflux on 400 VMs (one node per VM) to measure the throughput and the confirmation speed of Conflux. To obtain a representative workload, we collected the first four million transactions from the Ethereum blockchain [2]. This includes both payment transactions and smart contract transactions. We converted these col-

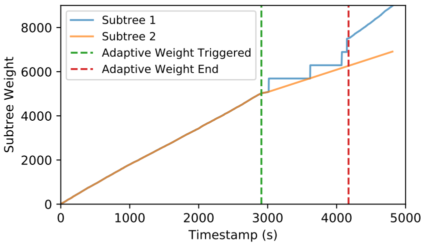

Figure 13: Subtree Weights under Liveness Attack

lected transactions into Conflux transaction format. We run two experiments, one experiment with the collected Ethereum transactions only and another experiment with a combined workload of the collected Ethereum transactions and randomly generated payment transactions. We terminate an experiment once Conflux processes four million transactions in total.

Figure 12 presents the number of processed transactions overtime. Our experimental results show that Conflux achieves a throughput of 1392 transactions per second for Ethereum workload and 3480 transactions per second for the combined workload. The average confirmation latencies are under one minute for both the Ethereum workload and the combined workload. Note that in the combined workload experiment, 14% of processed transactions are from Ethereum history.

Conflux achieves higher transaction throughput on the combined workload than on the Ethereum history workload. A primary reason is that Ethereum is a much slower blockchain and its transaction history does not have enough parallelism to saturates the Conflux consensus layer. We find that during the execution, future transactions in the Ethereum history often depends on previous transactions and full nodes of Conflux often do not have enough pending transactions ready to pick up so concurrent blocks pack duplicate transactions. A secondary reason is that Ethereum history contains more smart contract transactions which are more expensive to process than payment transactions.

Deferred Execution: Conflux by default defers the execution of transactions by five epochs $k = 5$. To illustrate the effect of the deferred execution optimization, we run a modified version of Conflux on the Ethereum history workload with $k = 1$. The results in Figure 12 show that this causes a 11.6% slowdown of Conflux on the transaction throughput because of the frequent re-execution of transactions during order oscillation.

6.3 Liveness Attack and Link-cut Tree

Liveness Attack: We conducted a liveness attack experiment to evaluate the security of Conflux. The experiment includes three nodes, two honest nodes and one attacker node. They keep a four block per second block generation rate for entire network. The block propagation network delay between the two honest nodes are 20 seconds and the attacker node does not relay honest blocks. We use only two honest nodes with significant delay to simulate the ideal liveness attack scenario in Figure 1c — a powerful attacker that evenly splits honest nodes in two groups and honest nodes with no latency inside a group and maximum latency between the two groups. The attacker node controls 30% of the total computation power. It launches the attack by finding the first fork between the two honest nodes and try to mine blocks under the lighter subtree to keep the two subtrees balanced.

Figure 13 shows how the weights of the two forked subtrees change along the time. The attack starts at the timestamp 0. During the time when the attack is performed and no adaptive weight is triggered, the weights of the two forked subtrees are almost perfectly balanced. The adaptive weight mechanism triggers the conservative strategy at timestamp 2,909 s. After that, the liveness attack quickly fails and the two honest nodes can then agree on the same pivot block and generate blocks under its subtree. After another 1,264 s, the two honest nodes come back to the optimistic strategy.

Link-cut Tree: To evaluate the benefits of link-cut tree, we run experiments on a micro-benchmark, a Tree-Graph that contains 1.5 million blocks, to measure the block processing throughput of the naive as well as our optimized approaches. Our experimental results show that the naive appraoch slows down to less than 4 blocks per second when the number of blocks in the Tree-Graph grows to one million, while our approach processes 5000 blocks per second on average.

7 Conclusion

Conflux is a scalable and decentralized blockchain platform with high throughput and fast confirmation. Its novel consensus protocol makes Conflux secure against both double spending attacks and liveness attacks, even if Conflux operates with a fast block generation rate. Conflux provides a promising solution to address the performance bottleneck of blockchains and opens up a wide range of blockchain applications.

Acknowledgments

We thank Bo Qiu and Yanpei Liu for their helps on the experiments. We thank Xi Wang and the anonymous reviewers for their insightful comments on the early draft of this paper. We note that [18] describes an early version of the Conflux system.

Reconstructing proprietary video streaming algorithms

Maximilian Grüner, Melissa Licciardello, Ankit Singla
Department of Computer Science, ETH Zürich

Abstract

Even though algorithms for adaptively setting video quality in online streaming are a hot topic in networking academia, little is known about how popular online streaming platforms do such adaptation. This creates obvious hurdles for research on streaming algorithms and their interactions with other network traffic and control loops like that of transport and traffic throttling. To address this gap, we pursue an ambitious goal: reconstruction of unknown proprietary video streaming algorithms. Instead of opaque reconstruction through, *e.g.,* neural networks, we seek reconstructions that are easily understandable and open to inspection by domain experts. Such reconstruction, if successful, would also shed light on the risk of competitors copying painstakingly engineered algorithmic work simply by interacting with popular services.

Our reconstruction approach uses logs of player and network state and observed player actions across varied network traces and videos, to learn decision trees across streaming-specific engineered features. We find that of 10 popular streaming platforms, we can produce easy-to-understand, and high-accuracy reconstructions for 7 using concise trees with no more than 20 rules. We also discuss the utility of such interpretable reconstruction through several examples.

1 INTRODUCTION

Video streaming is one of the most popular Internet services today, forming a majority of downstream Internet traffic [35]. Naturally, there is great interest in optimizing video delivery. One particularly well-studied problem is that of designing adaptive bitrate algorithms that adjust video quality in response to changes in network bandwidth. ABR algorithms attempt to maximize some notion of quality-of-experience, which typically combines video playback metrics like average video quality, and playback interruptions and stability.

The problem of maximizing QoE in video streaming is crisply defined, intellectually interesting, and practically valuable. Thus, numerous ABR algorithms have been suggested in recent work to tackle it, *e.g.,* Oboe [3] and MPC [46]. However, little is known about the proprietary algorithms actually deployed in widely used video streaming services such as YouTube, TwitchTV and Netflix.[1] We attempt to address this gap by exploring whether it might be possible to learn such algorithms by controlled observation of video streams.

Our goal is to produce ABR controllers that: (a) mimic the observed behavior of ABR logic deployed in target online video services across a wide range of network conditions and videos; and (b) are open to easy manual inspection and understanding. Note that the latter precludes the direct use of blackbox machine learning techniques like neural networks.

We are motivated by three factors. First, this effort helps understand the risk of competitors copying painstakingly-engineered algorithmic work simply by interacting with popular, public-facing front-ends. Second, being able to reconstruct widely deployed algorithms would allow head-to-head comparisons between newly proposed research ABRs and industrial ABRs, something lacking in the literature thus far. Third, given that video is the majority of Internet traffic, this traffic being controlled by unknown proprietary algorithms implies that we do not understand the behavior of most Internet traffic. This makes it difficult to reason about how different services share the network, and interact with other control loops such as congestion control and traffic shaping.

The above use cases help sharpen the goals for our reconstruction effort. Simplifying our task is the fact that instead of exact algorithm recovery, we need functional equivalence of a reconstruction with its target algorithm over a large, varied set of inputs – note that the same set of outcomes could be arrived at by two substantially different algorithms, making exact recovery of a particular algorithm impossible. However, our use cases also impose a difficult additional requirement: our reconstructions must be human-interpretable, allowing not only the mimicking of observed behavior, but also manual inspection and understanding. A competitor seeking to copy the ABR logic of an online service needs interpretability to be able to modify it as necessary for their use.[2] They would also like to ensure the robustness of the obtained logic, something that is difficult with blackbox learning — prior work has shown corner cases with undesirable behavior in blackbox learning methods applied to networking [17]. Likewise, in terms of comparisons between industrial and academic ABRs, we would not only like to observe the performance

[1] Researchers at Netflix published, in 2014, work on this problem [15], including tests on their commercial deployment. Per our conversations with them, their current deployment incorporates some features of this published work, but they are unwilling to share more details, including the differences from this published approach.

[2] Our work enables an understanding of whether this risk *exists*: "Can a competitor reconstruct an ABR in a meaningfully beneficial, robust way?" We leave the question of how this risk may be tackled to followup work.

differences empirically, but also understand where they stem from. Lastly, reasoning about interactions with other network control loops and competing services also requires having a richer understanding of the control logic under study than blackbox learning can provide.

Algorithmic reconstruction of this type is an ambitious goal, with the current tools available for general-purpose program synthesis still being fairly limited. However, there are two reasons for optimism if we can suitably narrow our scope: (a) the core of ABR algorithms involves a small set of inputs, and has a limited decision space; and (b) it is easy to collect large amounts of curated data for analysis.

Our approach automatically generates concise, human-interpretable rule-sets that implement ABR by learning from an existing target ABR algorithm. These rule-sets map the client and network environment, video features, and state over the connection, to a video quality decision for the next video chunk. To obtain generalizable, succinct, and interpretable pseudocode in a reconstruction, we find that it is insufficient to directly use sophisticated techniques from imitation learning [5, 34]. As we shall show later, such methods can either mimic the behavior of a target accurately with a large set of complex rules, or, when limited to a small set of rules, lose accuracy. Our approach sidesteps this tradeoff by embedding suitable domain knowledge in the learning mechanism: framing intuitive primitives familiar to domain experts, and making them available to the learning mechanism, results in rule-sets that are accurate, concise, and meaningful.

We use our approach to obtain concise reconstructions that can successfully mimic the decision-making of several target academic and industry ABR algorithms, achieving high agreement with their decisions and similar video QoE behavior. Of the 10 online streaming services we evaluate across, our reconstruction achieves behavior similar to its target for 7 services. In each case, we produce a concise decision-tree with 20 or fewer short rules, using primitives that are intuitive and easy to understand. We also explain the reasons for failure for the remaining 3 services.

We make the following contributions:

- We describe an approach for deriving accurate *and* concise rule sets for ABR, using a corpus of decision outcomes over network traces and videos. Our approach handles the complex output space corresponding to diverse video encodings, as well as noise in the data.
- We apply our method to the reconstruction of algorithms deployed in 10 popular streaming services. For 7 services, we successfully achieve high agreement with their decisions and closely similar streaming behavior.
- The rule sets we obtain are concise, with 20 or fewer rules in each case. Our code also generates a loose natural language translation, which we used extensively in understanding problems and improving performance.
- We also expose a likely fundamental compromise necessary for interpretable and effective learning: the time-consuming encoding of domain knowledge.
- Our code and reconstructed ABRs are open-source [12].

Beyond the above results, our ambitious effort raises several exciting questions for future exploration, such as: (1) on the tradeoffs between the effort invested in embedding domain knowledge, and the quality of the inferred pseudocode; (2) to what extent such domain knowledge may itself be learnt from a corpus of hand-designed algorithms broadly from the networking domain; (3) applying our approach to other networking problems, like congestion control, and newer problems where we have more limited experience, such as multipath transport; (4) and how online service providers may obscure their logic against reconstruction, if so desired.

2 RELATED WORK

Numerous high-quality ABR proposals have appeared just within the past few years [3, 11, 31, 37, 45], but relatively little is known about widely deployed industrial ABR algorithms.

There is a large body of work on reconstructing unknown algorithms. One may approach this using code analysis, like Ayad et al.'s analysis of Javascript code for some online video services [16]. However, some targets can be too large and obfuscated for such analysis – YouTube, for instance, comprises 80,000+ lines of obfuscated Javascript. We used JS NICE [36], the state-of-the-art in Javascript deobfuscation, but even coupled with a step-through debugger and with help from the authors of JS NICE, this provided little insight – ultimately, manually examining such a large piece of code with meaningless variable names to reconstruct its functionality seems futile. It also has the downside of potentially requiring substantial rework for even small changes in the target. Even more fundamentally, the code may not be available at the client at all, with decision-making residing on the server side.

Several prior efforts have used manual experimentation and analysis for dissecting the behavior of a variety of online services [2, 9, 16, 19, 21, 27, 44]. For instance, Mondal et al. [27] used network traces to experimentally study the behavior under changing network conditions, and then manually draw coarse inferences, such as that YouTube's requested segment length varies with network conditions. An earlier effort on inferring Skype's adjustment of its sending rate [19], was based on the researchers making experimental observations, then manually hypothesizing a control law, and finally tuning its parameters to fit the data. Our own parallel measurement study [21] experimentally examined the behavior of several deployed ABR algorithms in terms of metrics like stability of playback and convergence time after bandwidth changes. In concurrent work, Xu et al. [43] propose a method for inferring the quality of video chunks downloaded within encrypted streams, and apply it to experimentally study the streaming outcomes in response to different traffic throttling schemes. In contrast to all the above efforts, our goal here is to *automatically generate logic that mirrors a target ABR algorithm's behavior* by observing the target ABR's actions in response to variations in the environment and inputs.

There are also efforts in networking to inspect the internals of learning-based networked systems. This work is not directly applicable to our goal of reconstructing arbitrary ABRs, which are most likely non-ML, and more importantly, are not available to us. However, one could first train a blackbox-ML algorithm to mimic any reconstruction target, and then use such tools. Recent work on inspecting [10] or verifying [17] systems built using ML has examined Pensieve [23]. The authors frame hypotheses/questions about the system's behavior, and then evaluate them. However, this (a) requires knowing what hypotheses to examine, and (b) does not yield a reconstruction. Among efforts in this vein, the most closely related are the concurrent TranSys [26] and PiTree [25] studies. PiTree focuses on converting ABR algorithms to decision trees, and TranSys broadens this approach to NN-based strategies in networking. Both are networking applications of a broader paradigm in ML, which we discuss next.

Beyond networking efforts, *imitation learning* is a rich discipline in its own right. Most work in this direction uses (uninterpretable) neural networks [6, 14, 42], but recent work has also developed model-free approaches to approximate the learned neural network via, *e.g.,* a decision tree [5, 34]. As we show later in §6.2, directly using this approach (like TranSys and PiTree) does not meet both of our accuracy and interpretability goals simultaneously, instead requiring the sacrifice of one or the other. While complex decision trees, with a large number of rules with many literals, can robustly imitate a target algorithm, they are difficult, if not impossible, for even domain experts to understand and work with. On the other hand, restricting the complexity of the generated trees results in a loss of imitation accuracy and robustness. While the expressiveness and compactness of these approaches can be improved by employing genetic algorithms to craft features for use therein [13], this often leads to both overfitting, and complex, non-intuitive features.

Lastly, program synthesis is a rich and growing field. While we use one particular strategy for ABR reconstruction, there are other tools we plan to examine in future work. The most promising perhaps is recent work combining learning with code templates [41], where the core idea is to modify templates to minimize the distance from a target learning algorithm. An alternative "deductive synthesis" approach, as employed in Refazer [33], could also be fruitful.

To the best of our knowledge, our work is the first to attempt an interpretable reconstruction of unknown deployed ABRs.

3 DATA PREPARATION

We extend a trace collection harness that we built for a measurement study, where we used manual analysis to comment on the behavior of deployed ABR algorithms across 10 streaming platforms [21].

We launch a video stream on a target service, and according to an input network trace, shape the throughput at the client using Linux `tc`. We record the current client buffer occupancy, the video chunk qualities played out, video metadata, etc. The client buffer occupancy is directly measured through the instrumentation of the HTML5 player element. If the HTML5 player element were not available, we could instead use the captured HTTP chunk requests (locally at the client, making encryption irrelevant) to reconstruct the buffer occupancy — this strategy may be of use for future work exploring mobile ABR implementations. This alternative can be less accurate though, as "redownloading" (*e.g.,* to replace already downloaded low-quality chunks in the client player buffer by higher-quality ones) introduces an ambiguity into which chunk is actually played.

For each platform, by appropriate tailoring of HTTP requests, we also fetch all chunks for the test videos at all qualities, such that we can use these videos in an offline simulation, allowing the learned ABR to make choices different from those in our logs, as well as to enable us to study the behavior of academic ABRs. Ultimately, we obtain the following measurements:

- $\mathbb{C}_t$: segment size (Mb) downloaded for request t
- $\mathbb{R}_t$: segment bitrate (Mbps) for request t
- $\mathbb{V}_t$: segment VMAF[3] for request t
- $\mathbb{D}_t$: download time for request t
- $\mathbb{Q}_t$: quality level requested in request t
- $\mathbb{S}_t$: segment length (seconds) downloaded for request t
- $\mathbb{P}_t$: Percent of the video played at request t
- $\mathbb{B}_t$: buffer size (seconds) when requesting t
- $\mathbb{RB}_t$: rebuffer time (seconds) when requesting t
- $\mathbb{C}^i_{t+n}$: segment size of quality i for n^{th} chunk after t
- $\mathbb{R}^i_{t+n}$: segment bitrate of quality i for n^{th} chunk after t
- $\mathbb{V}^i_{t+n}$: segment VMAF of quality i for n^{th} chunk after t

4 RULE-SET BASED INFERENCE

We shall first consider a motivating example for why rule-sets are a simple and potent representation for our type of target algorithms, and then present our recipe for constructing succinct rule-sets that capture the target algorithm's behavior.

4.1 Motivating example

Let us examine a simple throughput-based ABR algorithm, similar to that described in prior work [15]. It uses only the throughput estimate for the last video chunk fetched, $\mathbb{T}_{N-1}$,

[3] VMAF is a video perceptual quality metric [20].

$$\begin{aligned}
\text{quality } 0 &\rightarrow \mathbb{T}_{N-1} \leq 4.99 \\
\text{quality } 1 &\rightarrow \mathbb{T}_{N-1} > 4.99 \;\&\; \mathbb{T}_{N-1} \leq 6.97 \\
\text{quality } 2 &\rightarrow \mathbb{T}_{N-1} > 6.97
\end{aligned}$$

Fig. 1: Minimal rule-set for a reservoir-based algorithm, which uses only the last chunk's throughput estimate to pick a quality level.

and two thresholds: *reservoir* and *cushion*. If $\mathbb{T}_{N-1}$ < *reservoir*, the lowest quality is served. If $\mathbb{T}_{N-1}$ > *reservoir* + *cushion*, the highest quality is served. For other values of $\mathbb{T}_{N-1}$, quality is linearly interpolated between these levels.

This algorithm, regardless of its specific instantiation with particular values of the thresholds, can be easily expressed as a set of rules. For a simple instantiation with only 3 quality levels, and both *reservoir* and *cushion* set to 4 Mbps, this rule-set is shown in Fig. 1.[4] The rule-set is inferred (which is why the rules contain imprecise values like 6.97) by the process we shall describe shortly.

We caution the reader against concluding from this small motivating example that only simple, stateless, "templates with parameters / thresholds" type of algorithms can be expressed in this way. Rule sets are capable of capturing complex stateful behavior, as long as primitives encoding this state are made available for their use.

4.2 Decision trees and rules

We first learn binary decision trees [18] that encode conditions for specific outputs, *e.g.,* the video quality levels requested. Further, in such a decision tree, each path from the root to a leaf can be naturally interpreted as a descriptive rule capturing the conditions for the outcome at the leaf to be reached.

Consider a single-threshold decision: "If throughput < 5 Mbps, pick low quality; otherwise, pick high quality.". This can be captured in a 3-node tree with the conditional at its root, and the two outcomes as leaves. In this case, the rule-lengths, *i.e.,* the path lengths from the root to the leaves, are 1; and so is the number of "splits" in the tree.

Fig. 2 shows a more complex target decision plane with two inputs (along the x and y dimensions), where there are still only two outcomes (labels), but the data samples that map to these labels are separated by more complex logic. If we constrain the decision tree that approximates this decision plane to use rules of only length one, we can use only one line separating the labels, as shown in the top-left smaller figure. Allowing more and more complex (longer) rules, allows a tighter representation of the target decision plane. Of course, using too many rules risks overfitting, especially under noisy data that is typical in networking. Fortunately, our goal to obtain concise rule sets aligns well with that of avoiding overfitting and preserving generalization.

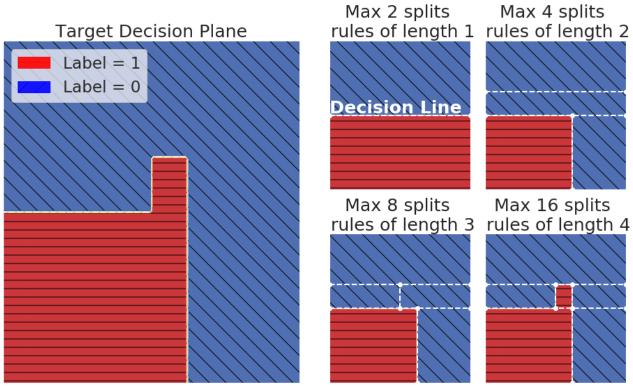

Fig. 2: The big image is the target decision plane, with 2 labels. On the right are its approximations with decision trees of different rule-lengths, going from 1 to 4.

Framing the output space: A key design consideration in using decision trees is the framing of the output decision space. Suppose we frame decision outcomes in terms of the video quality level that the client should fetch the next video chunk at. *If* all the videos being served were encoded with the same quality levels, both in terms of number and their bitrates, *e.g.,* 6 video qualities at bitrates of {200, 450, 750, 1200, 2350, 4300} Kbps, this would be easy: there are 6 *a priori* known outcomes that we can train decision trees for.

However, this is clearly overly restrictive: in practice, ABR algorithms must tackle a variety of videos encoded at different bitrates. The set of different bitrates at which a video is encoded in is referred to as its "bitrate ladder". Providers like Netflix even use per-video customization of bitrate ladders, varying the number and separation of bitrate levels [1]. This diversity in the output space is a challenge for learning approaches: what should we present as the potential output decision space? It is noteworthy that Pensieve [23] does not fully tackle this challenge, instead restricting the video bitrate levels to a small pre-defined set.

To overcome this issue, we formulate the decision process in terms of video quality being upgraded or downgraded relative to the current video quality. With one decision, a maximum of n quality shifts are permitted in either direction, with n being a tunable parameter. Of course, this prevents us from capturing some algorithms, where larger quality changes (than n) may be enforced in a single step. However, this is atypical, as video streaming typically targets smooth output. Even if some algorithm involves such decision making, our approach only differs from such a target's decisions transiently. This small compromise allows us to generalize to arbitrarily diverse video bitrate ladders.

[4] Readers may expect the rule-set in Fig. 1 to mean that *reservoir* $= 5$ and *cushion* $= 2$. The discrepancy stems from the discreteness of the interpolation: for some $\mathbb{T}_{N-1} >$ *reservoir i.e.,* $\mathbb{T}_{N-1} \in [4,5]$, quality 0 will be chosen.

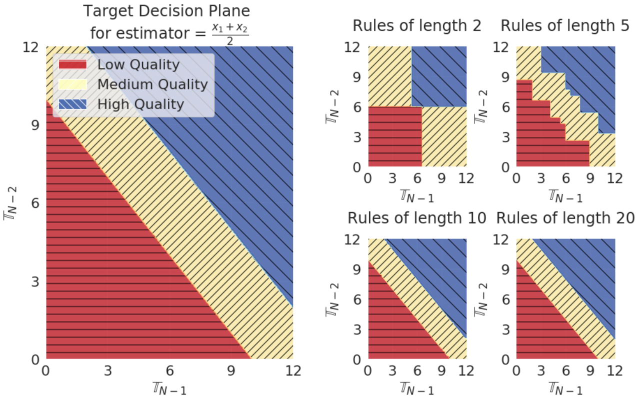

Fig. 3: Here, the target decision plane (big, left) is governed by the mean of $\mathbb{T}_{N-1}$ and $\mathbb{T}_{N-2}$. The smaller figures show that we need long rules to approximate this if we are restricted to using individual literals ($\mathbb{T}_{N-1}$ and $\mathbb{T}_{N-2}$) in our rules.

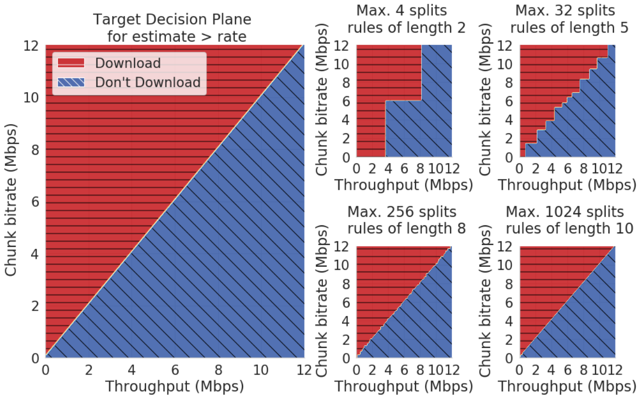

Fig. 4: A decision plane comparing the throughput estimate to the chunk bitrate is difficult to capture without long rules if rules can only be framed in terms of the individual literals.

4.3 Feature engineering

Applying textbook decision-tree inference, with the above framing, one can already infer simple algorithms. However, as we shall see, appropriate customization based on domain expertise is crucial to obtain concise and generalizable rules.

Consider, for instance, a target algorithm that uses the mean throughput across the last 2 video chunks fetched. Naively learnt rules will then contain complex conditionals across both $\mathbb{T}_{N-1}$ and $\mathbb{T}_{N-2}$. Fig. 3 shows this for rules of increasing length, up to 20. The target decision plane uses the mean, $\frac{\mathbb{T}_{N-1}+\mathbb{T}_{N-2}}{2}$ to decide between three video qualities. Rules of length 2 and 5 yield poor accuracy, necessitating much longer (complex) rules.

Of course, if we knew that the building block for throughput estimation is the mean, we could simplify such rules substantially by expressing them in terms of the mean. Thus, we can consider adding common estimators, based on our domain knowledge, to the feature-set available to our learning pipeline. Then, instead of only learning across primitive literals (like each individual chunk's throughput), more compact representation across these non-primitive literals becomes possible. We thus explore three classes of such non-primitive features that are intuitive and likely commonplace in ABR, and even more broadly, other networking algorithms.

Throughput estimators: Clearly, having the most accurate estimate of network throughput is advantageous in deciding on video quality. As such, throughput estimators are potentially useful building blocks. We consider two types of estimators. The first type is only parametrized by the number of past throughput measurements it aggregates using a mean, median, harmonic mean, etc., while the second type involves additional tunable parameters, such as the weight decrease, α, in an exponential weighted moving average (EWMA), which sets the relative weight of a new measurement compared to old measurements.

Encoding these estimators with a range of different parameter choices gives us a large set of features ranging from nearly stateless (*e.g.,* using only the last chunk's throughput) to those with long-term state (*e.g.,* a moving average). In addition to throughput, we also construct features capturing the *variation* across recent throughput measurements as it characterizes the stability of the network.

Comparisons: Decisions often depend on not just thresholding of certain primitive or non-primitive features, but also on comparisons among features. For instance, generalizing even a simple rate-based algorithm to work for arbitrary videos encoded with different bitrate ladders requires a comparison: is the throughput larger than a particular step in the bitrate ladder? Unfortunately, while decision trees can capture such comparisons using only primitive features, they require a large number of rules to do so. This is shown in Fig. 4, where the decision trees with rules of length 2 and 5 do not accurately represent a simple comparison-based target decision plane.

Thus, we must encode potential comparisons of this type as non-primitive features. These can also be parameterized in a similar manner to the throughput estimators discussed above, *e.g.,* by what *factor* should one feature exceed another.

Planning ahead: ABR, like many other control tasks, is not only about making one decision in isolation, but also considering its longer-term influence. For instance, it might be interesting to estimate the max, min, or mean rebuffering one should expect given the decision to download a chunk at a certain quality, assuming the throughput stays the same. We design features along these lines, such as QoE in MPC [46].

More features? Over time more features can be added to enhance our approach without having to reason about their mutual interactions, as would be the case with incorporating new ideas into human-engineered routines. One could also extend this approach by adding automatically engineered features [13]. However, maintaining interpretability would require limiting the complexity of auto-generated features.

5 IMPLEMENTATION

We implement the rule inference pipeline in Python3. For the decision tree, we use the standard implementation provided by the scikit-learn library [30]. If not otherwise mentioned we use a maximum of 20 rules and limit one-step changes in quality to upgrading or downgrading by at most 2 quality levels. The 20-rule limit is somewhat arbitrarily chosen as a quantitative threshold for interpretability, but we also find that for our approach, more rules do not improve performance substantively in *most* cases. This threshold is essentially a hyperparameter that could be tuned by practitioners based on where they seek to operate in the tradeoff space involving interpretability, avoiding overfitting, and performance.

Baselines: To put our results in context, we compare them against three neural network approaches, both as-is (blackbox approaches, always represented by a recursive neural network with GRU cells [7]), and translated to decision trees. The first blackbox approach is the simplest, attempting to directly copy the decisions in a supervised learning setting. The other two use more sophisticated imitation learning methods [14, 42].

For translating the blackbox approaches into decision trees, we test two state-of-the-art methods [5, 34]. One of these [5] needs a reward function. In the vein of other imitation learning approaches, we use a clustering algorithm to assign a similarity reward to every sample. In our implementation we use an isolation forest [22] implemented in scikit-learn [30] with the standard parameters as our clustering approach. At every training step, we sample 3000 samples (as this gave the best results) according to the cluster weighting. We also tried changing the weighting function to a more agnostic divergence measure as the proposed decision by the blackbox approach might not always be what the original algorithm had in mind. This makes the sampling approach more robust.

For each reconstruction, when we compare results to our approach, we use the best blackbox approach and the best tree-translation. Thus, we invested substantial effort in implementing sophisticated baselines from the ML literature.

We also test whether our approach benefits from learning from the blackbox, instead of directly from the data. We find that this yields only minor improvements for 2 of our 10 reconstruction targets. We also explore learning in two passes, where in the first pass, we learn a tree over engineered features, and use a classifier to label its decisions in terms of their similarity to decisions made by the reconstruction target. In the second pass, we re-learn across weighted data samples, such that samples corresponding to more similar decisions are weighted higher. This approach also results in only minor improvements for one of our ten reconstruction targets.

Feature engineering: We instantiate our features (§4.3) with appropriate parameter ranges as below. 'Action' refers to quality decisions, such as maintaining quality, or increasing or decreasing it by up to n quality levels. The 'any' operator instantiates all options for a parameter or primitive.

1. Standard deviation, mean, harmonic mean, EWMA, and q^{th} percentile over the last $\boldsymbol{n}$ chunks, with $n \in \{1 \ldots 10\}$. Additionally, for EWMA, $\boldsymbol{\alpha} \in \{0.15, 0.35, 0.55, 0.75, 0.95\}$.
2. For q^{th} percentile, $\boldsymbol{q} \in \{15, 35, 55, 75, 95\}$.
3. Reward $\mathcal{R}$ achievable by planning ahead 3 steps for **any** action with **any** throughput estimate. The 'any' operators here imply that we have numerous reward features, each of which combines one of the many available throughput estimators (from 1. and 2. above) with one of the possible actions. As the reward function, we use the linear QoE function introduced by Yin et al. [46], which converts bitrate, buffering and bitrate change per chunk downloaded into a score. Note that this is not necessarily what any of our reconstruction targets is optimizing for – each provider may have their own reward goals. We use this feature simply as a compact representation of QoE components.
4. Fetch time for **any** action, **any** throughput estimate.
5. Bitrate gained weighted by the buffer filling ratio for **any** action, **any** throughput estimate. Intuitively, this captures the gain in bitrate relative to its cost, *i.e.,* how much the buffer is drained by an action if throughput stays the same.
6. VMAF gained weighted by the buffer filling ratio for **any** action, **any** throughput estimate. Same as above, but with VMAF.

Ultimately we make ~ 1300 features available to the learner. Note the multiplicative effect of the **any** operator above.

Throughout, we use a standard training, validation, and testing methodology. The test set contains two videos combined at random with 60 traces randomly sampled from the overall set; these 60 traces are *neither* in the training nor in the validation set. We only discuss results over the test set.

Automated Feature Engineering: As a comparison and future outlook on the possibility of automated feature engineering, which has shown promise in other applications [13], we also coarsely implement an automated feature generator. This generator recombines the raw features in an iterative fashion so that the most used features "survive" and get recombined and the others "die" out. We use the library gplearn [39] with basic mathematical operators as usable functions. We limit the iterations to $s \in [50, 100, 150]$ seconds to avoid overfitting.

6 EVALUATION

We summarize below the experiments we conducted as well as their top-line conclusions:

1. How well can we reconstruct target algorithms? We can mimic the decision-making of 7 of 10 targets to a high degree, and obtain high similarity scores.
2. What influence does domain knowledge have? Certain engineered features are crucial to obtain rules that gen-

eralize beyond training data, are concise, and achieve similar QoE as the target algorithms.

3. How interpretable and generalizable are the output rule sets? We find that we can easily spot flaws in the learned algorithm and propose ways to adapt it. Further, trees with only 20 leaves suffice in most cases.
4. How do deployed ABRs compare to academic ones? We find that academic ABRs generally outperform industrial ones, with the caveat that our evaluation uses metrics from academic work. Interestingly, we observe that one provider's algorithm shows behavior closely matching the well known BOLA algorithm, indicating potentially that this provider uses BOLA or a derivative of it.

6.1 Experimental methodology

Target platforms: We use the same 10 popular streaming platforms we used in our measurement study of deployed ABRs [21]. While certainly not exhaustive, this is a diverse set of platforms, including some of the largest, such as Twitch and YouTube; some regionally focused, such as Arte, SRF, and ZDF; and some serving specific content verticals, such as Vimeo (artistic content), TubiTV (movies and TV), and Pornhub and XVideos. We exclude Netflix, Hulu, and Amazon Prime because their terms of service prohibit robotic interaction with their services [21].

Different platforms encode content at varied resolutions and number of resolutions, ranging from 3 quality levels for TubiTV to 6.5 on YouTube (on average across our test videos; YouTube has available resolutions for different videos.) For Twitch, which offers both live streams and video-on-demand of archived live streams, we only study the latter, as live streaming is a substantially different problem, and a poor fit with the rest of our chosen platforms. For several of the providers we study, there are multiple implementations, such as for desktop browsers, mobile browsers, or mobile apps; we only attempt reconstruction for the desktop versions.

We also evaluate our ability to emulate well-known academic approaches for ABR. We use the Robust-MPC (henceforth, just MPC throughout) and Multi-Video Pensieve (henceforth, NN, because it uses a neural network approach) implementation provided by the authors of the Pensieve paper [24]. We train and test these approaches on the Twitch video data set. To speed up our experiments, for MPC, we use a lookahead of 3 chunks instead of 5, finding that this did not make a large difference in performance.

Videos: The type of content can have a substantial bearing on streaming performance, *e.g.,* videos with highly variable encoding can be challenging for ABR. We thus used a set of 10 videos on each platform. Where a popularity measure was available, we used the most popular videos; otherwise, we handpicked a sample of different types of videos. Videos from each platform are encoded in broadly similar bitrate ranges, with most differences lying at higher qualities, *e.g.,* some content being available in 4K.

Network traces: Our experiments use synthetic and real-world traces from 3 datasets in past work [3, 8, 32]. Unfortunately, a full cross-product of platform-video-trace would be prohibitively expensive — the FCC traces [8] alone would require 4 years of streaming time. To sidestep this while still testing a diversity of traces, we rank traces by their throughput variability, and pick traces with the highest and lowest variability, together with some randomly sampled ones.

Our final network trace collection consists of the 5 least stable, 5 most stable, and 20 random traces from the Belgium trace collection [40]; and 10 most/least stable ones plus 25 random traces from each of the Norway [32], the Oboe [3] and the FCC datasets.[5] We also use 15 constant bandwidth traces covering the range from 0.3 to 15 Mbps uniformly. Lastly we add 10 step traces: after 60 seconds of streaming we suddenly increase/drop the bandwidth from/to 1 Mbps to/from 5 values covering the space from 1.5 to 10 Mbps uniformly. If a trace does not cover the whole experiment, we loop over it.

In total, we use 190 traces with throughput (average over time for each trace) ranging from 0.09 to 41.43 Mbps, with an average of 6.13 Mbps across traces. Note that we make no claim of our set of traces being representative; rather our goal is to test a *variety* of traces.

Evaluation metrics: For training our approach and evaluating its accuracy in a manner standard in learning literature, we use two metrics: one measures *agreement*, and another the *similarity* of sets of decisions. We train towards maximizing the harmonic mean of these. Additionally, for our ABR-specific use-case, we evaluate the video quality of experience [28].

Agreement, F_1 score: For each output decision, we compute the precision and recall of the inferred algorithm against its target. The F_1 score is the harmonic mean of these. $F_1 \in [0,1]$, with 1.0 being optimal. We compute an average over the F_1 scores across the labels in an unweighted fashion.

What is high/low agreement? If we were not interested in interpretability, we could obtain a procedure that mimics any target algorithm by using blackbox learning. We can think of the agreement such a blackbox approach achieves with its target as a baseline free of our conciseness constraint. On the other end of the spectrum, if the inferred rules do not achieve substantially higher agreement with the target than a generic 'reasonable' algorithm, then they are useless: this implies any reasonable algorithm would make at least that many decisions similar to the target. We use the simple rate-based approach as the concrete stand-in for this generic reasonable algorithm.

Similarity: As we cannot assume anything about how each provider designs their algorithm, we must use an agnostic approach in evaluating whether the experience under our reconstruction and the actual ABR is the same. Thus, we choose, as is typical in imitation learning, to learn whether the ex-

[5] Specifically, the stable collection from September 2017 [8].

perience of two streaming sessions is "similar". Similarity measures whether a set of samples (our reconstruction's decisions) is likely to be from a given distribution (the actual ABR's decisions). To classify whether a particular decision looks like it has been taken by the actual ABR or by our reconstruction, we choose an isolation forest [22].

Each of these two metrics is insufficient on its own. High agreement is useful, but making a few important decisions differently can substantially change a video stream's behavior. Thus the need for similarity. However, there's a benign solution to achieving high similarity: most commercial providers tend to keep the quality stable, so, by just keeping the same quality one can get high similarity. Conversely, agreement solves this problem: to get high agreement, we must match a large fraction of *each* decision type, matching only the "keep quality" decisions will result in poor agreement because of low matches on quality changes.

QoE: Agreement and similarity can be thought of as "micro-benchmarks" – these are standard measures in imitation learning, and are useful both for training our approach, and evaluating its learning accuracy. But ultimately, we also want to know: "How different is the user experience from an ABR versus from our reconstruction of it?". We thus directly compare how well different components of a visual QoE metric used in earlier work [28] match up between a target and its reconstruction. As we show below, agreement and similarity correlate well with QoE: when a reconstruction achieves high agreement and similarity, it typically also performs like the target algorithm in terms of different QoE components.

Finally, we also comment on the role of domain knowledge in achieving good results with our approach, and the interpretability of our reconstructions.

6.2 Results

Agreement and similarity, Fig. 5: We compare the agreement and similarity achieved by our rule-set approach against the (best) blackbox approach and the simple rate baselines across all 10 online providers. We also include MPC and Pensieve (NN) evaluated on the Twitch videos.

The rule-sets achieve nearly the same or better agreement than the blackbox approach achieves for a reconstruction target in each case – in the worst case (NN), the rule-set's agreement score is 8% lower. Note that in many cases, we achieve higher agreement than even the blackbox approach. This is due to the imitation learning approaches trying to achieve higher similarity in terms of behavior rather than matching each individual quality decision.

The rule-sets also achieve high similarity in most cases, in the worst case (Twitch), achieving a ≈20% lower similarity score than the best blackbox approach, and in the mean, 5% higher. In contrast, the rate-based approach achieves not only very low agreement, but also very poor similarity.

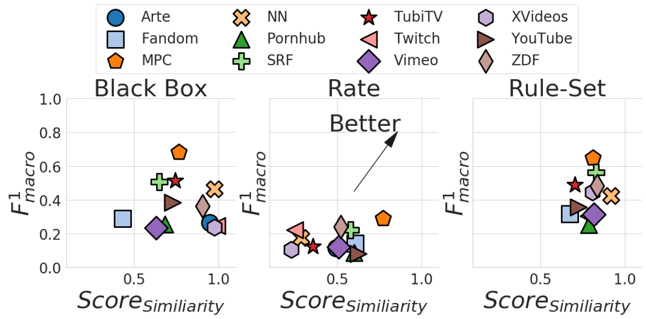

Fig. 5: The generated rule-sets are never worse by more than 8% and 20% than the blackbox approach on agreement and similarity respectively. In contrast, the rate-based approach achieves extremely poor results.

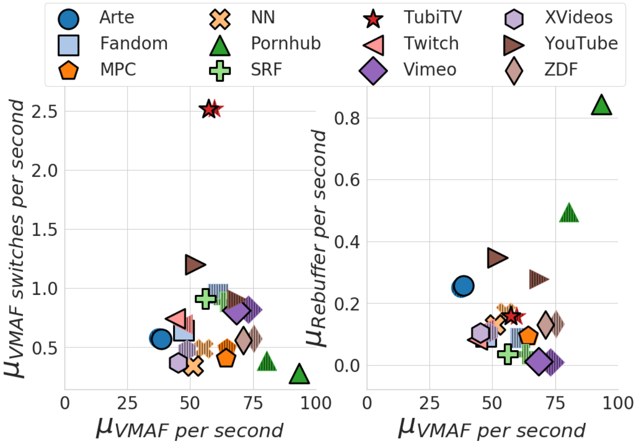

Fig. 6: For all but 3 of the 12 targets, the reconstruction matches the target algorithm very closely. For YouTube, Fandom, and PornHub, there is a substantial difference in performance; these are the same 3 providers in the bottom-left of Fig. 5, for which we achieve the lowest agreement and similarity scores as well.

Some readers may interpret the "low" absolute numbers in Fig. 5, *e.g.,* $F_1 \sim 50\%$, as a negative result. However, note that F_1 differences often don't cause appreciable video session quality differences, *e.g.,* if an ABR switches two quality levels in one step, and its reconstruction switches them in two successive steps, the F_1 score is lowered *twice*, but the video stream behavior changes negligibly. Also, rare labels (*e.g.,* increase quality by three levels) contribute equally to F_1 as common ones (*e.g.,* retain quality), so a few errors on rare labels have out-sized effect.

Video session quality metrics, Fig. 6: We compare metrics used to quantify video playback quality — VMAF [20], VMAF switches, and rebuffers – as seen in the actual algorithm (hatched points in the plot) and its rule-set reconstruction (solid points) across the same set of ABRs as in Fig. 5. For 9 of 12 targets, we achieve a very good match: the mean VMAF (x-axis in Fig. 6) for these 9 reconstructions is within 6% of the target ABR's on average; the maximum VMAF difference is 12%. These good matches include Twitch, SRF, Arte, ZDF, TubiTV, XVideos, Vimeo, MPC, and Pensieve (NN). On the other hand, for the other 3, YouTube, PornHub, and Fandom, there are large discrepancies, with quality metrics being very different for the reconstruction compared to the target. That our reconstruction does not yield good results on these targets is also supported by exactly these ABRs being in the low-agreement-low-similarity part of Fig. 5 (bottom-left in the rightmost plot). We further investigated these 3 negative results:

1. YouTube, in addition to making quality decisions, varies its segment length and can also redownload low-quality chunks to replace them with high-quality ones [27]. Ultimately, learning approaches will not frame new decision spaces, only logic for arriving at the asked-for decisions – in essence, YouTube is solving a different problem than we expected. This is a fundamental gap for efforts like ours: if the *decision space* is not appropriately encoded, outcomes will be sub-optimal. We could add the relevant primitives to achieve better results, but we resist such modifications that use the benefit of hindsight.
2. In a similar vein, we find that PornHub often switches to a progressive download, disabling video quality adaptation altogether. Our approach ends up overfitting to the progressive behaviour as we see few switches. If we exclude data where adaptation is disabled, we're able to match PornHub to within 4%, 0%, and 5% difference in terms of mean VMAF, rebuffering, and switching respectively.
3. For Fandom, we find that the issue is the limited complexity of our tree. A rule-set with a somewhat higher complexity (31 rules) performs substantially better, diverging from the target algorithm by 5%, 11%, and 22% in terms of mean VMAF, rebuffering, and switching respectively. Note that rebuffering and switching, being infrequent events are extremely difficult to *always* match, so a somewhat larger difference there is expected. As noted earlier, the rule-count is a hyperparameter that may need tuning for certain providers.

Role of domain knowledge, Fig. 8, 7: We already discussed in §4 why the use of domain knowledge is critical for interpretation: without simple primitives like moving averages, rules are framed in terms of various basic literals, resulting in complex and incomprehensible rules. Besides interpretation, we find that there is also substantial impact on agreement from adding useful domain knowledge.

We used our modified version of the DASH player to evaluate how the different trees emulating robust MPC generalize to other videos. We selected a mixed subset of 60 traces, that both include challenging and stable throughput measure and generated the distribution across them of linear QoE used in the MPC work [28]. Results are normalized to the mean QoE for the ground-truth MPC implementation across the same video-trace set.

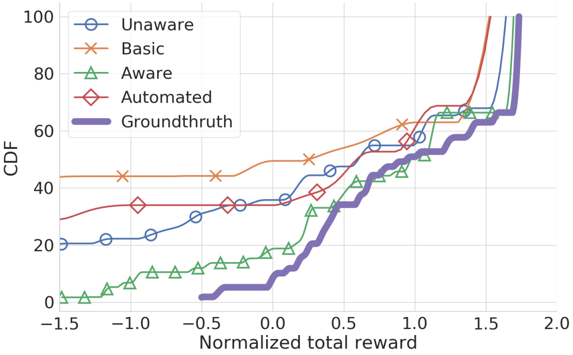

Fig. 7: Domain knowledge helps the rule-set (Bitrate-QoE).

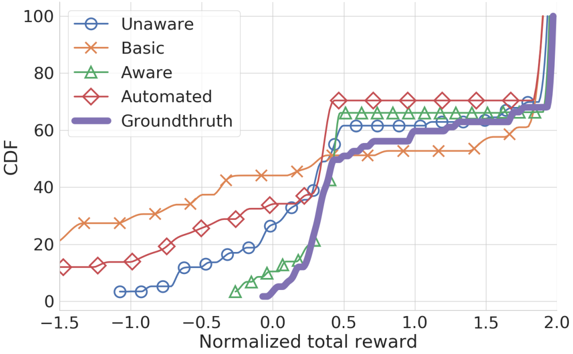

Fig. 8: Domain knowledge helps the rule-set (VMAF-QoE).

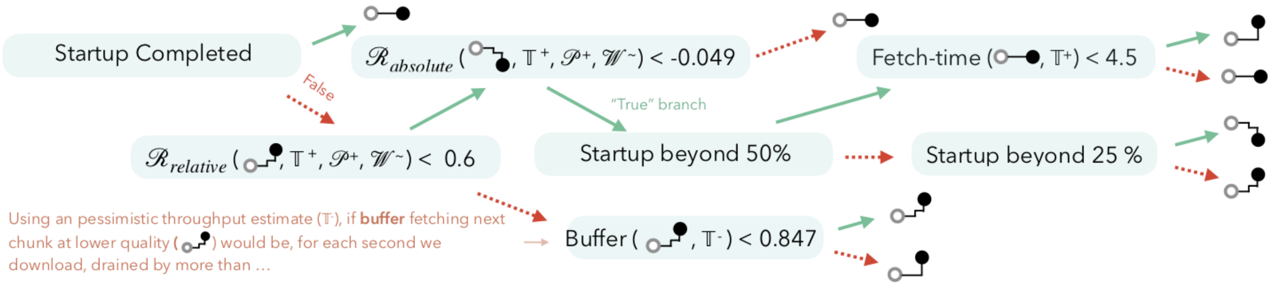
Fig. 7 shows how the rule-set reacts to additional building blocks being available for reconstruction in the form of engineered features. The 'Basic' rule-set is framed directly on the data features listed in §3, without any feature engineering. The 'Unaware' and 'Aware' approaches use several engineered features, as described in §4. The difference between them stems from the 'Unaware' approach only using engineered features related to buffer filling and draining in addition to the primitive data features. The 'Aware' approach with the benefit of all engineered features matches MPC the closest. 'Aware' improves average QoE over 'Unaware' by ∼5×. Thus, encoding domain knowledge helps not only with conciseness, but also performance and generalization. Also of note is the 'Automated' approach, which starts with the 'Basic' features, but can recombine them in the fashion described in §5. While promising for future exploration, it presently performs worse than manually engineering features, and does not produce features that are meaningful to humans.

Fig. 8 repeats the above experiment, but for a VMAF-based QoE function. The results are similar to those for bitrate -QoE. The average QoE of the 'Aware' reconstruction is within 10% of that of the target MPC algorithm, the median being within 2%. This is especially significant because we did not engineer any explicit features similar to this QoE function.

Interpretability: Across our efforts on reconstruction, the



Startup Completed
$\mathscr{R}_{absolute}$ (, $\mathbb{T}^+$, $\mathscr{P}^+$, $\mathscr{W}^-$) < -0.049
Fetch-time (, $\mathbb{T}^+$) < 4.5
False

$\mathscr{R}_{relative}$ (, $\mathbb{T}^+$, $\mathscr{P}^+$, $\mathscr{W}^-$) < 0.6
Startup beyond 50%
Startup beyond 25 %
Using an pessimistic throughput estimate ($\mathbb{T}^-$), if buffer fetching next chunk at lower quality ( ) would be, for each second we download, drained by more than …
Buffer (, $\mathbb{T}^-$) < 0.847

Fig. 9: The core of the decision tree generated by learning from the SRF example data. The green (solid) and red (dashed) arrows are the "True" and "False" evaluations of the predicates at the nodes. The video quality of the last fetched chunk is denoted by ○ and the next chunk's by ● . Potential decisions and decision outcomes are coded in terms of the relationships between these qualities: *e.g.,* ○↗● denotes that the next chunk is requested at one higher video quality level. The predicates are in terms of expected buffer size after a certain potential decision, based on throughput estimates (*e.g.,* $\mathbb{T}^+$ is an aggressive/optimistic estimator); or on a reward ($\mathscr{R}_{relative}$) calculated relative to the other obtainable rewards involving throughput, rebuffering penalty ($\mathscr{P}$), the lookahead horizon over which these are estimated ($\mathscr{W}$), etc.

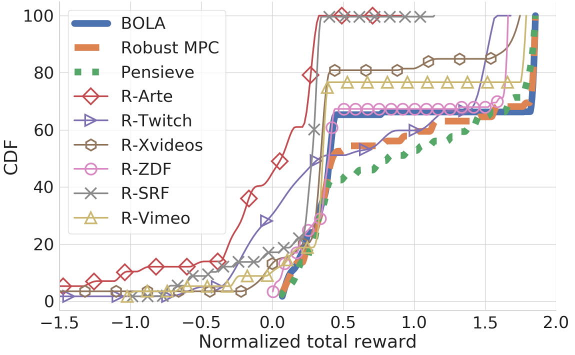

Fig. 10: Reconstructing commercial ABR algorithms allows us to uniformly compare them to both other commercial and academic ones under the same test conditions.

generated rule sets are concise, with no more than 20 rules. We realized early that being able to read and understand the generated trees would make debugging and improvements easier, and thus wrote a small, simple utility to translate the predicates in trees loosely into natural language. Fig. 9 shows an illustration of a tree generated for SRF. This version is hand-drawn for aesthetic reasons, but there is no fundamental reason it could not be auto-generated. Due to space constraints, this version is a compressed tree which was allowed to have at most 10 leaves instead of 20. We extensively examined and used our natural-language trees ourselves throughout this work, as we describe in a few instances in §7.

We also understand, to some extent, *why* small rule-sets suffice: (a) a single rule has implications capturing more than is plainly visible, *e.g.,* if the buffer is running too low, the best recourse is to lower quality, and not much new will be learnt from a long planning horizon; and (b) the domain-specific primitives are a dense encoding of useful knowledge. We caution readers against generalizing these observations to imply that small rule-sets will necessarily suffice for other problems where learning is effective — our exploration and results are limited to ABR. That small rule-sets would suffice for many ABRs, is also supported by prior work [10] showing, for instance, that the neural network ABR approach, Pensieve, largely depends on only 3 features.

Comparing academic and industry ABRs, Fig. 10: For targets we can reconstruct well, having a reconstruction enables us to compare them to each other and academic ABRs in the same test harness. This is non-trivial without a reconstruction, as each video platform has a very different streaming setup in terms of encoding, server architecture, and player design. For instance, if one platform uses more encoding levels than another, then the same ABR algorithm can make more fine-grained decisions on this platform than on the one with coarser encoding. Therefore the same algorithm on the same video would perform differently across video platforms, making it difficult to compare ABRs across providers without removing such confounding factors in a common test harness.

To this end, we extend the DASH architecture [37] with implementations of the (rule-set) reconstructions for the 6 targets we are able to match most closely. The same setup has ground truth implementations for BOLA [38], MPC [46], and Pensieve [23]. We evaluate VMAF-QoE [28] using the Envivio video typically used in academic work, and normalize the results to the mean QoE for Pensieve.

As the results in Fig. 10 show, Pensieve and MPC generally outperform the deployed ABRs' reconstructions, although, for a subset of traces, R-Twitch achieves the same or better performance as MPC. This is perhaps not unsurprising: we are evaluating all providers with QoE functions used in academic literature, while the providers may, in fact, be optimizing for a different goal. Amongst the providers, R-Arte's ABR achieves the worst performance on this QoE metric.

But perhaps most striking is the distribution-wide extremely close match between R-ZDF and BOLA – except for a few outliers at the tails, for most video-trace pairs, their performance is virtually identical. Thus, it is likely that ZDF is using BOLA, or a derivative of it.

7 THE UTILITY OF INTERPRETABILITY

Human insight can be crucial to robust solutions that account for gaps and unanticipated changes in the data that drives the behavior of learned control procedures. We discuss several ways in which preserving the ability of expert designers to understand the decision procedure helps.

Tracing the input-output mapping: With concise decision trees, human experts can easily trace the decision process used for particular inputs or sets of inputs. For any input conditions, a path can be traced to a leaf (decision output), and for any output, how it was arrived at can be understood as well. Such tracing can allow easy debugging — "Why were bad outcomes seen for these traces?". This also opens the door to more rigorous analyses of the outcomes for sets of inputs, based on methods like symbolic execution [4].

Identifying potential issues: Experts can often identify overfitting and other problems *a priori* if they understand the procedure, as is the case with the concise decision trees we produce. Our experience itself revealed three such instances:

(1) One feature we encoded for use in our decision trees was a prospective reward from fetching the next chunks at different bitrates. This worked for most videos, giving good average performance. However, for some videos with much higher/lower average bitrate than most other videos, results were inferior. This is due to the reward function using absolute bitrates, and thus not being meaningful across videos. Defining reward in relative terms, *i.e.,* normalized to the maximum possible reward, addresses this issue. A blackbox method, by hiding from human experts the logic used in the rules, makes such improvements more challenging.

(2) We noticed that even after training across the sizable network traces used in past work, our rule sets largely depended on optimistic estimators for throughput, unlikely to work well in more challenging environments, *e.g.,* new geographies a video service expands to where connectivity is more limited and variable. To force more conservative behavior, we can either add such traces to the training data, or restrict the learning approach to use only conservative throughput estimators leading to more stable behavior. Another possibility is to add new features to detect situations where conservative or optimistic behavior would be appropriate. Note that while *given enough appropriate data* blackbox solutions would also potentially overcome such problems, this requires noticing the problem in the first place. Also, such data may not always be available: *e.g.,* if the video service performs poorly in a geography, users may self-select themselves out by dropping the service, thus further skewing the data.

(3) Early in our experiments, we observed a peculiar learned rule that translates to "Never fetch the lowest quality after 45 video chunks." This stemmed from overfitting due to training on one video with 49 chunks (on which most other academic ABR work is also evaluated), where even over a sizable set of traces, typically a large enough buffer was built such that the lowest quality was ruled out for the last few chunks. While this particular artifact would be unlikely to arise in a large provider's pipeline given enough diverse training data, similar problems may occur and go undetected in blackbox methods, especially when the underlying data changes, *e.g.,* if a short-form video service introduces longer videos.

Across these examples, blackboxes can hide problems that might otherwise have been obvious to human experts. Prior work [17] has found problems of this type, *e.g.,* Pensieve, even if conditions are highly favourable, does not always download the last chunk of a video at the highest quality.

Finally, when such problems do present themselves, the recourse with blackboxes, depending on the problem's nature, can involve blindly tinkering with the inputs to the blackbox approach until the outcomes improve, or adding extraneous safeguards for each discovered problem.

7.1 Examining two reconstructions

We next give a view of two reconstructions of different complexity: SRF (simplified, same as in Fig. 9) and Twitch.

Simplified SRF: The output tree reveals an intuitive structure and highlights obvious flaws as we discuss below. (These are only present in the simplification, and not SRF's full tree.)

Fig. 9's caption explains how to read the tree. First it checks the point in playback, concluding that it is in a startup phase *if* playtime is below a threshold. In the startup phase, it checks *if* the possible gain in Reward is large enough to warrant the leveling up by two levels. This is only done *if* we deplete the buffer by not too much when doing so; etc. Of course, behind these loose statements are concrete, parametrized features which describe what the particular throughput estimator is, what reward function is used, etc.

An interesting characteristic of the simplified-SRF tree is that there are no quality changes beyond the startup phase. This is clearly unsuitable in practice, and would be an obvious red flag to any domain expert examining this tree. The full tree does, in fact, use adaptation after startup too, although it is infrequent. We have verified this behavior experimentally as well, where SRF makes frequent quality switches during startup, and much fewer later.

Twitch: Having examined a small simplified tree, we discuss the (full) reconstruction for a more complex target, Twitch.

Twitch's tree visually reveals 3 "branches" of activity, which we call panic, cautious, and upbeat. The panic mode is entered when the throughput is very low. Here the tree is most likely to downgrade the quality by two levels to try to build up buffer, regardless of current buffer occupancy. An example trace captured online shows such behavior at roughly 100 s in playback in Fig. 11.

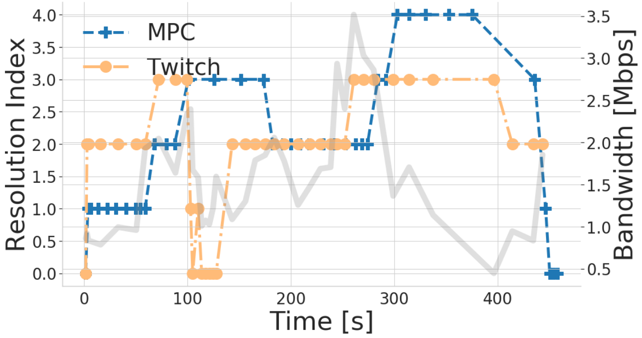

Fig. 11: Twitch shows only marginally more reluctance towards switching when compared to MPC

The cautious mode is entered at mediocre connection quality and, unlike the panic mode, examines the buffer level. In this mode, the most likely action is to either keep the quality or, if buffer-level is low, downgrade it. Downgrading can also be induced by high throughput variance, which indicates uncertain networking conditions.

If throughput is above mediocre, the tree enters the upbeat mode. Here the most common action is upgrading the quality, or if we approach higher quality levels (and therefore, longer download times even with good network conditions), the decision to upgrade is weighted against the buffer drain it would incur, and the current buffer occupancy.

Unlike several other providers, Twitch's reconstruction reveals a willingness to switch qualities often. This is in line with our experimental observation that Twitch and MPC make similar number of switches in the same conditions, while other providers switch much less frequently compared to MPC. Based on this analysis, if a switching-averse provider wanted to adopt Twitch's approach by reconstructing it, they would have to suitably tweak it to reduce switching.

To summarize, with interpretability, we can catch problems before they occur, reason about generalization and behavior across sets of operating conditions instead of just point testing, and methodically discover and fix encountered problems.

8 LIMITATIONS & FUTURE WORK

Over the course of this work, unsurprisingly, we uncovered several shortcomings of our approach, which offer interesting avenues for future exploration:

- Accurate and concise trees require intuitive primitives, *e.g.,* moving averages, which must be manually encoded (§4). Perhaps such primitives can be automatically captured from a corpus of available hand-designed networked algorithms. But this is likely a challenging task.
- We explored a limited set of features, some across only a small part of their possible parameter ranges, *e.g.,* only 5 discrete values for the α parameter in moving averages. A potentially highly effective avenue of improvement lies in tuning the features using a black box optimizer, *e.g.,* a Gaussian Process Optimizer [29], to suggest useful values.
- We can only train for an appropriately specified decision space, as is clear from the failure of our approach for YouTube (§6.2). We can expand the decision space with the benefit of manually-drawn observations from experiments, but automatically discovering it seems difficult.
- We do not expect our approach to always be able to match a target algorithm. However, failures of our approach also help: they often flag "atypical" ABR designs for manual analysis, like for YouTube and Pornhub, and could help uncover unknown (proprietary) insights.
- We used an intuitive but *subjective* definition of "interpretable": trees with under 20 leaves on domain-specific literals. Our own experience with understanding the results was positive, but we hope feedback from other researchers will help sharpen the interpretability goal for future work.
- For providers that customize their ABR for different regions and sets of clients, we can only reconstruct the behavior we observe from our test clients. For future work, this opens an interesting opportunity: observing differently-tuned versions of the same ABR, it may be possible to achieve higher-quality reconstructions, which also identify the parameters whose tuning varies across regions.

9 CONCLUSION

We take the first steps towards an ambitious goal: reconstructing unknown proprietary streaming algorithms in a human-interpretable manner. We customize and evaluate a rule-set approach, achieving good results for reproducing the behavior of algorithms deployed at several popular online services. Our approach produces succinct output open to expert interpretation and modification, and we discuss through several examples, the utility of this interpretability.

While promising, our results also expose a likely fundamental limitation — we need to encode and make available suitable domain knowledge to the learning approach. This can be interpreted as suggesting that we should reconcile learning with our already acquired human expertise, instead of starting afresh. We hope to apply this approach, suitably customized, to congestion control as well, where it is unclear how much diversity there is in actual deployment of different, unknown congestion control algorithms across popular Web services.

Midgress-aware traffic provisioning for content delivery

Abstract

Content delivery networks (CDNs) cache and deliver hundreds of trillions of user requests each day from hundreds of thousands of servers around the world. The traffic served by CDNs can be partitioned into hundreds of traffic classes, each with different user access patterns, popularity distributions, object sizes, and performance requirements. Midgress is the cache miss traffic between the CDN's servers and the content provider origins. A major goal of a CDN is to minimize its midgress, since higher midgress translates to higher bandwidth costs and increased user-perceived latency.

We propose algorithms that provision traffic classes to servers such that midgress is minimized. Using extensive traces from Akamai's CDN, we show that our midgress-aware traffic provisioning schemes can reduce midgress by nearly 20% in comparison with the midgress-unaware schemes currently in use. We also propose an efficient heuristic for traffic provisioning that achieves near-optimal midgress and is suitable for use in production settings. Further, we show how our algorithms can be extended to other settings that require minimum caching performance per traffic class and minimum content duplication for fault tolerance. Finally, our paper provides a strong case for implementing midgress-aware traffic provisioning in production CDNs.

1 Introduction

Content delivery networks (CDNs) carry more than 50% of all Internet traffic today [35] and that fraction is projected to increase over the coming years. Modern CDNs host a wide variety of content such as videos, software downloads, web pages, etc. that belong to hundreds of content providers. CDNs deploy hundreds of thousands of servers in clusters at the edge of the Internet to serve the hosted content to billions of end-users around the world. If the requested content is available in the edge server, a cache hit occurs and the end-user experiences a quicker response with lower latency. Otherwise, a cache miss occurs, and the edge server must fetch the content from the content provider's origin. A cache miss increases the user-perceived latency for a response and also increases the "midgress" traffic, which is the cache miss traffic between the CDN's edge servers and the content provider origins.

A CDN has many performance and cost objectives that must be optimized. Three important metrics are *origin offload* that is the amount of traffic offloaded from the origin servers, *end-user latency* that is the time between request and response for content as perceived by the end-user, and the *midgress bandwidth cost*[1] that is the cost of internal traffic in the CDN caused mainly due to cache misses at the edge servers. A metric that ties the three objectives together is the cache miss rate[2] which is the fraction of content bytes that were not present in the edge caches and needed to be fetched from origin. Smaller miss rate implies lesser cache miss traffic. Reduced cache miss traffic in turn implies increased origin offload, reduced end-user latency and reduced midgress bandwidth cost. Hence, minimizing the midgress, is a key performance objective from multiple perspectives.

Traffic classes. When users request content that is hosted on a CDN, the requests are classified into *traffic classes*. A traffic class is a collection of domains that host a specific type of content belonging to one or more content providers with similar requirements. For example, CNN videos and Apple iOS software downloads are each examples of a traffic class. Large CDNs host content that belong to hundreds of traffic classes. Recent work [66] has shown that traffic classes hosted on CDNs exhibit wide variations in popularity distributions, object size distributions and caching characteristics.

How CDNs serve content to users. Two interacting systems determine how content is served to users.

1) The *traffic provisioning system* decides which servers serve what fraction of each traffic class. Traffic provisioning

[1] The CDN also incurs a bandwidth cost for the "egress" traffic of content sent from the edge servers to the end-users. However, content providers pay the CDN for their egress traffic, while the midgress traffic is purely an overhead for the CDN operator that must be minimized.

[2] The miss rate metric that we use in this paper is sometimes called *byte* miss rate. An alternate definition is the (unweighted) fraction of *requests* that are cache misses and is less relevant for our work.

is performed periodically (say, once every few hours) as an *offline process* and uses the predicted user demand for the traffic classes and available server resources to produce an assignment of traffic classes to servers. Subsequently, each user request of each traffic class is routed [12] in *real-time* to a server that is provisioned to serve that traffic class[3].

2) Each CDN server has a cache that stores the content requested by users. Each server employs a *cache management system* that implements policies for managing the cache, such as an admission policy to decide what objects are cached and an eviction policy to decide what objects are evicted.

Minimizing midgress. The midgress bandwidth could cost tens of millions of dollars a year[4]. Thus, even a small reduction in midgress can be significant. Much of the prior work has focused on better cache management for reducing cache misses The past decades have seen research on numerous caching algorithms, such as Adapt-Size [4], Cliffhanger [15], SLRU [40], TLRU [23], S4LRU [34], CFLRU [59], ARC [53], LRU-S [65], LRU-K [56], and GDS [7]. However, the *complementary* problem of optimizing the traffic provisioning process to minimize midgress has not received much attention. In the current state-of-the-art, production CDNs assign traffic classes to servers with the goal of not overloading the servers, without explicitly minimizing midgress.

Our work shows that traffic provisioning in a midgress-aware manner can provide additional benefits to what can accrue from better cache management alone. Our traffic provisioning approach incorporates *both* traditional load balancing and the newer midgress considerations to minimize midgress traffic. *The main thesis of the paper is that by explicitly incorporating midgress considerations, it is possible to devise traffic provisioning schemes that minimize midgress traffic by nearly 20%, potentially resulting in millions of dollars of bandwidth cost savings.* Further, the midgress reduction due to better traffic provisioning is *complementary* to any improvements in cache management. As CDNs already implement traffic provisioning algorithms, albeit in a midgress-unaware manner, our contribution can be viewed as a drop-in replacement for an existing (midgress-unaware) traffic provisioning system.

Why be midgress-aware? "Midgress-aware" traffic provisioning algorithms explicitly incorporate cache miss traffic in addition to "balancing" the load. We illustrate the need for midgress awareness through a simple example. Consider two servers and three traffic classes. Each server has a cache size of 4 TB and sufficient capacity to serve all traffic classes. The three traffic classes have equal load of λ that need to be assigned to the two servers. The miss rate curves (MRCs) for the three traffic classes are as shown in Figure 1. The MRCs of traffic classes TC_1 and TC_3 flatten out quickly. This means that they require very little cache space to achieve the best possible performance. On the other hand, traffic class TC_2 has a slowly decreasing gradient. Thus, the miss rate of TC_2 keeps decreasing as more cache space is allocated to it.

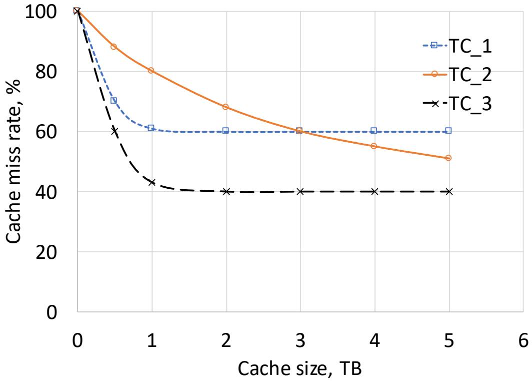

Figure 1: MRCs of traffic classes TC_1, TC_2 and TC_3.

Current traffic provisioning algorithms are *midgress-unaware* in that they only ensure that no server is overloaded. Such an algorithm could choose *any* assignment of traffic classes to servers, since any server has sufficient capacity to serve all classes, e.g., assigning TC_1 and TC_2 to server 1 and TC_3 to server 2 is one possible solution. More generally, any assignment with $(x+y+z)\times\lambda$ traffic to server 1 and $((1-x)+(1-y)+(1-x))\times\lambda$ traffic to server 2 is feasible, where x,y and $z\in[0,1]$, are the traffic fractions of TC_1, TC_2 and TC_3 respectively. Note that in this paper, we split the load of a traffic class by requests.

On the other hand, a midgress-aware algorithm would choose an assignment that minimizes the overall cache miss traffic from the two servers, while also ensuring that no server is overloaded. In the above example, assigning all of TC_1 and TC_3 to server 1 and all of TC_2 to server 2 would result in the least amount of cache miss traffic from the two servers. This is because TC_2 gets the largest cache space possible for its entire load and TC_1 and TC_3 get enough space to achieve the smallest cache miss rates.

1.1 Contributions

We make the following contributions.

1) We develop an optimization model for midgress-aware traffic provisioning that assigns traffic classes to servers in a manner that minimizes midgress traffic. The model is a non-convex mixed-integer linear program (MILP) that we solve using CPLEX. Our work is the first to explicitly model and minimize midgress in the traffic provisioning process. *Since a large CDN could incur a midgress of 10+ Tbps at a cost of $60+ million/year, even a small midgress reduction translates into large cost savings for the CDN.*

[3] The results of the traffic provisioning are used to create DNS records that can be resolved by the user in real-time using a DNS lookup [12].

[4] As a back-of-the-envelope calculation, a large CDN serving 50 Tbps of egress traffic at a 20% miss rate at the edge has a midgress traffic of 10 Tbps. The price of network bandwidth varies greatly throughout out the world. Though hard to estimate accurately, assuming a blended price of 50 cents per Mbps per month, midgress bandwidth costs 60 million dollars per year.

2) We apply our optimization solution to *metro-level traffic provisioning* where the traffic classes provisioned to server clusters within a metro area (e.g., NY city) are re-provisioned to minimize midgress. Metro-level traffic re-provisioning is a common operation, since the latency impact of moving a traffic classes across clusters within the same metro is likely minimal. Using extensive production traces from Akamai, we show that our midgress-aware traffic provisioning can reduce the midgress of a metro-area by 18.37% on average compared to midgress-unaware provisioning.

3) We also use our optimization solution for *cluster-level provisioning* where the traffic classes assigned to servers within a cluster are re-provisioned to minimize midgress. Cluster-level traffic (re-)provisioning is also a common operation since moving a traffic class across servers within the same cluster will likely not impact end-user latencies. Using production traces from Akamai's CDN, we show that cluster-level provisioning in conjunction with metro-level provisioning can reduce the midgress of a traffic class by 41.07% on average compared to midgress-unaware provisioning.

4) To be useful in practice, midgress-aware traffic provisioning has to be computationally efficient. We propose a midgress-aware heuristic called `local search` that is fast and near-optimal. The midgress achieved by `local search` was within 1.1% of optimal for both the metro-level and the cluster-level traffic provisioning. Further, in our experiments, `local search` completed in only 2 minutes, while finding the optimal took several hours.

5) We also show that our traffic provisioning algorithms are robust across different cache management policies and provide a midgress reduction in the range of 7.76% - 13.3%.

6) CDN operators often have to deal with additional constraints such as maintaining a certain level of traffic class redundancy or guaranteeing a minimum level of caching performance for traffic classes. We show how the optimization model for midgress-aware traffic provisioning and the heuristic algorithm, `local search`, can be extended to accommodate such constraints.

7) While the above results are for "shared" caches where a single unpartitioned cache is used to store objects from all traffic classes, we show that our traffic provisioning approach can be modified to work with "partitioned" caches where each traffic class is assigned a separate cache partition. We show that the midgress of partitioned caches can be reduced by more than 14% using our midgress-aware traffic provisioning approach, when compared to a midgress-unaware baseline.

1.2 Roadmap

The rest of the paper is organized as follows. In Section 2, we model midgress-aware traffic provisioning as a non-convex mixed-integer optimization problem. In Section 3, we propose a faster heuristic for midgress-aware traffic provisioning called `local search`, as well as a midgress-unaware baseline called `baseline fit`. In Section 4, we evaluate our optimization model and heuristics using extensive traces from Akamai's production CDN to empirically understand the midgress reduction achieved by our algorithms. In Section 5, we extend and evaluate our midgress-aware traffic provisioning algorithms to include other constraints such as minimum redundancy and maximum cache miss rates. Further, we extend our work to partitioned caches. We discuss some related work in Section 6 and conclude in Section 7.

2 Optimization model for traffic provisioning

We model traffic provisioning in a CDN as follows. We are given a set of N traffic classes. For each traffic class j, we are given the (predicted) amount of load of λ_j Gbps, $\forall j \in 1 \ldots N$. The predicted load for traffic provisioning is derived from historical load values for these classes by the CDN. Further, we are given M sites where the i^{th} site has a cache of size C_i TB and a capacity of T_i Gbps, $\forall i \in 1 \ldots M$. In cluster-level traffic provisioning, each site models a single CDN server within a cluster of M servers. In the more complex setting of metro-level traffic provisioning, we model an *entire* cluster as a single site within a metro area with M clusters. While not strictly accurate, we show that viewing the entire cluster as a single site in the metro-area setting is useful in practice. The capacity (resp. cache size) of each site is calculated as either the capacity (resp. cache size) of a single server in the former setting or as the aggregate capacity (resp. cache size) of the entire cluster in the latter setting. Henceforth, a site refers to a server in the cluster-level setting and a cluster in the metro-level setting.

The goal of traffic provisioning is to produce an assignment of traffic classes to sites, such that the total midgress across all the sites is minimized within the constraint that no site is assigned more load than its capacity. Note that a traffic class may be fractionally assigned across multiple sites, e.g., a traffic class with 10 Gbps of load can be assigned across two sites to host 7 Gpbs and 3 Gbps each of that class[5].

2.1 Modeling cache eviction and midgress

Given a site with an assignment of traffic classes, we need to model the miss traffic (i.e., midgress) that will result from serving those classes. The miss traffic is dependent on the cache management policies used by the sites. Nearly all production CDN caches use LRU (least-recently-used) variants as their eviction policy, since it is very efficient and achieves a comparable (byte) miss rate for typical CDN content traffic in comparison with other more complex eviction policies. For example, Akamai servers evict content using LRU, while admitting objects on second hit [47]. Production installations of the popular content caches Varnish [39] and NGINX [63]

[5] A CDN can implement such a fractionally-provisioned traffic class via a DNS mechanism that returns the ip address of the first site 70% and ip address of the second site 30% of the time.

also use LRU variants, as do recent academic work on content caching such as AdaptSize [4].

Production CDN servers also typically use a shared cache architecture where each server uses a single unpartitioned cache to serve all its traffic classes [66]. It is known that a partitioned cache that is sized in an optimal fashion can yield a greater reduction in midgress over a shared unpartitioned cache under the independent reference model (IRM) traffic assumptions [20]. However, in a production CDN, each server hosts a large number of traffic classes. Further, both the set of traffic classes hosted by a given server and the volume of traffic served per class by that server varies throughout the day. Thus, there is *significant* overhead involved in maintaining multiple cache partitions whose sizes must be dynamically varied throughout the day. The constant resizing of cache partitions could itself also lead to an increase in the midgress [61]. For these reasons, a shared unpartitioned cache is typically used by CDNs in practice.

In light of the above discussion, since our goal is to devise traffic provisioning algorithms to reduce midgress in production CDN settings, we develop a model for sites that use an LRU cache eviction policy with a shared cache architecture. But, later, we show empirically that our optimization model and algorithms produce a significant reduction in midgress, even if the CDN were to use other eviction policies (Section 4.3). Further, we show that our approach can also be easily extended to provide midgress reduction in a partitioned cache architecture (Section 5.3).

Eviction age equality. The eviction age of an object in cache is the difference between the time the object is evicted and the time that it was last accessed. In an LRU cache, at the time of access, the object goes to the head of the LRU list. Then, the eviction age of the object is the time for that object to move from the head to the tail of the LRU list and then get evicted. Thus, this time is about the same for all objects, when the size of an object is small with respect to the size of the cache. *We make the modeling assumption that the eviction age of all objects in cache are equal.* This assumption is also borne out in production caches and the common eviction age of the objects is logged as the eviction age of the cache.

The notion of eviction age can be extended to a traffic class by averaging the eviction age of all the requested objects from that traffic class. Since we model each object as having the same eviction age, all traffic classes assigned to a site share the same cache, and so they must have the same eviction age, which we also denote to be the eviction age of the cache. The eviction age of a cache has a direct relationship with the cache hit rate. Requests that have inter-arrival times less than or equal to the eviction age experience a cache hit and the rest experience a cache miss. So, for a given mix of traffic classes, as the cache size increases, the eviction age increases and so does the cache hit rate. Eviction age of a cache is similar to the concept of window size in [24]. Eviction age equality is crucial in our modeling of the midgress of traffic classes that share a single LRU cache.

2.2 Formulation of our optimization model

We now formulate our optimization model (referred to as OPT henceforth) for midgress-aware traffic provisioning.

Inputs of OPT. The input parameters used in the model are summarized in Table 1. We are given N traffic classes and M sites. The load λ_j of the j^{th} traffic class is given, for all $1 \leq j \leq N$. The cache size C_i and the capacity T_i of the i^{th} site is also given, for all $1 \leq i \leq M$. Further, for each traffic class, we are given the miss rate curve (MRC) and eviction age function as described below.

1) Miss rate curve (MRC), $\mathcal{M}_j(c)$. The MRC of a traffic class plots the cache miss rate as a function of cache size c. In this work, we assume that this function is convex (decreasing) which is generally true for stack-based algorithms [66]. As examples, MRC of two traffic classes, traffic class 2 and 14 (see Table 3) are shown in Figure 2.

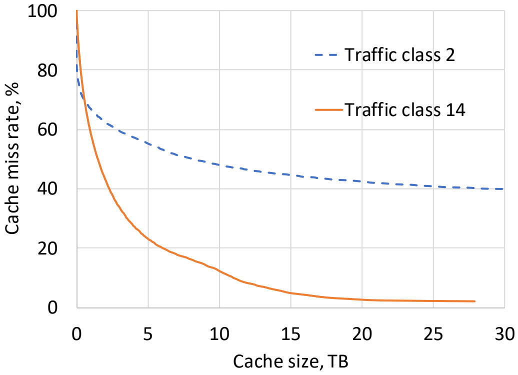

Figure 2: MRCs of two traffic classes.

From Figure 2, we can see that the MRCs are both convex. However, their gradients vary at different rates. Traffic class 2 has higher gradient at very small cache sizes but gradually flattens out as it reaches a cache space of 30 TB. Traffic class 14 on the other hand has a relatively high gradient until about 15 TB after which the MRC flattens out.

2) Eviction age function, $\mathcal{T}_j(c,\lambda)$. The eviction age function of a traffic class plots the eviction age at load λ as a function of the cache size c. The eviction age function also gives us information about *footprint pressure* of a traffic class, which is a relative measure of the amount of unique bytes accessed over a time period. A traffic class has high footprint pressure if a large number of unique bytes are accessed over a short time period. In this work, we assume that the eviction age function is convex (increasing) based on observations from production traces. The eviction age functions of two traffic classes, 2 and 14 (see Table 3) are shown in Figure 3.

From Figure 3, we can see that the eviction age functions are convex. As expected, at the given load, the eviction age increases with increase in cache size. Note that until about an eviction age of 2.1 days, traffic class 14 has higher footprint

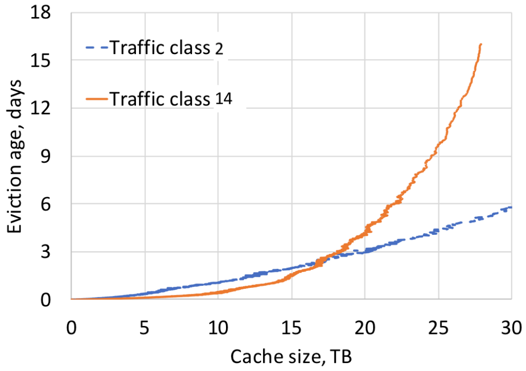

Figure 3: Eviction age functions of two traffic classes.

pressure when compared to traffic class 2, after which this behavior is flipped. Hence, if traffic classes 2 and 14 are assigned to the same site, traffic class 14 gets more cache space at smaller eviction ages ($\leq$ 2.1 days) due to higher footprint pressure and lesser cache space at larger eviction ages ($>$ 2.1 days) due to smaller footprint pressure.

To efficiently compute the MRC and eviction age function for every traffic class, we use a succinct space-time representation of the cacheability properties of a traffic class known as footprint descriptors [66].

We now briefly describe footprint descriptors.

Footprint descriptors. A footprint descriptor is a space-time representation of the caching properties of a traffic class. It is the joint probability distribution of the stack distance [51] (aka reuse distance) and the interarrival time distributions of a traffic class. A footprint descriptor can be used to determine the cache size and the eviction age that is required to achieve a certain cache hit rate, as a function of the traffic load. A footprint descriptor can also be used to determine the eviction age of a cache at different cache sizes and vice versa.

A reuse sequence is a sequence of requests where the first and the last request in the sequence is for the same object and that object is not requested anywhere else in that sequence. A simplified version of a footprint descriptor of a traffic class j is a tuple $<\lambda_j, P^r(s,t))>$ where λ_j is the load of traffic class j and $P^r(s,t)$ is the reuse-sequence descriptor which is the joint probability distribution that a reuse sequence of the traffic class has s unique bytes and time duration t. Given a footprint descriptor, the miss rate curve at cache size s is defined as $MRC(s) = 1 - \sum_{s' \leq s} \sum_{t} P^r(s',t)$. The eviction age function $\mathcal{T}_j(s,\lambda_j)$, is computed from $P^r(s,t)$ by plotting the duration t as a function of unique bytes s at load λ_j.

Given the footprint descriptor of different traffic classes, the footprint descriptor of a traffic mix can be computed using the addition operator ($\oplus$) of the footprint descriptor calculus [66]. The crux of the addition operation is the convolution of the joint probability distribution, $P^r(s,t)$, of all the traffic classes, which can be efficiently computed using the Fast Fourier Transform algorithm. The MRC of the traffic mix can then be computed from the footprint descriptor of the traffic mix as described above. Note that the request characteristics of a traffic class could change slowly over time, requiring the footprint descriptor to be recomputed periodically.

Outputs of OPT. The output parameters of OPT are presented in Table 2. The primary output is x_{ij} that represents the fraction of traffic class j assigned to site i.

Notation	Description
N	Number of traffic classes
M	Number of sites
λ_j	Load of traffic class j
$\mathcal{M}_j(c_{ij})$	Miss rate of traffic class j at cache capacity c_{ij} in site i
$\mathcal{T}_j(c_{ij},\lambda_j)$	Eviction age of traffic class j at cache capacity c_{ij} and load λ_j in site i
C_i	Cache size of site i
T_i	Capacity of site i

Table 1: Input parameters of optimization model.

Notation	Description
c_{ij}	Cache size occupied by traffic class j in site i
ρ_i	Eviction age of site i and of traffic classes assigned to site i
x_{ij}	Fraction of $\lambda_j \in [0,1]$ assigned to site i

Table 2: Output parameters of optimization model.

Objective function. The objective of midgress-aware traffic provisioning is to assign the N traffic classes to the M sites such that the midgress traffic from all the sites is minimized as follows.

$$\min. \sum_{i=1}^{M}\sum_{j=1}^{N} x_{ij}\lambda_j \mathcal{M}_j(c_{ij}) \tag{1}$$

Resource constraints. The first set of constraints are the cache size and the capacity constraints of each site.

$$\sum_{j=1}^{N} c_{ij} \leq C_i \quad \forall i = 1 \dots M \tag{2}$$

$$\sum_{j=1}^{N} x_{ij}\lambda_j \leq T_i \quad \forall i = 1 \dots M \tag{3}$$

The cache size constraint (Equation 2) states that the cache size occupied by all traffic classes assigned to all sites must not exceed the cache size of the site. The capacity constraint (Equation 3) states that the load of all traffic classes assigned to all sites should not exceed the capacity of the site.

Eviction age equality constraint. The eviction age function, $\mathcal{T}_j(c_{ij},\lambda_j)$ is defined at load λ_j for traffic class j. When traffic class j is assigned to site i, its load can be less than or equal to λ_j due to fractional assignments. Let the load of traffic class j assigned to site i be $\lambda'_j \leq \lambda_j$. Then, the eviction age of traffic class j in site i is.

$$\mathcal{T}_j(c_{ij},\lambda'_j) = \frac{\mathcal{T}_j(c_{ij},\lambda_j)}{\lambda'_j/\lambda_j} = \frac{\mathcal{T}_j(c_{ij},\lambda_j)}{x_{ij}} = \rho_i$$

The first equality is due to the fact that decreasing the load of a traffic class by a factor increases the eviction age of that class by the same factor, since eviction rate decreases by that factor. In the last equality, ρ_i is the eviction age of site i which is also the eviction age of all traffic classes that are assigned to site i. The eviction age equality constraint for all traffic classes at all sites is then given by

$$\mathcal{T}_j(c_{ij},\lambda_j) = \rho_i x_{ij} \quad \forall j(i) = 1 \ldots N(M). \tag{4}$$

As previously discussed, the eviction age equality constraint in Equation 4 establishes the condition under which traffic classes assigned to site i share the cache.

Load assignment constraint. The load of a given traffic class can be fractionally assigned across sites. This means that for some traffic class j, 50% of the load λ_j could be assigned to site 1, 30% to site 2 and the remaining 20% to site 3, and so on. The load assignment constraint ensures that all the load of each traffic class is assigned to one or more sites.

$$\sum_{i=1}^{M} x_{ij} = 1 \quad \forall j = 1 \ldots N \tag{5}$$

Non-negativity constraints. The output parameters ρ_i, c_{ij} and x_{ij} should be non-negative.

$$\rho_i > 0 \quad \forall i = 1 \ldots M \tag{6}$$

$$c_{ij} \geq 0 \quad \forall j = 1 \ldots N \tag{7}$$

$$x_{ij} \in [0,1] \quad \forall j(i) = 1 \ldots N(M) \tag{8}$$

Together, Equations 1-8 constitute the optimization model for midgress-aware traffic provisioning OPT.

2.3 Solving the optimization model OPT

The complexity of solving the optimization model OPT proposed in Section 2.2 is evaluated as follows. The objective function (Equation 1) is biconvex since the load fraction x_{ij} is linear and the MRC $\mathcal{M}_j(c_{ij})$ is convex. Equations 2-3, 5-8 are affine constraints. The eviction age function $\mathcal{T}_j(c_{ij})$ is convex and the product term $\rho_i x_{ij}$ is bilinear. Equation 4 is a non-convex constraint because the feasible set defined by this constraint is non-convex. Overall, the optimization problem is non-convex and in general an NP-hard problem. We make a number of mathematical transformations to convert the optimization problem to a mixed integer linear program (MILP), which in turn can be solved efficiently using CPLEX.

3 Traffic provisioning heuristics

The optimization model OPT proposed in Section 2.2 is an NP-hard problem and it can take several hours for a solver to obtain the exact optimal solution. A faster but approximate solution is valuable for a large production CDN that has hundreds of traffic classes, 1000+ clusters with deployments in every major metro region of the world. To that end, we propose a traffic provisioning heuristic called `local search` that is fast and sufficiently accurate to be used in production. Intuitively, our traffic provisioning heuristic is a “hill climbing” solution for our optimization model in Section 2.2. We also consider a midgress-unaware traffic provisioning algorithm called `baseline fit` that we use as a baseline to evaluate the benefits of being midgress-aware. The `baseline fit` algorithm is similar to the midgress-unaware algorithms currently used in production settings.

3.1 Midgress-unaware baseline

The midgress-unaware traffic provisioning algorithm called `baseline fit` (see Algorithm 1) is based on consistent hashing, similar to the algorithms used in production settings [47]. The algorithm takes as input the set of N traffic classes and the set of M sites that are both hashed to points on a unit circle. The traffic classes are picked in a random order and assigned to sites as follows. Each traffic class j is assigned to the nearest site i on the unit circle in the clockwise direction. If the chosen site i does not have enough capacity to host the entire load λ_j, then a first fit algorithm is used, starting from the chosen site i, and continuing to subsequent sites on the unit circle in the clockwise direction, until all traffic is assigned. The key point to note is that `baseline fit` does not explicitly minimize the miss traffic, but rather it only ensures that no site gets more load than its capacity. That is, it produces a *feasible* solution for our model OPT by obeying Equations 2 - 8, but does not minimize midgress.

Algorithm 1 `Baseline fit` algorithm

```
Input: $N, M, \lambda_j, C_i, T_i$
Output: Fraction of traffic class $j$ assigned to site $i$, $x_{ij}, \forall j(i) = 1 \ldots N(M)$
$x_{ij} = 0$
$TC_{set}$ = set of all traffic classes arranged in random order
$S_{set}$ = set of all sites hashed to a unit circle
for all $j \in TC_{set}$ do
    $i$ = Site chosen by consistent hashing
    if site $i$ has remaining traffic capacity $\geq \lambda_j$ then
        $x_{ij} += 1$
    else
        Assign traffic fraction $\lambda_j$ using first fit starting from site $i$ on the unit circle
```

3.2 Midgress-aware local search

We propose a midgress-aware traffic provisioning algorithm called `local search` (see Algorithm 2) that uses a hill climbing approach to solve the optimization model OPT. It is designed to be fast, but may not always produce the optimal solution. The algorithm `local search` begins with a feasible assignment as determined by `baseline fit`. The algorithm operates in rounds where every traffic class is picked one at a time in each round. The traffic class that is picked is reassigned in small increments of a fraction δ ($0 < \delta < 1$) of its load to the server that minimizes the midgress objective while maintaining feasibility. If a round does not decrease the midgress traffic objective by at least a specified $\varepsilon << 1$, the algorithm stops and outputs the final assignment.

Note that `local search` could end up in a local optimum that isn't close to the global optimum. However, `local search` is efficient enough that it can be run multiple times (in parallel) with different starting points to improve a suboptimal solution. We discuss the running time of `local search` in Section 4.

Computing the midgress of a traffic assignment. The `local search` algorithm requires an efficient way to compute the midgress traffic of each site, given a traffic class assignment. A known technique for computing miss traffic of a site is footprint descriptor calculus [66]. Knowing the footprint descriptor of each traffic class that is assigned to a site, we use the calculus to efficiently derive the footprint descriptor for the traffic mix, that in turn provides the MRC of the traffic mix, from which we derive the midgress of the traffic mix.

4 Experimental evaluation

Using production traces collected from a metro area of Akamai's CDN, we compare the midgress of OPT with that of `baseline fit` and `local search` in both metro-level and cluster-level traffic provisioning. We perform the evaluation in two steps: 1) We evaluate metro-level traffic provisioning by viewing each cluster as a site. The site is assumed to have cache size and capacity equal to the sum of the cache sizes and capacities of all servers in that cluster. The output of metro-level traffic provisioning is an assignment of traffic classes to clusters that minimizes the midgress of the metro area. 2) The output of metro-level traffic provisioning is the input to cluster-level traffic provisioning. We evaluate cluster-level traffic provisioning by assigning traffic classes to servers within a cluster to further minimize midgress.

Production traces. To perform our evaluation, we collect production traces from all Akamai CDN servers from a metro area serving traffic for 25 traffic classes over a period of 16 days. The characteristics of the traffic classes are listed in Table 3. From Table 3, we see that, in this metro area, 9 traffic classes serve web content, 11 traffic classes serve media content and the remaining 5 traffic classes serve software downloads. The traffic classes exhibit a wide variation in load (Gbps), arrival rate (requests/sec), content footprint (in unique bytes), and number of objects. The majority of the load is for media content at 47.3% followed by software downloads at 41.5% and web content at 11.2%. In terms of the unique bytes that are cached in the metro area, the majority is again for media content at 60.9%, followed by 25.6% for web content and 13.5% for software downloads.

Algorithm 2 `Local search` algorithm

```
Input: $N, M, \lambda_j, C_i, T_i$
Output: Fraction of traffic class $j$ assigned to site $i$, $x_{ij}, \forall j(i) = 1 \dots N(M)$
Get feasible assignment using baseline fit algorithm
$TC_{set}$ = set of all traffic classes arranged in random order
$S_{set}$ = set of all sites
while True do
    $mg_{curr}$ = midgress of current assignment
    for all $j \in TC_{set}$ do
        $x_{ij} = 0 \quad \forall i = 1 \dots M$
        $\lambda' = \lambda_j$
        while $\lambda' > 0$ do
            $S^j_{set} \subseteq S_{set}$ = set of all sites with remaining traffic capacity $\geq \delta\lambda_j$
            if $S^j_{set} \neq \emptyset$ then
                $i$ = site in $S^j_{set}$ that gives the lowest overall midgress after assigning TC $j$
                $x_{ij}$ += $\delta$
            else
                Assign load $\delta\lambda_j$ using fractional first fit starting from a random site
            $\lambda'$ −= $\delta$
    $mg_{new}$ = midgress of new assignment
    if $mg_{curr} - mg_{new} < \varepsilon$ then
        break
```

Footprint descriptors described in [66] are periodically computed for all traffic classes on the production CDN. We use these footprint descriptors to compute the MRCs and the eviction age functions for the 25 traffic classes in Table 3, to be used as inputs to our traffic provisioning algorithms.

Evaluation setup. To evaluate the traffic provisioning algorithms, we simulate a small metro region with 10 clusters, each containing 10 servers[6]. The capacity of the metro region is set so that the average load is 70% of capacity to reflect the load-to-capacity ratio in a typical CDN. We evaluate the traffic provisioning algorithms at different cache sizes per cluster of 1 TB, 5 TB, 10 TB, 20 TB, 40 TB and 50 TB. For simplicity, we assume that every cluster in the metro area has equal capacity and cache size. Every server within a cluster is also assumed to have equal capacity and cache size.

OPT is solved using CPLEX as part of the GAMS modeling

[6] While a metro region in a large CDN typically has much larger server deployments, we simulate a scaled-down version to keep our experiments computationally tractable.

Traffic class id	Content type	Load (Gbps)	Arrival rate (req/s)	Unique bytes (TB)	Unique objects (million)

Table 3: Traffic class characteristics

language. We use a macOS machine with a 3 GHz Intel Xeon processor with 10 cores and 128 GB RAM for all our experiments. The GAMS program is set to run in parallel mode using 20 threads with a relative optimality gap of 1e-9 and a maximum run time of 40,000 s. Given the complexity of the optimization model, the GAMS program almost always runs for 40,000 s. At that point, the solver has converged to a solution that seldom changes and achieves a relative gap of under 5% at smaller cluster cache sizes less than or equal to 10TB and a relative gap of under 10% at larger cache sizes. A single run of `baseline fit` takes about 1 s and a single run of `local search` takes about 120 s.

4.1 Metro-level traffic provisioning

We evaluate OPT, `baseline fit`, and `local search` by computing the cache miss rate of the entire 10-cluster metro area for different cache sizes. These three algorithms each assign the set of 25 input traffic classes to the clusters in the metro. In the case of `baseline fit` and `local search`, we report the average cache miss rate of 100 runs, where each run considers the traffic classes in a random order. The 95% confidence intervals of the expected cache miss rates have a margin of error of less than 0.4%.

From Figure 4 we can see that OPT gives a 18.37% reduction in midgress on average compared to the midgress-unaware `baseline fit` algorithm. This is because OPT takes into account the impact on midgress while assigning traffic classes to clusters in the metro area. This significant improvement in midgress makes the case for implementing midgress-aware traffic provisioning algorithms in CDNs.

From Figure 4, we also see that `local search` performs quite well and gives a 15.44% reduction in midgress on average compared to `baseline fit`. `local search` also performs fairly well compared to OPT, with a modest 3.69% increase in midgress compared to OPT on average.

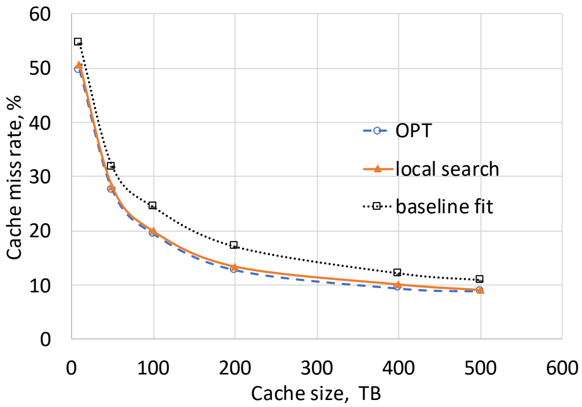

Figure 4: MRCs of OPT, `local search` and `baseline fit`.

4.1.1 How traffic provisioning impacts midgress

In Figure 5, we plot the cache miss rate of the 25 traffic classes when they are provisioned using OPT versus the midgress-unaware `baseline fit`, when the cumulative cache size of clusters in the metro area is 100TB. In addition, we also plot the average number of sites (across the 100 runs) that each traffic class is assigned to in Figure 6. From these figures, we see that OPT reduces the cache miss rate of 21 traffic classes when compared to `baseline fit`. In the case of traffic class 11, OPT results in almost 97% reduction in miss rate when compared to `baseline fit`. On the other hand, OPT increases the cache miss rate of four traffic classes, namely 4, 5, 13 and 19. By trading off the cache miss rates for these four traffic classes, OPT is able to reduce the overall midgress. But why does OPT choose this trade-off? There are three key insights that midgress-aware traffic provisioning takes into account to optimize midgress that `baseline fit` does not.

1) *In OPT's solution, traffic classes that have higher load, higher footprint pressure and greater MRC gradients get to occupy larger portions of the available cache space.* A traffic class has high footprint pressure if a large amount of unique content bytes is requested in a short period of time. This is true for traffic classes 11, 14, 15, 25 and 16 that account for 66.04% of the total load. OPT assigns traffic class 11 to two clusters because its load is greater than the capacity of a single cluster, resulting in that traffic class occupying 6 TB in one

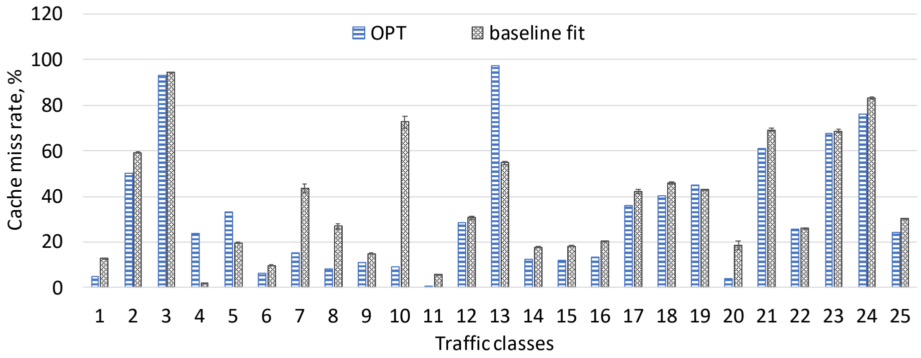

Figure 5: Average miss rate of each traffic class in a metro area of cache size 100 TB.

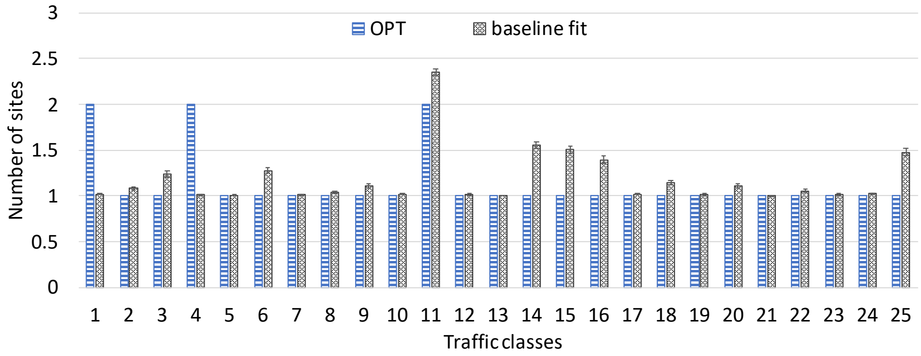

Figure 6: Average number of sites each traffic class is assigned to in a metro area of cache size 100 TB.

cluster with a miss rate of 0.5% and 7 TB in another cluster with a miss rate of nearly 0%. OPT also assigns an entire cluster each to traffic classes 14, 15, 25 and 16.

2) *OPT may split a traffic class and assigns it to multiple clusters if it has a relatively flat MRC.* This is true of traffic class 1 which has a relatively flat MRC and is assigned to two clusters. By reducing its footprint pressure in each of its assigned clusters, traffic class 1 is able to cede cache space to other traffic classes that are in more need.

3) *In OPT's solution, traffic classes that have lower footprint pressure occupy smaller portions of the available cache space.* This is true for traffic classes 4, 5 and 13. It also happens to be the case that these 3 traffic classes have very low load among the traffic classes considered. Both these factors render a higher cache miss rate relative to `baseline fit` that is midgress unaware. Note that low load alone does not indicate that it will occupy a smaller portion of the cache. For instance, traffic class 24 has moderate load but it has high footprint pressure and a greater MRC gradient, and ends up occupying 4.2 TB in one cluster.

4.2 Cluster-level traffic provisioning

The goal of cluster-level load balancing is to assign traffic classes to servers such that the midgress of the cluster is minimized. In our evaluation, we take the output of metro-level traffic provisioning from Section 4.1 that assigns traffic classes to each cluster and treat them as the inputs to cluster-level traffic provisioning. In this manner, we are able to understand the additional midgress reduction that is achievable by performing optimization at the cluster level, given that the metro level has already been optimized.

For cluster-level traffic provisioning, each traffic class defined at the metro-level is typically split into multiple finer-grained subclasses. The subclasses allow better allocation of traffic classes within a cluster. Traffic class 14 has very high load and hence was assigned to a cluster all by itself (Figure 6) by OPT at the metro-level. We considered that cluster for our evaluation of cluster-level traffic provisioning. Traffic class 14 consisted of 66 traffic subclasses that must be assigned to the 10 servers within a cluster, each server with a 1 TB cache.

OPT reduced the midgress for traffic class 14 by 31.26% after the metro-level optimization, when compared to the midgress achieved by `baseline fit`. Further, after using OPT for cluster-level provisioning, the midgress for traffic class 14 reduced further by 14.26%. In aggregate, the overall reduction of the midgress due to both provisioning steps of OPT is 41.07%, when compared to the baseline. Algorithm `local search` provided nearly as much reduction as OPT. For instance, `local search` provided a midgress reduction of 35.49%, compared to the baseline. However, `local search` was much faster and completed within 2 minutes, as opposed to the nearly 40,000 s (∼11 hours) taken by OPT.

4.3 Robustness to cache management policies

So far, we have developed traffic provisioning algorithms that model an LRU cache and evaluated the midgress reduction resulting when the sites also use LRU. The past decades have seen much academic research on numerous cache management algorithms that admit and evict objects using some combination of *recency* of access, *frequency* of access and object *size* to reduce cache miss rates (see Table 2 of [4]). We show that midgress-aware traffic provisioning algorithms proposed in this work, that model an LRU cache, achieve significant midgress reduction even when a CDN *does not* actually implement LRU at its sites.

We choose three typical algorithms from the literature for our evaluation. The first is an LRU variant called second-hit-LRU (or, SH-LRU) where the object is admitted to an LRU cache on second hit. The second is segmented LRU (SLRU) [40] that uses both recency and frequency for cache management. Finally, we implement the Greed-Dual-Size-Frequency (GDSF) [13] that uses all three of recency, frequency and size. Our evaluation uses the same cluster-level scenario as described in Section 4.2, where the goal is to assign the 66 traffic subclasses of traffic class 14 across 10 servers of size 1 TB each. First, we solve OPT that models LRU to get the optimal traffic class assignment across all servers within the cluster. The midgress of OPT's assignment is then computed by simulating the different cache management algorithms using the request traces of the subclasses. For comparison, we use the midgress-unaware `baseline fit` for traffic provisioning followed by a trace-based simulation of the different cache management algorithms to provide a baseline. When LRU cache management is used, OPT reduces the midgress by 13.3% when compared to `baseline fit`. In comparison, OPT reduces the midgress by 7.78%, 8.45% and 7.76% for SH-LRU, SLRU and GDSF respectively. The midgress reduction for the non-LRU algorithms is not as much as that for LRU. However, the midgress reductions for other algorithms are still quite robust and significant. The reason is that even when other factors are used for cache management decisions, most reasonable algorithms *still* use recency of access in a very significant way, and recency is well-captured in OPT. It is plausible that OPT can be reformulated to capture other cache management policies besides LRU and such an extension is a topic for future work.

5 Extending midgress-aware provisioning

We propose two extensions of midgress-aware traffic provisioning that address constraints in production settings. The first extension enforces a minimum number of sites that a traffic class must be assigned to and the second extension enforces a maximum cache miss rate per traffic class.

All results presented until now are for shared caches. While partitioned caches are not commonly used in production settings due to the overheads of dynamically resizing those partitions, there is increasing interest to implement and evaluate partitioned caches [1,5,9,14,16,21,25,36,43,44,46,62,67,69]. We propose a third extension to show that our traffic provisioning approach can reduce midgress in partitioned caches.

5.1 Minimum redundancy guarantee

Let M_j be the minimum number of sites that traffic class j should be assigned to. M_j is an integer $\in [1,M]$, where M is the total number of sites. Let y_{ij} be an indicator variable that is set to 1 when $x_{ij} > 0$ and 0 otherwise. Then, the load assignment constraint in Section 2.2 is appended to include the following minimum redundancy constraints.

$$y_{ij} = \lceil x_{ij} \rceil \quad \forall\, j = 1 \ldots N \tag{9}$$

$$\sum_{i=1}^{M} y_{ij} >= M_j \quad \forall\, j = 1 \ldots N \tag{10}$$

$$y_{ij} \in \{0,1\} \tag{11}$$

Equations 9 and 10 ensure that traffic class j is assigned to at least M_j sites. We call the modified optimization model OPT-M. The additional constraints are affine and they do not increase the complexity of the optimization problem. Both `local search` and `baseline fit` can also be modified to incorporate the redundancy constraint by simply ensuring that each traffic class j is assigned to at least M_j sites in each (re-)provisioning step.

Experimental evaluation. We measure the reduction in midgress by OPT-M and the modified `local search` when compared to the modified `baseline fit`. We use the same evaluation parameters as Section 4.1 where the cache size of each cluster in the metro area is 10 TB. We find that the cache miss rates increase with increase in redundancy for all three algorithms. We also find that the cache miss rate of `baseline fit` with minimum redundancy = 1 (resp. 2) is similar to the cache miss rate of `local search` and OPT-M with minimum redundancy 2 (resp. 3). This shows that midgress-aware traffic provisioning can provide the same midgress as `baseline fit` with added redundancy.

5.2 Maximum cache miss rate guarantee

Let MR_j be the maximum cache miss rate for traffic class j. Then, the optimization model in Section 2.2 can be extended to incorporate the maximum cache miss rate guarantee.

$$\sum_{i=1}^{M} x_{ij} m_j(c_{ij}) \leq MR_j \quad \forall j = 1 \ldots N \tag{12}$$

Equation 12 states that the average miss rate of traffic class j across all M sites should be at most MR_j. We call the modified optimization model, OPT-MR. Equation 12 is a biconvex constraint and doesn't increase the complexity of the problem.

We make two modifications to `local search`. First, `baseline fit` in the first step does not always provide a feasible solution when $MR_j < 100\%$. This is because `baseline fit` is midgress unaware. Hence, we start with all traffic classes being unassigned. Second, the re-provisioning step assigns a traffic class to a site only when the miss rate guarantees of all traffic classes assigned to that site are not violated.

Infeasible solutions. OPT-MR can be infeasible in cases where certain traffic classes fail to meet the maximum cache miss rate MR_j guarantee. For example consider a cache size of 10 TB. The lowest miss rate that traffic class 3 (Table 3) can possibly achieve at 10 TB is 91%. Hence, any maximum cache miss rate target less than 91% cannot be achieved.

Experimental evaluation. We choose traffic classes 13, 23 and 24 that have high miss rates in OPT and set their maximum cache miss rates to 70%. We evaluate the performance of metro-level traffic provisioning under the same conditions as in Section 4.1 where the cache size is 10 TB.

OPT-MR returns a feasible solution. The overall miss rate of the metro area is 20.04%, a 3.24% increase in midgress compared to OPT. In the process, three traffic classes experience a significant increase in their respective miss rates relative to OPT. The miss rate of traffic class 2 increases from 50.12% to 65.85%, of traffic class 17 from 36.11% to 54.2% and of traffic class 21 from 61.22% to 68.01%. This is because traffic classes 13 and 24 occupy more cache space with OPT-MR than they do in OPT, so they meet their miss rate guarantee, despite traffic class 13 having the lowest load and low footprint pressure, and traffic class 24 having low load.

We run the modified `local search` 100 times with different random orderings of the input traffic classes. `local search` returns a feasible solution 67% of the time indicating that its feasibility depends on the ordering of the traffic class inputs. For feasible assignments, `local search` has an average miss rate of 21.69%, about 8.23% more than that of OPT-MR. `baseline fit` is footprint-unaware and cannot guarantee cache miss rates.

5.3 Traffic provisioning in partitioned caches

In a partitioned cache, each traffic class is assigned to its own separate cache partition and each partition performs evictions independently. Production CDNs do not typically implement partitioned caches due to the significant overheads involved in implementing and dynamically maintaining the partitions. However, we show that our optimization model for midgress-aware traffic provisioning can be extended to work with partitioned caches.

Modeling and implementing traffic provisioning for partitioned caches. In partitioned caches, every traffic class occupies a separate partition with its own LRU list, assuming the LRU eviction policy. Thus, the eviction age of each traffic class assigned to the same cache can be different. Therefore, the optimization model for midgress-aware traffic provisioning for partitioned caches is the same as that of OPT (Section 2.2), minus the eviction age constraint. Hence, Equations 1-3 and 5-8 accurately model midgress minimization for partitioned caches. We call this modified model OPT-part.

We implement a baseline midgress-unaware algorithm called `baseline fit-part` for partitioned caches that is based on consistent hashing. The algorithm takes as input the set of N traffic classes and the set of M sites that are both hashed to points on a unit circle. Each traffic class j is assigned to the nearest site i on the unit circle in the clockwise direction. If the chosen site i does not have enough capacity to host the entire load λ_j, then a first fit algorithm is used, starting from the chosen site i, and continuing to subsequent sites on the circle in the clockwise direction, until all load is assigned. After all traffic class assignments are made, in each site, we determine the sizes of the partitions that host each traffic class. To compute the partition sizes, we use a known gradient descent algorithm [62] that minimizes the midgress of each site. The total midgress achieved by `baseline fit-part` is then the sum of the midgress across all sites.

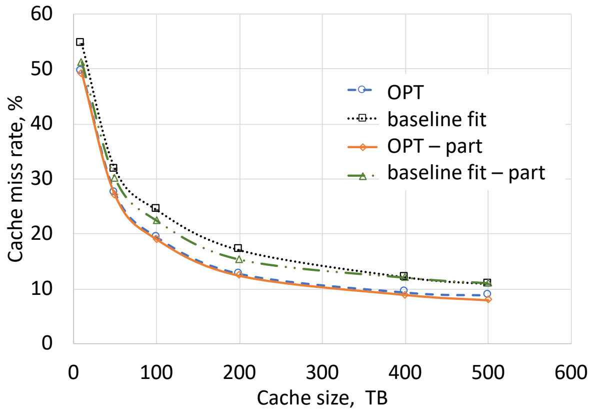

Figure 7: MRC of OPT and baseline fit on shared and partitioned caches.

Experimental evaluation. We evaluate `baseline fit-part` and OPT-part at the metro-level using production traces described in Section 4 and at different cache sizes per cluster of 1 TB, 5 TB, 10 TB, 20 TB, 40 TB and 50 TB. We report the average cache miss rate of 100 runs. The 95% confidence intervals of the expected cache miss rates have a margin of error of less than 0.4%.

As shown in Figure 7 we find that OPT-part reduces midgress when compared to `baseline fit-part` by more than 14%, on average across the different cache sizes. Thus midgress-aware traffic provisioning can significantly reduce the midgress even for partitioned caches. As comparison, in Figure 7, we also plot OPT and `baseline fit` that we described for shared caches in Sections 2 and 3. Interestingly, we find that the cache miss rate of OPT-part is only 0.49% less than that of OPT, on average across the different cache sizes. Hence, while OPT-part has the lowest cache miss rate, OPT has nearly the same miss rate without the additional overhead of cache partitioning.

5.3.1 Implementing cache partitioning for traffic provisioning in production settings

In the previous section, we have seen that cache partitioning can further reduce the midgress of a metro area since each traffic class occupies a separate partition and traffic classes assigned to the same site could have different eviction ages. But it is not implemented in practice for traffic provisioning due to the following reasons.

1) In large CDNs, many different traffic classes must share a cache. Further, the mix of traffic classes sharing a cache and their respective loads change frequently over time at the whim of the load balancer. To obtain the benefits of cache partitioning, the partitions need to be constantly resized by shrinking cache space for certain traffic classes and expanding the cache space for others. Such resizing is resource intensive. Further, constantly resizing dynamic partitions may not lead to lower midgress, especially during transitions between cache sizes. While partitioning the cache statically is easier to implement, static partitions do not adjust to changes in the traffic mix, leading to sub-optimal performance. On the other hand, an unpartitioned shared cache dynamically adjusts the cache space occupied by different traffic classes based on the load and the traffic characteristics, without the need for complex (re)partitioning operations.

2) From the previous section, we see that traffic provisioning in a shared unpartitioned cache provides nearly the same midgress as a partitioned cache. Thus, there is little incentive to redesign the traffic provisioning system to work with partitioned caches and incurring the additional software complexity and resource overhead.

For the reasons outlined above, the shared unpartitioned cache studied in our work is the implementation of choice for many major CDNs, including Akamai.

6 Related work

Traffic provisioning in CDNs has been studied in the context of load balancing. However, the load balancing algorithms focus on ensuring that servers are not overloaded and do not explicitly minimize midgress. Likewise, minimizing cache misses through better cache management policies has a rich literature. However, we view cache management as complementary to midgress-aware traffic provisioning. We review relevant existing literature in these areas.

Load balancing. Request redirection schemes at the network layer, based on DNS [8,32], and at the application layer, based on URL rewriting or HTTP redirection [48], have been proposed to load balance traffic across multiple servers. Dynamic load balancing algorithms [10, 11, 71] continuously measure the load on different servers and load balance end-user requests to improve performance. Consistent-hashing and randomized load balancing algorithms [41, 42, 54, 55] have also been proposed to load balance end-user requests in content delivery systems. Extensions to traditional load balancing, that minimize the energy consumption of CDNs [50] have also been proposed in the literature. Much of the work above are in the context of routing user requests in real-time to servers. But, they can be adapted to our context of performing (offline) traffic provisioning, a step that precedes request routing in a production CDN. *However, there is no prior work on explicitly minimizing midgress.*

Cache management. There has been a significant amount of research on cache management policies to minimize cache miss rates [2, 3, 6, 17–19, 22, 26–31, 33, 37, 38, 45, 49, 52, 57, 58, 60, 64, 68, 70]. Some proposed caching policies include Adapt-Size [4], Cliffhanger [15], SLRU [40], TLRU [23], S4LRU [34], CFLRU [59], ARC [53], LRU-S [65], LRU-K [56], and GDS [7]. Dynamically partitioning the cache to reduce miss rates has also been explored [1, 5, 9, 14, 16, 21, 25, 36, 43, 44, 46, 62, 67, 69]. However, production CDNs do not employ dynamically-partitioned caches since it introduces significant performance and operational overheads. We view work on cache management as a complementary technique to traffic provisioning, both with the goal of midgress reduction.

Recent work on footprint descriptors [66] is focused on efficient techniques for evaluating the miss rates of traffic mixes. We use footprint descriptors to quickly compute the midgress of a traffic class assignment, as well as to efficiently compute the MRC and eviction age function of traffic classes. However, the work on footprint descriptors does not minimize midgress.

7 Conclusion

We propose midgress-aware traffic provisioning that explicitly minimizes the midgress traffic of a CDN, while ensuring that no server or cluster is overloaded. Using extensive traces for 25 traffic classes from Akamai's CDN, we show that the midgress of a metro can be reduced by 18.37% when compared to a midgress-unaware baseline. We propose a midgress-aware heuristic, `local search`, that provisions traffic classes to achieve a midgress reduction that is within 1.1% of the optimum, and is very fast and well suited for production settings. We also show that using our traffic provisioning algorithms at the cluster level results in significant reductions in midgress. Given that a large CDN can have midgress of over 10 Tbps, even a small reduction in midgress can result in millions of dollars of savings per year. Our work provides a strong case for implementing midgress-aware provisioning in CDNs.

Abstract

Traditional graph systems mainly use the *iteration-based model* which iteratively loads graph blocks into memory for analysis so as to reduce random I/Os. However, this iteration-based model limits the efficiency and scalability of running random walk, which is a fundamental technique to analyze large graphs. In this paper, we propose GraphWalker, an I/O-efficient graph system for random walks by deploying a novel *state-aware I/O model* with *asynchronous walk updating*. GraphWalker is efficient to handle very large disk-resident graphs consisting of hundreds of billions of edges with only a single commodity machine, and it is also scalable to run tens of billions of random walks with thousands of steps long. Experiments on our prototype system show that GraphWalker can achieve more than an order of magnitude speedup when running a large amount of long random walks when compared with DrunkardMob, which is tailored for random walk based on the classical system GraphChi, as well as two state-of-the-art single-machine graph systems, Graphene and GraFSoft. Furthermore, comparing with the most recent distributed system KnightKing, which optimizes for random walks and runs on cluster machines, GraphWalker achieves comparable performance with only a single machine, thereby making it a more cost-effective alternative.

1 Introduction

To improve the performance of analyzing large graphs on a single-machine, many out-of-core graph processing systems are proposed [6, 10, 11, 20, 24, 29, 31, 37, 42, 43, 49]. One major effort of these systems is to reduce random disk I/Os. Generally, when a graph is too large to fit into the memory, these systems partition the entire graph into many subgraphs, and store each subgraph as a block on disk, e.g., *shard* in GraphChi [24]. To carry graph analysis, they adopt an *iteration-based model*. In each iteration, blocks are sequentially loaded into memory, then analysis related to the loaded subgraph is performed. This way, it turns massive random I/Os into a series of sequential I/Os, and guarantees synchronized analysis over all blocks in each iteration.

Random walks have been proven to be efficient to analyze large graphs [7,12,15,19,23,26,27,36,38]. For example, Personalized PageRank (PPR) [12, 23] starts thousands of walks from the source vertex to compute visit frequencies in order to approximate PageRank values. SimRank (SR) [19] computes the similarity for a vertex pair by first starting many random walks from each of the vertex pair, and then computing the expected meeting time. Random walk domination (RWD) [27] starts walks from all vertices to measure the influence diffusion over the whole graph. To compute PPR for all vertices, and all-pair similarity, it is also required to start random walks from every vertex, which results in massive concurrent walks.

We observe that current graph systems with the iteration-based model cannot efficiently support random walks. The major limitations are three folds. First, due to the high randomness nature, many walks are unevenly scattered at different parts of the graph, so some subgraphs may contain only few walks. However, the iteration-based model is unaware of these walk states, and just sequentially loads all needed subgraphs into memory for analysis, so it results in very low I/O utilization. Second, as the iteration-based model ensures a synchronized analysis, all walks move exactly one step in each iteration. As a result, the walk updating efficiency is also limited and thus further exacerbates the I/O efficiency. This is true especially for applications demanding long walks. Lastly, due to the randomness of walks, the number of walks at each vertex varies dynamically, so existing graph systems usually use massive dynamic arrays to record the walks currently traveling through each edge or each vertex in the graph. However, this indexing design requires large memory space and thus limits the scalability of handling very large graphs.

Various design efforts are made in recent years to improve the I/O efficiency of the iteration-based model, e.g., DynamicShards [43] and Graphene [29] dynamically adjust the layout of graph blocks to reduce the loading of useless data in each iteration. CLIP [6] proposes the *re-entry scheme* and Lumos [42] proposes the *cross-iteration value propagation technique*, and both of them aim to make full use of the loaded blocks to avoid loading the corresponding graph portions in future iterations. These systems greatly improve the performance, but they do not take into account the random walk features. To efficiently support parallel random walks, DrunkardMob [23]proposes several optimizations to reduce the memory usage of walk indexes so as to support a large amount of random walks. However, its scalability is still limited, e.g., it costs 2.3 hours to run one billion random walks with ten-step long on a medium-scale graph

YahooWeb [5], and it is even unable to run random walks on very large graphs like CrawlWeb [3] due to its high memory consumption. KnightKing [46] is the most recent distributed graph system which is also optimized for random walks. It provides a unified framework to support various random walks, and mainly focuses on optimizing the walking process without addressing disk I/Os.

To address the I/O efficiency problem so as to efficiently support fast and scalable random walks, we develop GraphWalker, which is an I/O-efficient and resource-friendly graph system. GraphWalker mainly focuses on improving the I/O efficiency by developing a state-aware I/O model with asynchronous walk updating. It also utilizes a lightweight block-centric walk management scheme to improve memory efficiency. In summary, our main contributions are as follows.

- We develop a novel *state-aware I/O model*, which leverages the state of each random walk to preferentially load the graph block with the most walks from disk into memory, so as to improve the I/O utilization. We also propose a walk-conscious caching scheme to improve cache efficiency.
- We adopt an *asynchronous walk updating scheme* based on the *re-entry* method [6], which allows each walk to move as many steps as possible so as to fully utilize the loaded subgraph and greatly accelerate the progress of random walks. To address the straggler issues caused by asynchronous update, we also employ a probabilistic approach to balance the progress of each walk.
- We propose a *lightweight block-centric indexing scheme* to manage walk states and adopt a fixed-length walk buffering strategy to reduce the memory cost for recording walk states. We also develop a disk-based walk management scheme and use asynchronous batched I/Os to write walk states back to disk so as to support running massive random walks in parallel on huge graphs.
- We implement a prototype and conduct extensive experiments to demonstrate its efficiency. Results show that GraphWalker can achieve more than *an order of magnitude speedup* compared with the random-walk-specific system DrunkardMob [23], as well as two state-of-the-art single-machine graph systems, Graphene [29] and GraFSoft [20]. Furthermore, GraphWalker is more resource friendly as its performance is even comparable with the state-of-the-art distributed random walk system KnightKing [46] running on a cluster of machines.

2 Background and Motivation

We first introduce the storage and computation process of the iteration-based model, then analyze its limitations in supporting random walks.

2.1 Iteration-based Graph Computation

For simplicity, we take GraphChi [24], the pioneering single-machine iteration-based graph system, as an example to illustrate its key idea. We like to point out that this iteration-based model is widely used in many graph systems like [10, 11, 20, 29, 37, 42, 43, 49]. GraphChi splits all vertices into disjoint intervals and associates each interval with a *shard*, which stores all the edges whose destination vertices lie in this interval. Edges in each shard are sorted according to their source vertices. For example, for the graph in Figure 1(a), its data organization in shards is illustrated in Figure 1(b).

To perform analysis, GraphChi loads all subgraphs iteratively by using the parallel sliding window (PSW), which is illustrated in Figure 1(c). In each iteration, it loads the subgraphs in a round-robin order and guarantees synchronization between all computation tasks over the whole graph. Specifically, at each time slot, GraphChi loads one subgraph corresponding to one interval into memory for analysis. It first loads the in-edges from its corresponding shard, then loads the out-edges from other shards. As edges are sorted by source vertices in each shard, at most P sequential disk reads are needed to load the subgraph corresponding to one interval if there are P shards. Then GraphChi traverses the vertices of the loaded subgraph and conduct computation. This way, GraphChi transfers random accesses to a series of sequential accesses and greatly improves the performance of disk-resident graph processing.

2.2 Limitations in Supporting Random Walks

A random walk proceeds by starting at a source vertex, then repeats the process of randomly selecting a neighbor to visit. Many applications often need to simultaneously run massive random walks [12, 27, 44, 47]. When supporting massive parallel random walks, graph systems with the iteration-based model suffer from several limitations, e.g., low I/O utilization and low walk updating rate, as well as high memory cost for managing walks. In the following, we analyze these limitations in details.

Limitation 1: Low I/O utilization. First of all, the iteration-based model leads to low I/O utilization for random walks, which is defined as the number of edges used for updating walks divided by the number of edges loaded in one I/O, i.e., a subgraph loading. The main reason is that walks may be unevenly scattered across the entire graph after a few steps even if they started from the same source vertex. As a result, even if there are only few walks in some blocks, they are still required to be loaded into memory, so it brings extremely low I/O utilization. Some recent works like DynamicShards [43] and Graphene [29] adopt an *on-demand* I/O strategy to dynamically adjust graph block layout and skip loading blocks which do not contain any walks so as to reduce the loading of useless edges, but the low I/O utilization problem is still not fully addressed. As long as there is one walk in a block, then this block still has to be loaded into memory for computation.

(a) Example graph (b) Data organization in shards (c) Graph loading with parallel sliding window

Figure 1: Storage and I/O model in GraphChi

We also run experiments to demonstrate the skewed walk distribution and low I/O utilization. We use DrunkardMob to run 10^4, 10^6 and 10^8 walks of length ten on the Friendster graph consisting of 68.3 million vertices, and consider starting random walks from a single source (SSRW) or multiple random sources (MSRW). Please refer to §4.1 for detailed experiment setting. Figure 2(a) shows the average I/O utilization, which is 3.1×10^{-6}, 3.2×10^{-4} and 0.032 for SSRW with 10^4, 10^6 and 10^8 walks, respectively, and the results are similar for MSRW. We point out that the I/O utilization is very low, especially for the case of small number of walks. Figure 2(b) further shows the distribution of walks over blocks after four iterations when running 10^6 walks started from a single source, which demonstrates heavily skewed distribution. We also run the same experiments with Graphene, the average I/O utilization is 6.1×10^{-3}, 3.1×10^{-3} and 0.032 for MSRW when running 10^4, 10^6 and 10^8 walks, respectively. We find that Graphene can greatly improve the I/O utilization when the number of walks is small, but the I/O efficiency is still limited when running massive walks.

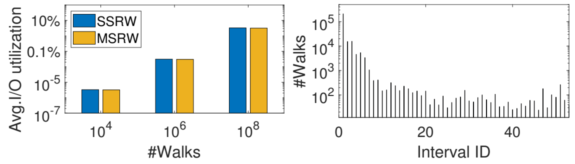
In our GraphWalker, we propose a *state-aware I/O model*, which loads graph blocks by considering the states of walks. Precisely, it always preferentially chooses to load the block with the maximum number of walks so as to make more walks get updated by using an I/O. Our experiment results show that GraphWalker brings 2× to 4× I/O utilization (see §4.2.3).

Limitation 2: Low walk updating rate. The iteration-based model also leads to low walk updating rate, which is defined as the sum of walked steps of all walks in the loaded subgraph divided by the total steps needed to walk. This is because with the iteration-based model, each walk can only move one step in each iteration in a synchronized pace, which severely wastes the data in memory as many walks can still make more moves over the loaded subgraph. To demonstrate, we run 10^6 random walks started from a single vertex by using the same setting as above. Figure 3(a) shows the walk updating rate. We find that all walks together move only 1K steps on average in one I/O, except for the first one, but we have total 10^9 steps to walk, so the updating rate is as low as 10^{-6}. We also count the fraction of walks that still remain in the first block in each iteration as shown in Figure 3(b). We find that on average, 75.3% walks still remain in the first block, and they could move more steps in the current iteration, so it results in the low walk updating rate. Recently, CLIP [6] proposes a *re-entry* method and Lumos [42] proposed the *cross-iteration value propagation* technique to reuse the loaded data to improve the I/O and computing efficiency, but it also brings extra cost as it accesses the whole subgraph multiple times.

In GraphWalker, we propose an *asynchronous walk updating scheme* based on the *re-entry* technique to allow walks to move as many steps as possible within the currently loaded subgraph without extra subgraph accesses.With our asynchronous walk updating scheme, GraphWalker greatly increases the walk updating rate and reduces the completion time of all walks. We also develop a probabilistic approach to balance walk progress so as to address the straggler issues.

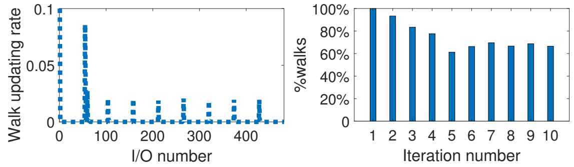
Limitation 3: High memory cost for managing walk data. Since the number of walks at each vertex is dynamic and unpredictable, walks are usually stored with massive dynamic arrays, e.g., GraphChi associates each edge with a dynamic array to store the walks currently traveling through the edge. This design incurs high memory cost, e.g., it needs at least 26.4 GB space to store only the walk array indexes, not including the walk states information, for a medium scale graph like YahooWeb [5], which has 1.4 billion vertices and 6.6 billion edges.Some systems use a vertex-centric way to manage walks [6, 10, 29], but it also incurs high memory cost, e.g., 5.6 GB to store the walk array indexes for YahooWeb.

DrunkardMob encodes the states of a walk into a 32-bit or 64-bit representation and puts walks of adjacent 128 vertices



(a) I/O utilization (b) Distribution of walks

Figure 2: I/O utilization under different walk settings and the distribution of number of walks over blocks (intervals).



(a) Walk updating rate (b) Walks in the 1^{st} interval

Figure 3: Walk updating rate and the fraction of walks that still remain in the first block in each iteration.

into the same walk buffer to reduce the total size of walk indexes. It reduces the size of walk array indexes to 1/128 of that of the vertex-centric management, e.g., only 44.8 MB for YahooWeb. However, each walk buffer in DrunkardMob is also managed with a dynamic array, so it still suffers from the scalability problem. First, as it creates too many dynamic arrays for large graphs, e.g., 11.2 million for YahooWeb, it causes frequent memory re-allocation, which not only introduces memory fragmentation, but also brings extra time cost and limits the graph scale that could be analyzed. Second, DrunkardMob keeps all walks in memory, so the number of walks is limited by memory space, e.g., 10 billion walks cost at least 40GB memory. Besides, it also incurs high cost to flush walk indexes to disk as they are related to many files.

In our GraphWalker, we adopt a block-centric method to manage walk data, so it greatly reduces the size of walk indexes. We also use fixed-length buffers to cache walks so as to avoid frequent memory re-allocation. With our lightweight scheme, both the scale of graphs and the number of walks that can be handled are no longer limited by memory capacity.

3 Design of GraphWalker

In this section, we first introduce the main idea of GraphWalker, which is an I/O-efficient and resource-friendly design targeted for random walks on single machine. We then present the details of its key design techniques, including state-aware graph loading, asynchronous walk updating, and lightweight walk management.

3.1 Main Idea

We target for supporting not only a very large number of walks, say tens of billions of walks, but also very long walks, say thousands of steps for each walk. To achieve this goal, the main idea is to adopt a *state-aware model* which leverages the states of each walk, e.g., the current vertex at which the walk stays. Briefly speaking, unlike the iteration-based model which blindly loads graph blocks sequentially, the state-aware model chooses to load the graph block containing the largest number of walks, and makes each walk move as many steps as possible until it reaches the boundary of the loaded subgraph. By doing this, walks can get updated as much as possible within each I/O. As a result, both the low I/O utilization and low walk updating rate problems can be efficiently addressed.

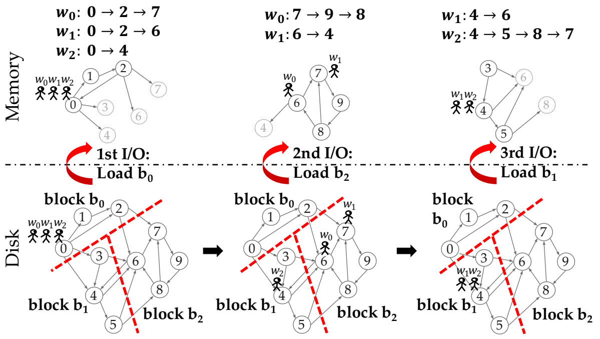


Figure 4: Main idea of the state-aware model

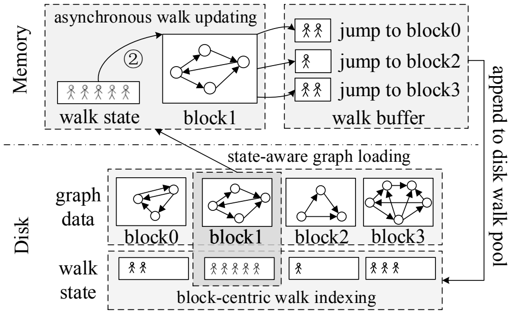

Figure 5: Overall design of GraphWalker

To further illustrate the above idea and analyze its benefits, we still consider the example graph in Figure 1(a). Suppose that we have to run three random walks which start at node 0 and have to move four steps. Figure 4 shows the process of graph loading and walk updating with the state-aware model. Specifically, in the first I/O, graph block b_0 is loaded into memory as it contains all the three walks. With the loaded graph block b_0, walk w_0 and w_1 move two steps, and w_2 moves only one step as it requires other graph blocks which are not in memory for walking more steps. As two walks fall into block b_2, in the second I/O, block b_2 is loaded into memory, and walk w_0 finishes and w_1 can move one step. Finally, both the remaining two walks are in block b_1, so we load b_1 into memory, and all walks can be finished. Note that only three I/Os are required in this example. However, for the iteration-based model, it may need 12 I/Os, because it uses four iterations, and generates three I/Os in each iteration.

Remark. We would like to emphasize that the state-aware model is different from the on-demand I/O model proposed in DynamicShards [43] and Graphene [29]. Note that the on-demand I/O model dynamically adjusts the graph blocks layout in each iteration and skips the blocks without containing any walks, but it still follows the iteration-based manner. Besides, even if there is only one walk in a block, it has to load the block into memory for analysis.

Based on the above idea, we develop an I/O-efficient graph system, GraphWalker, which supports fast and scalable random walks. GraphWalker mainly consists of three parts: (1) *State-aware graph loading,* (2) *Asynchronous walk updating,* and (3) *Block-centric walk management*. The overall design of GraphWalker is also illustrated in Figure 5. In the following subsections, we present its design in details.

3.2 State-Aware Graph Loading

Graph data organization and partition. GraphWalker manages graph data with the widely used *Compressed Sparse Row (CSR)* format, which sequentially stores the out neighbors of vertices as a *csr file* on disk, and uses an *index file* to record the beginning position of each vertex in the *csr file*. GraphWalker partitions a graph into blocks according to vertex IDs. Specifically, we sequentially add vertices and

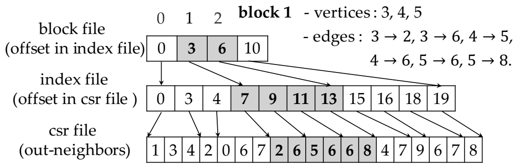

Figure 6: Graph data organization of the example graph in Figure 1(a). The graph is stored in CSR format and block partition ranges are recorded in the block file.

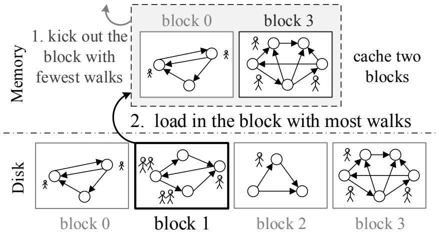
their out-edges into a block according to the ascending order of their IDs until the data volume in the block exceeds a predefined *block size*, and then we create a new block. Figure 6 shows the data layout of the example graph in Figure 1(a). Besides, this lightweight graph data organization decreases the storage cost of each subgraph, and thus reduces the time cost of graph loading. As GraphWalker partitions a graph by simply reading through the *index file* once to record the beginning vertex of each block, it is also flexible to adjust block size for different applications.

For setting the graph block size, we find that a trade-off exists. That is, using smaller blocks can avoid loading more data which are not needed for updating random walks, while using larger blocks can have more walks getting updated in each subgraph loading. Besides, different analysis tasks require different walk scales, and thus prefer different block sizes. Lightweight tasks with a small number of walks prefer a small block size as the I/O utilization can get improved under this setting. In contrast, heavyweight tasks with a large number of walks prefer a large block size as large block size can increase the walk updating rate. Based on this understanding, we use an empirical analysis (see §4.4), and set the default block size as $2^{(\log_{10} R+2)}$ MB, where R is the total number of random walks. For example, in the case of running one billion walks, the default block size is 2 GB, which is usually smaller than the memory capacity of a commodity machine, so it is easy to keep a graph block in memory.

Graph loading and block caching. GraphWalker converts the graph format and partitions graph blocks in preprocessing phase. During the phase of running random walks, GraphWalker chooses a graph block and loads it into memory according to the the states of walks, and in particular, it loads the block containing the largest number of walks. After finishing analysis over the loaded graph block, it then chooses another block to load in the same way.

To ease the impact of block size and improve cache efficiency, GraphWalker also enables block caching by developing a walk-conscious caching scheme to keep multiple blocks in memory. The rationale is that blocks with more walks are more likely to be needed again in near future. Thus, the graph loading process with block caching works as follows. As illustrated in Figure 7, we first select a candidate block based on the state-aware model, to load this block, we check whether it is cached in memory or not. If it is already in memory, then we directly access memory to perform analysis.



Memory
1. kick out the block with fewest walks
block 0
block 3
cache two blocks
2. load in the block with most walks
Disk
block 0
block 1

block 3

Figure 7: State-aware graph loading with block caching

Otherwise, we load it from disk, and also evict out the block in memory containing the fewest walks if the cache is full. The maximum number of blocks cached in memory depends on the usable memory size.

We emphasize that this walk-conscious block caching scheme differs from conventional page cache in the following aspects. First, we do not adopt prefetching as the state-aware model does not prefer to access graph blocks sequentially. Second, page cache manages data in memory at a *page* granularity, while we manage at a *block* granularity so as to fit the block-based graph loading and computing. Last but not least, the eviction policy also leverages walk states, which is different from LRU. Our experiments show that the walk-conscious block caching scheme always outperforms conventional page cache scheme.

3.3 Asynchronous Walk Updating

Note that in iteration-based systems, after loading a graph block, each walk in the loaded subgraph walks only one step, which induces to very low walk updating rate. In fact, after walking one step, many walks are still staying at the vertices in the current subgraph, so they can be further updated with more steps. To improve the I/O efficiency, some works use the *loaded data re-entry* [6], which allows the walks to reuse the loaded data. Lumos [42] uses cross-iteration value propagation to formalize reusing of loaded data for the subsequent iteration in order to provide synchronous guarantees. The idea is to re-enter the subgraph again to walk one more step by traversing the vertices in the subgraph again. Moreover, one can also keep re-entering the subgraph until all of the walks reach the boundary of the subgraph.

However, the re-entering scheme may cause local straggler problem. That is, many walks are able to move one step at the first time when the graph block was just loaded, and as the number of re-entries increases, most walks may reach the boundary of the subgraph, and only few walks remain in the subgraph, and they cost multiple re-entries to finish. Our experiments show that the last 20% of walks in a block may cost 60% of re-entries. These re-entries have very low utilization and cost a lot of time. We also find that simply stopping walking over the currently loaded subgraph after certain re-entries cannot address the local straggler problem either, and it does not reduce the completion time as the last few walks still remain in the subgraph and we still need to

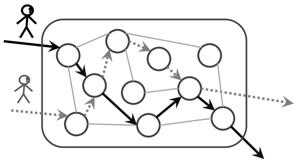

Figure 8: Asynchronous walk updating in parallel

re-load it with extra I/Os to finish the walks.

To further improve the I/O utilization and walk updating rate, GraphWalker adopts an asynchronous walk updating strategy, which allows each walk to keep updating until it reaches the boundary of the loaded graph block. After finishing a walk, we choose another walk to process until all walks in the current graph block are processed. Then we load another graph block based on the state-aware model described above. Figure 8 shows an example of processing two walks within the same graph block. To accelerate the computation, we also use multi-threading to update walks in parallel. We emphasize that with our asynchronous walk updating model, we completely avoid useless visits of vertices and eliminate the local straggler problem.

However, the state-aware model may lead to the *global straggler problem*. That is, some walks may move very fast and make a large progress as the graph data they needed can always be satisfied, while some other walks may move very slowly as they may be trapped in some coldblocks which are not loaded into memory for a long time. As a result, GraphWalker can quickly complete most walks, but takes a long time to finish the remaining few walks. Our experiments show that a few walks often incur nearly half of total I/Os.

To address the global straggler problem, we introduce a probabilistic approach into the state-aware graph loading process in GraphWalker. The idea is to give stragglers a chance to move some steps such that they can catch up the progress of most walks. Specifically, every time when we choose a graph block to load, we assign a probability p to choose the block containing walks with the slowest progress, i.e., with the smallest number of walked steps, and with probability $1-p$, we still load the block with the most walks. Note that the global straggler problem will be mitigated more efficiently as p increases, but the efficiency of the majority of walks will decrease. So there is a trade-off for setting p. Based on our empirical analysis, we find that $p = 0.2$ is an appropriate setting, and we can get 20% improvement in some cases.

3.4 Block-Centric Walk Management

We record each walk with three variables, source, current and step, which indicate the start vertex, the offset of the current vertex in the block, and the number of moved steps, respectively. We record each walk with 64 bits. The number of bits allocated for each variable is shown in Figure 9. This data structure can support starting random walks at 2^{24} source vertices simultaneously and it also allows each walk to move up to 2^{14} steps. Note that there is no limit on the total number of walks as we can start many walks at each vertex.

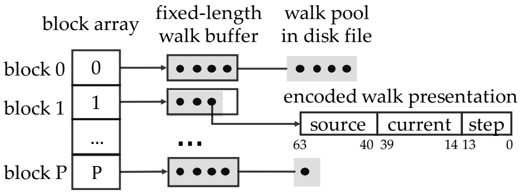

Figure 9: Block-centric walk management

To reduce the memory overhead of managing all walk states, we propose a block-centric scheme. For each graph block, we use a walk pool to record the walks which are currently in the block, referring to Figure 9. We implement each walk pool as a fixed-length buffer, which stores at most 1024 walks by default, so as to avoid dynamic memory allocation cost. When there are more than 1024 walks in a block, we flush them to disk and store them as a file called *walk pool file*. Note that we encode each walk with a 64-bit *long* data type, so each walk pool only costs 8 KB. This way, the memory cost for managing walk state is very low. For example, for running one billion walks in YahooWeb, GraphWalker costs only 800 KB if it uses 100 graph blocks. However, DrunkardMob costs more than 4 GB as each walk uses at least four bytes. Besides, these walks jump among the 11.2M dynamic arrays (refer to §2.2), and thus cause frequent memory re-allocation and bring extra time cost.

When we load a graph block into memory, we also load its walk pool file into memory and merge the walks with those stored in the in-memory walk pool. Then we perform random walks and update walks in current walk pool. During the update process, when a walk pool is full, we flush all walks in the walk pool to disk by appending them to the corresponding walk pool file and clear the buffer. When finish computing with the loaded graph block, we clear the current walk pool and sum up the walks in both walk buffer and walk pool file of each block so as to update the walk states.

With this lightweight walk management, we save a lot of memory cost for storing walk states, thus it is able to support massive concurrent walks. Besides, the fixed-length walk buffering strategy turns many small I/Os for updating walk states into several large I/Os, which largely reduces the I/O cost for providing persistent storage of walk states.

4 Evaluation

GraphWalker aims for providing fast and scalable random walks, so we take DrunkardMob [23], the state-of-the-art single-machine random walk specific graph system, as a baseline for performance comparison. Besides, there are also a number of single-machine graph systems, which further optimize the system performance from different aspects. For completeness, we also compare GraphWalker with two state-of-the-art graph systems Graphene [29] and GraFSoft [20]. To further validate its scalability, we compare GraphWalker with the most recent distributed random walk graph system, i.e., KnightKing [46].

4.1 Experiment Settings

Testbed. All experiments are performed on a Dell Power Edge R730 machine with 64GB memory and 24 Intel(R) Xeon(R) CPU E5-2650 v4 @ 2.20GHz processors. The entire graph data are stored on a 3.2TB RAID-0 consisting of seven 500GB SamSung 860 SSDs if we do not state specifically. We also study the performance of GraphWalker on HDDs. For the distributed system KnightKing [46], it is run on an 8-node cluster with 10Gbps Ethernet inter connection, each node is equipped with two 8-core Intel Xeon E5-2620 v4 processors with 20MB L3 cache and 64GB DRAM.

Dataset. Table 1 lists the statistics of the six graph datasets we used. TT [4], FS [1], YW [5] and CW [3] are real-world graphs. K30 and K31 are two synthetic graphs generated with Graph500 kronecker [2]. These graphs are all widely used in graph system evaluations. CSR Size indicates the minimum storage cost by storing graphs in CSR format, and Text Size is the size of the dataset stored in text format as an edge list. We point out that Kron30, Kron31 and CW are large graphs that can not be entirely put into the memory in our testbed, and CW is the largest web corpus available in public.

Dataset	$\lvert V\rvert$	$\lvert E\rvert$	CSR Size	Text Size
Twitter (TT)	61.6M	1.5B	6.2GB	26.2GB
Friendster (FS)	68.3M	2.6B	10.7GB	47.3GB
YahooWeb (YW)	1.4B	6.6B	37.6GB	108.5GB
Kron30 (K30)	1B	32B	136GB	638GB
Kron31 (K31)	2B	64B	272GB	1.4TB
CrawlWeb (CW)	3.5B	128B	540GB	2.6TB

Table 1: Statistics of Datasets

Graph algorithms. Besides directly evaluating the performance of running random walks, we also consider the following four common random walk based algorithms.

- *Random Walk Domination (RWD)* [27]. We start one walk of length six from each vertex in the graph to find a vertex set which has the maximum influence diffusion.
- *Graphlet Concentration (Graphlet)* [34, 35]. We use a special graphlet, triangle, as a study case. We randomly start 100 thousand random walks of length four to estimate the ratio of triangles in the graph.
- *Personalized PageRank (PPR)* [12]. We simulate 2000 random walks of length 10 starting at each query source vertex to approximate the PPR, which was shown to be sufficient to ensure the accuracy.
- *SimRank (SR)* [19]. We start 2000 random walks of length 11 respectively from the query pair vertices to compute the expected meeting time,

Remark. The first two are graph computation algorithms which utilize the entire graph, while the other two are graph query algorithms which need only a portion of the graph. We point out that all of them are classical and representative graph algorithms. We run each experiment ten times and compute the average completion time. Before each execution, we also clear the page cache to avoid its impact.

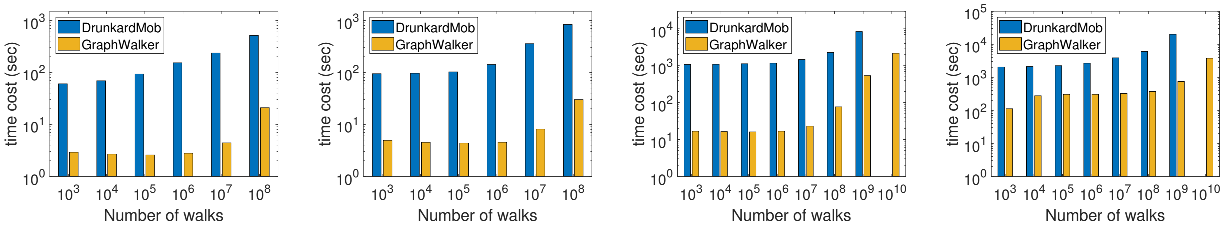
4.2 Comparison with RW-Specific Systems

We validate the efficiency of GraphWalker by comparing it with DrunkardMob, the state-of-the-art single-machine system that is specially optimized for random walk. Both GraphWalker and DrunkardMob are implemented based on GraphChi. Note that random walk based algorithms usually require to start certain number of random walks with certain walk length, so we evaluate the performance by considering different random walk configurations, so as to study the performance of the entire design space and demonstrate the scalability of GraphWalker in supporting large amount of random walks with very long walk length. We also show the performance of the four random walk based algorithms. Finally, we justify the improvement achieved by GraphWalker by using micro-benchmark results.

4.2.1 Performance Study in Entire Design Space

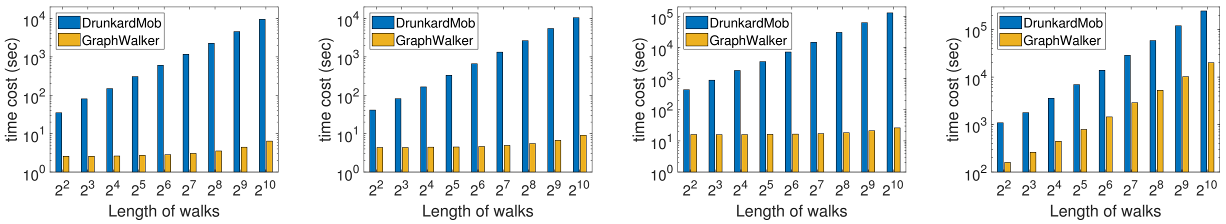
We first show the results by fixing the walk length to ten, but varying the number of walks from 10^3 to 10^{10}, as depicted in Figure 10. In each figure, the x-axis indicates the number of walks configured in each experiment, and the y-axis shows the time needed to finish running all these walks. First, we can see that GraphWalker is consistently faster than DrunkardMob under all settings for different numbers of walks and different graph datasets. In particular, in the case of running 10^6 walks on YahooWeb, DrunkardMob costs near 20 minutes, while GraphWalker takes only 17.8 seconds. That is, GraphWalker achieves 70× speedup. In general, GraphWalker achieves 16× to 70× speedup under all settings. In addition, for the case when the number of walks is not too large, then I/O cost is a dominate factor, so the total time of running different number of walks is almost a constant. However, as the number of walks continues to increase, computation cost becomes larger, so the total time cost also increases linearly when we run more random walks.

One attractive feature of GraphWalker we like to highlight is its scalability. We point out that even for running tens of billions of random walks on large graphs, GraphWalker can still finish within a reasonable time. However, DrunkardMob even fails to run 10^{10} walks on large graphs, due to the out-of-memory error, so we do not show the results of DrunkardMob in the setting of more than 10^{10} walks. More importantly, when the graph becomes really large, DrunkardMob may fail to run. For example, for Kron31 and CrawlWeb, DrunkardMob also encounters the out-of-memory error. Thus, we do not show the results on them for the interest of space. The main reasons are as follows: (1) DrunkardMob keeps all walk states in memory, so it's hard to support massive walks. (2) DrunkardMob employs a dynamic array index for every 128 vertices, so it incurs a large memory overhead when the graph becomes really large, and its also hard to write the walks to



(a) Twitter (b) Friendster (c) YahooWeb (d) Kron30

Figure 10: Performance of random walks with different number of walks by fixing walk length as 10.



(a) Twitter (b) Friendster (c) YahooWeb (d) Kron30

Figure 11: Performance of random walks with different walk lengths by fixing the number of walks as 10^5.

disk for too many open files needed. However, because of the block-centric walk indexing design and keeping walk states on disk, GraphWalker is capable to support huge graphs, e.g., Kron31 and CrawlWeb, even for running tens of billions of random walks, e.g., GraphWalker finishes running 10^{10} walks on CrawlWeb within around one hour.

We also evaluate the performance by varying the walk length. Here we fix the number of walks as 10^5 and vary the length of each walk from 2^2 to 2^{10}. The results are shown in Figure 11. First, we can see that GraphWalker is always much faster than DrunkardMob, and it achieves even more than three orders of magnitude in the best case. In particular, when the graph is not extremely large, e.g., for Twitter, Friendster, and YahooWeb, the time cost of DrunkardMob continues to increase when running longer walks, while that of GraphWalker is almost a constant, this is because GraphWalker can cache almost the whole graph in memory for medium-sized graphs, due to the lightweight block storage and optimized block catching strategy, and thus incurs very low I/O cost. For very large graphs which can not be fully put in memory, e.g., Kron30, the time cost of both DrunkardMob and GraphWalker increases as walks get longer, as GraphWalker needs to swap in and kick out blocks between memory and disk in this case. However, we point out that GraphWalker is much faster, e.g., it achieves 7× to 10× speedup even for Kron30. This experiment also demonstrates the scalability of GraphWalker in supporting long random walks which have thousands of steps.

4.2.2 Performance of Random Walk based Algorithms

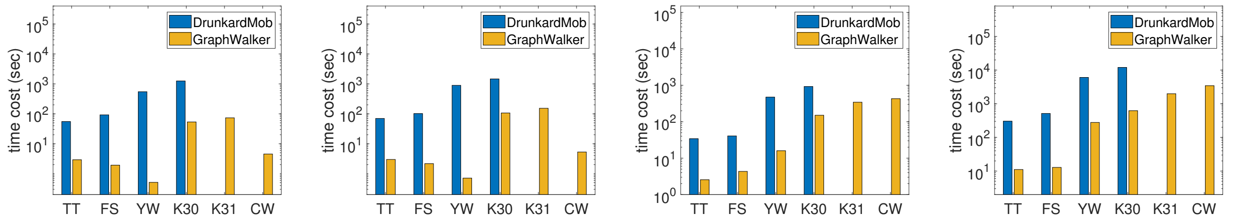
We now evaluate the performance of the four common random walk based algorithms described in §4.1. From Figure 12, we can see that GraphWalker achieves 9× to 48× speedup upon DrunkardMob. In particular, in some special cases, e.g., running PPR and SR on YahooWeb, GraphWalker even achieves more than three orders of magnitude speedup, this is because YahooWeb has a very good locality at the query vertices, so GraphWalker only needs to load several corresponding subgraphs to run random walks. However, DrunkardMob needs to iteratively scan the entire graph and updates walks in a synchronized manner, so it has a very low I/O utilization and takes long time.

We like to point out that DrunkardMob again fails to handle the two largest graphs. due to the same reason explained in §4.2.1, so we skip the results in these cases. Note that this experiment also demonstrates the scalability of GraphWalker in supporting massive walks and huge graphs.

4.2.3 Micro-benchmarks

Recall that the inefficiency of existing systems in running random walks mainly come from the iteration-based I/O model, and thus they suffer from low I/O utilization and low walk updating rate (refer to §2). To better understand why GraphWalker could significantly improve the overall performance as presented in the last subsection, we further consider these two micro-benchmarks to show how the state-aware I/O model in GraphWalker address the limitations. We also show the time cost breakdown to see how GraphWalker improves the performance of each part along the random walk process. *We only show the results of running RWD algorithm on YahooWeb, and results are similar for other settings.*

I/O utilization. I/O utilization is defined as the edge usage amount for updating walks divided by the total number of edges loaded by one I/O. Note that an edge may be reused by different walks, so we sum up the total times of being used for all edges. Thus, the I/O utilization defined here may exceed



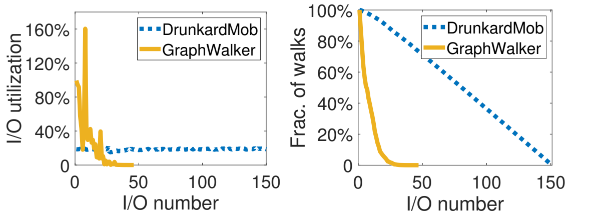
(a) Personalized PageRank (b) SimRank (c) Graphlet (d) Random Walk Domination

Figure 12: Performance of random walk based algorithms.

100% when one edge is used by multiple walks. We point out that DrunkardMob partitions the YahooWeb graph into 25 shards, and the walk length is six, so the total number of I/Os required by DrunkardMob is 150. We can see that the I/O utilization is only around 20% as shown in Figure 13(a). In contrast, GraphWalker needs only 46 I/Os to complete all walks, so the number of I/Os is significantly reduced. The I/O utilization of GraphWalker is also much higher than that of DrunkardMob. Specifically, the utilization of the first few I/Os reaches up to 80%-160%, this is because the subgraphs loaded by the first few I/Os have the most walks, and many of them may use more than one edge to update. Even for most I/Os, the I/O utilization of GraphWalker is between 40% to 80%, which is 2× to 4× compared to that of DrunkardMob.

Walk updating rate. Now we study the walk updating rate, shown in Figure 13(b). Recall that DrunkardMob updates 50 million steps per I/O on average and costs 150 I/Os to finish the computation. While GraphWalker significantly improves the walk updating rate, it only needs 46 I/Os to complete all walks and updates 185 million steps per I/O on average, which is 3.7× higher than that of DrunkardMob. The main reason is that DrunkardMob adopts the iteration-based I/O model, it walks only one step for each walk when loading one block. In contrast, GraphWalker develops an asynchronous walk updating method to fully utilize the loaded graph data in memory (see §3.3), so each walk may move multiple steps over the subgraph loaded by each I/O. As a result, GraphWalker saves a lot of I/Os and completes all random walks more quickly than DrunkardMob.

Time cost breakdown. To better understand the effect of the design optimizations in GraphWalker, we also show the time cost breakdown in Table 2. Note that in the whole execution procedure, there are three key operations: (1) graph loading, which loads graph blocks into memory with disk I/Os, (2) walk updating, which updates the walk states maintained in memory, and (3) walk persisting, which includes to read walk states from disk into memory and write back updated states to disk for persistency. Besides, the three operations are proceeded in an interleaved way, so we aggregate the total time of executing each operation. From the results, we can see that GraphWalker outperforms DrunkardMob in all aspects. The improvement is achieved by the integration of multiple design optimizations, which all contribute to the high efficiency of GraphWalker, e.g., the improvement of graph loading performance mainly comes from the state-aware scheme with the lightweight data organization and block caching policy, and it also benefits from the asynchronous updating strategy.



(a) I/O utilization (b) Walk updating rate

Figure 13: I/O utilization and walk updating rate (DrunkardMob needs 150 I/Os and GraphWalker only needs 46 I/Os)

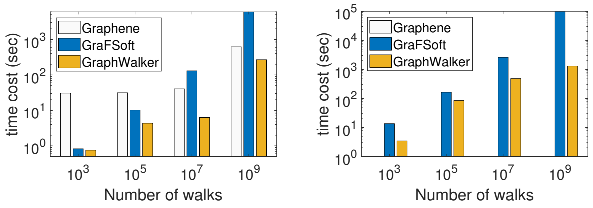
4.3 Comparison with State-of-the-art Systems

Single-machine graph systems. There are a number of optimizations being proposed in recent single-machine graph systems, e.g., fine-grained block partition, asynchronous I/O to support pipeline between I/O and computation, huge page support to reduce TLB miss, etc. These optimizations are not specific for random walks, so many of them are also orthogonal to the optimizations in GraphWalker. Thus, to further demonstrate the efficiency of GraphWalker, we also compare it with two state-of-the-art open-source single-machine systems, Graphene [29] and GraFBoost [20]. For fair comparison, we only focus on the pure software implementation of GraFBoost called GraFSoft. Note that GraphWalker is implemented based on the baseline system GraphChi, so it does not include the above mentioned design optimizations.

In this experiment, we focus on the case of running random walks starting from a single source due to page limit. We fix the walk length as ten and vary the number of walks. Note that Graphene is a semi-external system which stores graph data on disk while keeps all walk states in memory, so it is unable to handle the case of massive walks, e.g., greater than 10^9 walks, or large graphs, e.g., larger than Friendster, due to its high memory cost. In the interest of space, we only show

Time cost (s)	DrunkardMob	GraphWalker	Speedup
Graph Loading	1005	47	21×
Walk Updating	3029	214	14×
Walk Persisting	1056	16	66×
Total Runtime	5110	278	18×

Table 2: Time cost breakdown



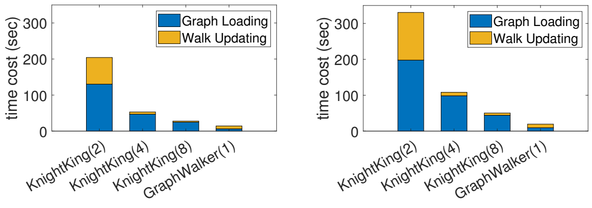
(a) Friendster (b) CrawlWeb

Figure 14: Comparison with Graphene and GraFSoft

the results for Friendster, the largest graph that Graphene can process, as well as the largest graph CrawlWeb. We observe similar results for other graphs.

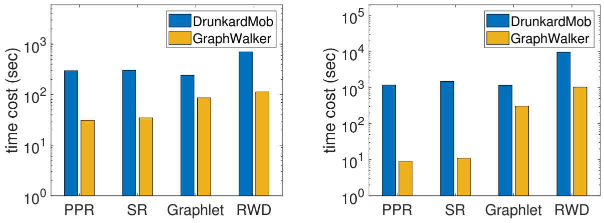
The results are shown in Figure 14, and we can have several conclusions. First, GraphWalker consistently outperforms Graphene even though Graphene is a semi-external system which does not require I/Os to write back walk states, and it achieves up to 19× speedup. More importantly, GraphWalker is also scalable to run huge amount of walks, as well as process extremely large graphs, while Graphene fails to run in these cases due to its high memory cost caused by the semi-external design. Second, compared with GraFSoft, when the number of walks is small, the improvement of GraphWalker is limited, because each block can only have a few walks given the small total number and the state-aware I/O model can not bring too much benefit. However, the improvement of GraphWalker increases as the number of random walks gets larger.For example, when running one billion random walks on CrawlWeb, GraphWalker spends only 21.8 minutes while GraFSoft can not even complete the task within 24 hours. That is, GraphWalker achieves at least 40× speedup. More importantly, as we increase the number of walks, the increase of time for GraphWalker is *sub-linear* and much slower than that of GraFSoft, this further demonstrates the scalability of GraphWalker in supporting huge amount of random walks.

Distributed random walk system. To further demonstrate the scalability of GraphWalker, and its resource-friendly feature, we also compare it with a distributed graph system, KnightKing [46], which is the most recent distributed graph system optimized for random walks. In the interest of space, we focus on a random walk based algorithm which is also used in KnightKing, i.e., PPR. Specifically, it starts one walk at each vertex, and each walk terminates with probability t in each step. We set $t = 0.15$, which is a very common setting in various applications [12, 25]. Note that smaller t means larger average number of walk steps and requires more computations, so KnightKing uses a small t to demonstrate its computing efficiency. As KnightKing uses a cluster of eight machines for evaluation in its paper, to enable cross-validation, we also use eight machines at most, and focus on the largest two graphs that can be handled by KnightKing with eight machines, i.e., Twitter and Friendster. We also convert the two graphs to be undirected as in KnightKing.



(a) Twitter (b) Friendster

Figure 15: Comparison with KnightKing



(a) Friendster (b) YahooWeb

Figure 16: Performance on HDDs

Figure 15 shows the results, and the number after each system name denotes the number of machines being used. We can see that for KnightKing, as the cluster size increases, the computing time, i.e., the time for updating walks, gets reduced greatly, but it still costs a lot of time for processing I/Os, i.e., loading graph blocks. This is because KnightKing mainly focuses on optimizing the computing efficiency, but not disk I/Os. Note that the results of the computing time in this experiment are consistent with those in the KnightKing paper. In contrast, GraphWalker mainly targets for the I/O efficiency problem, and also adapts the walk updating process accordingly based on its I/O model, so it can realize very fast random walks over disk-resident graphs. Here the walk updating time also incudes the time for walk index persistency. We also see that GraphWalker achieves comparable performance even compared with KnightKing running on eight machines. Even more, for the largest graph CrawlWeb, KnightKing may need a larger cluster to run according to the estimation of its used resources when processing other smaller graphs. Thus, we can conclude that GraphWalker is also a more resource-friendly alternative.

4.4 Impact of System Configurations

Performance on HDDs. We also study the impact of storage devices by running experiments on hard disk drives (HDDs). Figure 16 shows the time cost of running the four algorithms we considered in this paper, and we only show the results for Friendster and YahooWeb here. Since HDDs have much lower random I/O performance than SSDs, the time cost of both DrunkardMob and GraphWalker is increased. When comparing GraphWalker with DrunkardMob, we observe similar results as in the case of SSDs studied before. Precisely, GraphWalker achieves 3× to 135× speedup under different settings.

Impact of block size. In GraphWalker, block size has an impact on both I/O utilization and walk updating rate.

Specifically, smaller block size improves the I/O utilization, while larger blocks can make walks move more steps for each single I/O and thus improves the walk updating rate. To study the impact of block size, we keep only one block in memory and run the PPR algorithm on CrawlWeb as a study case. Here, we consider two PPR algorithms which start random walks from 1000 and 100000 sources, respectively. Note that the two cases are representative to denote two typical scenarios of accessing only a part of the graph or accessing most of the entire graph.

Figure 17 shows the results. We find that it necessitates an appropriate block size setting to achieve the best performance due to the above analyzed tradeoff. The insight is that small blocks may be beneficial to lightweight tasks which require only a small number of random walks, as the I/O utilization can get improved under this setting. In contrast, large blocks may be beneficial to heavyweight tasks which require a large number of random walks, as large block setting increases the walk updating rate. Based on this observation, we also propose a method to set the block size, which is determined according to the number of walks (see §3.2).

5 Related Work

A number of graph systems have been proposed in recent years, and some of them develop distributed systems based on a cluster of machines so as to handle very large graphs which can not reside on a single machine [8, 9, 13, 14, 21, 30, 32, 40, 48]. However, distributed graph systems usually require efficient graph partition and low-cost communication between machines. Besides, research efforts are also made to leverage large memory in analyzing large graphs [16, 33, 39] or utilizing GPUs to accelerate the computation [22, 28, 45].

Graph processing on single machine for disk-resident graphs also receives a lot of attentions. GraphChi [24] is the pioneering work, and X-Stream [37] further develops a different computation model based on edge streams. GridGraph [49] optimizes I/Os by selectively loading needed graph blocks to bypass useless graph data. DynamicShards [43] and Graphene [29] also aim to reduce the loading of useless edges by dynamically adjusting the graph partition layout. CLIP [6] and Lumos [42] improve the utilization of the loaded graph blocks so as to reduce the number of I/Os. There are also a body of works to leverage high-performance emerging devices to improve performances [10, 11, 20, 31]. The above systems are not designed specially for random walks, so most of them still follow the iteration-based model. Different from them, GraphWalker targets for supporting massive concurrent random walks in a fast and scalable way, and its key idea is to utilize the states of walks to optimize the process of graph loading and computing so as to improve the I/O and computing efficiency.

In terms of random walk, besides developing new algorithms, such as random walk with restart [41], FolkRank [17] and TrustWalker [18], etc., there are also some works focusing on system design. To support massive random walks on large graphs, DrunkardMob [23] proposes an encoded representation and a lightweight efficient index so as to be able to run billions of random walks on a single machine. As it follows the iteration-based model, it still suffers from the I/O deficiency problem. Different from DrunkardMob, GraphWalker focuses on optimizing the I/O management, and it develops a new state-aware model with asynchronous walk updating to improve I/O performance. In addition, GraphWalker also allows walk states to be stored on disk, instead of putting only in memory as in DrunkardMob, so it is more scalable to run more walks on larger graphs.

Besides single-machine random walk systems, there is also a distributed system KnightKing [46], which is recently proposed and also optimized for random walks. It provides a unified framework to support various random walks and focuses on optimizing the walking process without addressing disk I/Os. Different from KnightKing, GraphWalker mainly targets for addressing the I/O problem, and it is also more resource friendly as it can process massive random walks on large graphs on just a single machine.

6 Conclusion

In this paper, we proposed GraphWalker which is an I/O-efficient system for supporting fast and scalable random walks over large graphs on a single machine. GraphWalker carefully manages graph data and walk indexes, and optimizes I/O efficiency by using state-aware graph loading and asynchronous walk updating. Experiment results on our prototype show that GraphWalker outperforms state-of-the-art single-machine systems, and it also achieves comparable performance with distributed graph system running on a cluster machine. In the future work, we will consider to extend the state-aware design idea in GraphWalker to distributed clusters so as to process massive analytic tasks in parallel.

Abstract

We introduce Scaph, a GPU-accelerated graph system that achieves scale-up graph processing on large-scale graphs that are initially partitioned into subgraphs at the host to enable iterative graph computations on the subgraphs on the GPU. For active subgraphs to be processed on GPU at an iteration, the prior work always streams each in its entirety to GPU, even though only the neighboring information for its active vertices will ever be used. In contrast, Scaph boosts performance significantly by reducing the amount of such redundant data transferred, thereby improving the effective utilization of the host-GPU bandwidth drastically. The key novelty of Scaph is to classify adaptively at each iteration whether a subgraph is a high-value subgraph (if it is likely to be traversed extensively in the current and future iterations) or a low-value subgraph (otherwise). Scaph then schedules a sub-graph for graph processing on GPU using two graph processing engines, one for high-value subgraphs, which will be streamed to GPU entirely and iterated over repeatedly, one for low-value subgraphs, for which only the neighboring information needed for its active vertices is transferred. Evaluation on real-world and synthesized large-scale graphs shows that Scaph outperforms the state-of-the-art, Totem (4.12×), Graphie (8.93×), and Garaph (3.71×), on average.

1 Introduction

Graph processing is used in a variety of real-world applications, including path navigation [23], social network analysis [9], and financial fraud detection [27]. Graph processing, typically memory-bound, often benefits substantially from memory optimizations [50]. Compared to CPU-based graph systems [15, 16, 30, 36, 40, 46, 51, 68], GPU-accelerated graph systems can have high internal bandwidth and massive parallelism, therefore offering superior speedup [19, 25, 39, 66], even for graph algorithms that involve substantial light-weight integer and comparison-based operations [28].

Unfortunately, many real-world graphs still cannot fit into GPU memory to enjoy high-performance in-memory graph processing. For example, NVIDIA's high-end Tesla V100 has 32GB global memory [42], while real-world graphs such as `Facebook`'s can easily reach the terabyte-scale [9]. This gap has spurred the development of many distributed graph systems, which partition a graph into sub-graphs and then assign these sub-graphs to different machines for distributed computing [13, 15, 16, 33, 36, 67]. However, these distributed graph systems suffer from prohibitive communication overheads [8, 15, 58] and also require an extensive range of domain knowledge to maintain [11, 16, 24, 38, 56, 59].

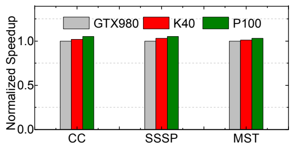

Figure 1: Performance of Graphie [17] for three representative graph algorithms on `fb-2009` (a graph with 139.1M vertices and 12.3B edges, taking 137.8GB (unweighted) and 275.6GB (weighted)) on three different generations of GPUs plugged (separately) in a 28-core host machine with 512GB memory

There is nowadays a viable alternative of turning a single machine plugged in with a GPU to support scale-up large-scale graph processing. Such a GPU-accelerated heterogeneous platform is easy to use and maintain [30, 62, 68]. In addition, we can take advantage of the large host memory (at the terabyte scale) to store large-scale graphs while still enjoying high-performance graph processing on GPU.

In this paper, we focus on building graph systems on GPU-accelerated heterogeneous platforms to achieve scale-up graph processing for large graphs that cannot fit into GPU memory. This would enable high-performance graph analytics on large-scale graphs everywhere by simply plugging a GPU into an off-the-shelf commodity PC. In this case, a large graph must be partitioned into subgraphs at the host. Any subgraphs to be processed on GPU must be streamed asynchronously to GPU when some previously transferred subgraphs are being concurrently processed on GPU (in an overlapping manner). We consider vertex-centric graph processing [36], where a graph algorithm is performed in a sequence of iterations until convergence [15,36]. In each iteration, a graph algorithm processes only the *active vertices* (vertices with ongoing updates) in each subgraph, updates their neighbors (along their outgoing edges) and activates the neighbors whose values have been updated. In this paper, we restrict ourselves to handle large-scale graphs that can entirely fit into the host memory. Meanwhile, all the vertex data, including vertex states (active or not), are assumed to be resident in the GPU memory. In contrast, the edge data of a graph are stored at the host and partitioned into subgraphs. During graph processing, *active subgraphs* (containing all out-going edges of an active vertex) must be transferred to GPU for iterative processing.

Achieving scale-up graph processing for large-scale graphs on GPU-accelerated heterogeneous platforms is challenging. The power-law graphs [15] can result in substantial load imbalance among threads and warps [39]. Irregular data accesses made in graph algorithms often lead to non-coalesced memory accesses for GPU graph processing. Fortunately, effective techniques for addressing these performance-limiting issues exist [14, 17, 34]. Currently, the performance bottleneck in a GPU-accelerated graph system has shifted to the limited host-GPU bandwidth, which was relatively sufficient in the past (e.g., ∼11.4GB/s for PCI-Express 3.0). However, existing graph processing engines [17, 26, 34, 47] focus still on overcoming the GPU memory capacity limitation to enable large-scale graph processing, without paying adequate attention to the effective utilization of the host-GPU bandwidth.

Simple heuristics are used to reduce the number of data transfers. Totem [14] partitions a graph into two subgraphs, one for the host and one for GPU, by keeping the amount of data transfers to a minimum at the expense of severe load imbalance. Garaph [34] concurrently processes all active subgraphs on both the host and GPU. Graphie [17] processes all subgraphs on GPU but re-processes only the recently processed subgraphs in the next iteration (before they are removed from GPU memory). However, these graph systems always transfer an active subgraph in its entirety to GPU (even though only the neighboring information for its active vertices will usually be used), resulting in poor utilization of the host-GPU bandwidth. To see this, Figure 1 compares the performance results of Graphie [17] for running three graph algorithms on a large graph on a PC with three generations of GPUs (one at a time). We see little performance gains when increasingly more powerful GPUs are used. For example, P100 has over 3× as many #SMX's and 4× as much memory as GTX980, but it offers small performance improvements.

Recently, hardware vendors have launched several advanced interconnect technologies to mitigate the impact of the "bandwidth wall". For example, compared to PCI-E 3.0, NVLINK 2.0 (50GB/s per link) and PCI-E 4.0 (32GB/s) are several times faster, but still cannot keep up with the growth in GPU computing capabilities. Specifically, these advanced technologies cannot yet provide ∼500GB/s required by graph analytics under existing computing platforms [1].

In this work, we argue that we can improve the performance of large-scale graph processing on a GPU-accelerated architecture significantly by improving the effective utilization of the host-GPU bandwidth. Our key observation is that the majority of the data in an active subgraph (once streamed to GPU) are never used in current and future iterations (§2.2). We introduce Scaph that achieves significantly improved performance than state of the art by adopting value-driven differential scheduling for active subgraphs. The key novelty is to classify an active subgraph adaptively into a *high-value subgraph* (if it will be extensively traversed in current and future iterations) and a *low-value subgraph* (otherwise). Thus, a high-value subgraph contains a significant amount of *useful data (UD)* to be used by active vertices in the current iteration and of *potentially useful data (PUD)* to be used by its future active vertices in future iterations. On the other hand, a low-value subgraph contains a lot of *never-used data (NUD)* in current and future iterations.

Unlike earlier graph systems [17,26,34,47], which transfer an active subgraph to GPU in its entirety (but with only its UD used usually), Scaph uses the host to stream an active sub-graph to GPU by using two graph processing engines for handling high-value and low-value subgraphs, respectively. For the high-value subgraph, it will be transferred to GPU entirely. Inspired by the data movement reduction in out-of-core settings [2, 53, 69], we propose to compute each high-value subgraph multiple times to exploit its PUD ahead of schedule for accelerating convergence. Unlike these earlier efforts focusing on exploiting only the PUD in a subgraph, we present a GPU-context-friendly delayed scheduling to enable exploiting the PUD *across subgraphs on GPU* such that the value of the high-value subgraphs can be maximized. For the low-value subgraph, only the neighboring information for its active vertices is transferred and scheduled once.

In summary, this paper makes the following contributions:

- *Subgraph Value Characterization.* We quantify the value of a subgraph adaptively (dynamically) in terms of its UD and PUD used in current and future iterations.
- *Value-Driven Differential Scheduling.* We propose a scheduler that adaptively distinguishes high- and low-value subgraphs in each iteration and dispatches a subgraph to an appropriate graph processing engine for acceleration.
- *Value-Driven Graph Processing Engines.* We introduce two graph processing engines to squeeze the most value out of high- and low-value subgraphs to maximize the effective utilization of the host-GPU bandwidth in each case.
- *Evaluation.* We evaluate Scaph on both real-world and synthesized large graphs. Scaph outperforms state-of-the-art heterogeneous graph systems, Totem (4.12×) [14], Graphie (8.93×) [17], and Garaph (3.71×) [34], on average.

The rest of this paper is organized as follows. §2 describes the background and motivation. §3 gives an overview of

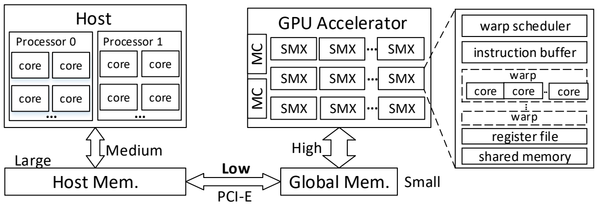

Figure 2: A GPU-accelerated heterogeneous architecture

Scaph. §4 describes value-driven differential scheduling while §5 discusses how to accomplish this effectively. §6 presents results. §7 discusses the related work. Finally, §8 concludes.

2 Background and Motivation

We first review the background. We then present some case studies to reveal why the poor host-GPU bandwidth utilization has limited the performance achieved by existing heterogeneous graph systems, finally motivating Scaph.

2.1 Host-GPU Heterogeneous Architectures

Figure 2 shows a representative GPU-accelerated heterogeneous architecture that integrates the hardware advantages of the host (with a larger host memory) and the GPU (with a stronger computing ability). A GPU consists of multiple *streaming multiprocessors* (SMXs), each of which includes hundreds of cores. Compared to the high-speed internal bandwidth (e.g., ∼720GB/s for NVIDIA Tesla P100 [41]) of GPU cores accessing global memory, a GPU is generally connected to the host with a relatively slow interface. For example, the host-GPU bandwidth via PCI Express 3.0 can be limited to be as low as ∼11.4GB/s in practice [5]. This significant performance gap often severely limits the performance potential achieved on a GPU-accelerated heterogeneous architecture if the host-GPU data transfers are frequent [17, 26]. This work makes use of a PCI Express interconnect since it is commonly used in the current commodity market.

2.2 A Motivating Study

Existing heterogeneous graph systems [17, 26, 47], with Graphie [17] as a representative compared against in our evaluation, generally use host memory to store large-scale graphs (partitioned into subgraphs) and rely on GPUs exclusively to accelerate graph analytics on these subgraphs. Figure 3 depicts their generic graph processing engine used, with the function calls in blue executed on GPU. Due to the limited GPU memory, a graph G is first divided into subgraphs, $\tilde{G}_1, \cdots, \tilde{G}_n$ (line 2). During the entire iterative graph processing, the vertex data of G always reside in GPU memory, but the edge data of G, which are spread across these subgraphs, will be streamed to GPU on-demand [17, 26, 34, 47].

At each iteration (lines 5 – 12), $\tilde{G}_{active}$ represents the set of active subgraphs, i.e., the ones containing some out-going edges of an active vertex. In each iteration, all active vertices are processed. If their out-going edges are not in the GPU, their containing (active) subgraphs are transferred to GPU in their entirety. Afterward, these active vertices will be processed on the GPU (lines 13 – 18) to activate more destination vertices possibly. Note that Graphie [17] may schedule first the subgraphs processed at the end of the previous iteration as they are still in GPU memory (line 8).

```
1   Procedure SimpleSubgraphEngine(Graph $G$)
2       Load $\tilde{G}$'s subgraphs in $\{\tilde{G}_1, \cdots, \tilde{G}_n\}$ into the host
3       VertexInitialization($G$)
4       $\tilde{G}_{active} \leftarrow$ FindActiveSubgraph($G$)
5       while $\tilde{G}_{active} \neq \emptyset$ do
6           foreach $\tilde{G}_i \in \tilde{G}_{active}$ do
7               $stream \leftarrow$ DispatchStream($\tilde{G}_i$)
8               if $\tilde{G}_i$ is not resident in GPU memory then
9                   $GBuf \leftarrow$ AllocateDeviceMemory( )
10                  TransferData($stream$, $GBuf$, $\tilde{G}_i$, CPU2GPU)
11              Kernel ($stream$, $\tilde{G}_i$)
12          $\tilde{G}_{active} \leftarrow$ FindActiveSubgraph($G$)
    /* Graph Processing Kernel on the GPU */
13  Procedure Kernel(Subgraph $\tilde{G}$)
14      foreach $v \in \tilde{G}.SetOfVertices$ do
15          if $v$ is active then
16              foreach $e \in v.outedges$ do
17                  if Update($v$, $e$) = SUCCESS then
18                      Activate($e.destination\_vertex$)
```

Figure 3: Existing graph processing engine on a GPU-accelerated heterogeneous architecture (with the function calls in blue executed on GPU and all the rest on the host)

Table 1: The amount of used/unused data in the subgraphs transferred to GPU

	Algo.	Used	Unused
TW	CC	12.15GB	21.44GB
	SSSP	22.74GB	77.42GB
	MST	25.78GB	106.47GB
UK	CC	43.41GB	688.43GB
	SSSP	81.64GB	1302.85GB
	MST	134.97GB	2099.25GB

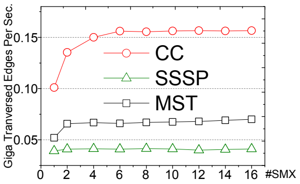

Figure 4: Performance of Graphie for TW with different number of SMXs

This simple graph processing engine does not effectively utilize the limited, scarce host-GPU bandwidth since many vertices in an active subgraph are not active. Simply transferring an entire subgraph to GPU (line 10) but consuming only a fraction of its data (lines 14 – 15) will waste a considerable amount of the host-GPU bandwidth. As a result, all the required data cannot arrive at the GPU promptly, limiting the performance that can be potentially achieved on GPU.

Let us examine the ratios of the unused over used data in the subgraphs transferred to GPU for three graph algorithms operating on two graphs, twitter (TW) [29] and uk-2007 (UK) [6], by Graphie [17] using the graph processing engine given in Figure 3. Table 1 gives the results obtained through an offline trace analysis, showing that these ratios range from 6.29 to 36.17. This indicates that the host-GPU bandwidth under Graphie is utilized rather ineffectively. Consequently, as shown further in Figure 4, the performance of Graphie for

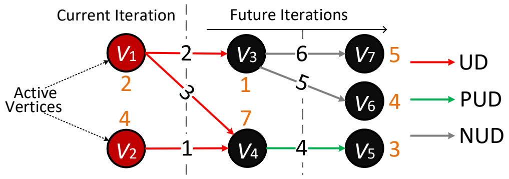

Figure 5: UD, PUD, and NUD in a subgraph, which may change across the iterations, illustrated for SSSP. The weight of an edge denotes its distance. The shortest distance found so far by SSSP at a vertex is depicted next to it in orange.

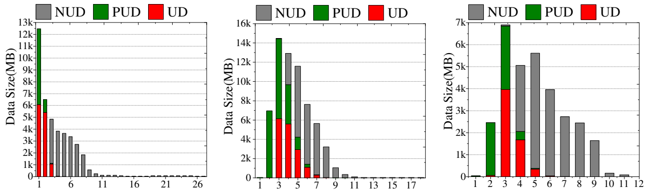

(a) CC

(b) SSSP

(c) MST

Figure 6: The amount of UD, PUD, and NUD across the iterations for three graph algorithms on twitter (TW) [29]

each graph algorithm (operating on TW) has plateaued as soon as #SMXs = 4. However, mainstream GPU accelerators usually have far more than 4 SMXs. For example, NVIDIA's Tesla K80 has 26 SMXs, while P100 has been integrated with 56 SMXs. Thus, a significant gap remains between the poor provision of data and high-speed computation of GPU.

2.3 Value-Driven Subgraph Scheduling

For a subgraph, its active vertices vary across the iterations. However, from the perspective of an active vertex, it always contains three types of edge data, as illustrated in Figure 5:

- *Useful Data (UD).* These are the edge data associated with all the active vertices in a subgraph, i.e., $V_1 \xrightarrow{2} V_3$, $V_1 \xrightarrow{3} V_4$, and $V_2 \xrightarrow{1} V_4$ in Figure 5. UD will definitely be used in the current iteration (lines 15 – 16 in Figure 3) and must be transferred to GPU [17, 26, 47].
- *Potentially Useful Data (PUD).* These are the edge data associated with all the future active vertices in future iterations in a subgraph. In Figure 5, PUD will be just $V_4 \xrightarrow{4} V_5$, since V_4 will be the only one activated by both V_1 and V_2 in current and future iterations. Unlike UD, PUD is not actually used in the current iteration, but may be transferred repeatedly to GPU if not handled carefully (as in the case of Figure 3 where PUD is usually discarded).
- *Never Used Data (NUD).* These are the edge data that will never be used again in a subgraph, associated with its vertices that have converged and will thus never be active. In Figure 5, NUD are $V_3 \xrightarrow{5} V_6$ and $V_3 \xrightarrow{6} V_7$.

Note that the same vertex may be activated many times in different iterations. Given a subgraph, its UD, PUD, and NUD computed at different iterations can vary dynamically.

Figure 6 shows the amount of UD, PUD, and NUD for the

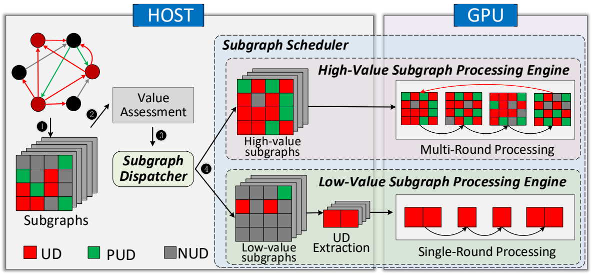

Figure 7: The workflow of Scaph

active subgraphs across all the iterations for three graph algorithms operating on twitter (TW) [29], partitioned sequentially into subgraphs of 32MB each. Graphie [17], a representative of existing heterogeneous graph systems [17, 26, 47], wastes the host-GPU bandwidth in two ways (Figure 3). First, PUD, usually discarded by Graphie but needed in future iterations, is substantial in earlier iterations. Second, NUD, which is becoming increasingly more dominant as the iteration progresses, is streamed to GPU redundantly.

For a subgraph, it will be cost-ineffective to stream just its UD, since its PUD cannot be exploited simultaneously. Instead, our key insight for improving the effective utilization of the host-GPU bandwidth is to look beyond the current iteration, by considering not only its UD in the current iteration but also its PUD in future iterations. Based on a cost-benefit analysis, we aim to leverage rather than discard its PUD (once streamed to GPU) in iterative graph processing. Thus, the value of a subgraph at an iteration should be measured in terms of not only its UD but also its PUD.

Now, how do we extract the UD and PUD from a subgraph at a given iteration so that both can be transferred to GPU? Extracting the UD from a subgraph is easy as its active vertices in the current iteration are known (lines 4 and 12 in Figure 3). However, extracting precisely the PUD (without NUD) from a subgraph is difficult, as its future active vertices are not known yet during the current iteration.

For a given subgraph, we propose to predict its PUD size at an iteration from the UD sizes in the current and past iterations. This enables to adopt a value-driven differential scheduler that computes the value of a subgraph adaptively and schedules it depending on if it has a high value (when its UD and PUD are dominant) or a low value (otherwise).

3 Scaph Overview

Figure 7 shows the workflow of Scaph, in which all the subgraphs of a graph are computed on the GPU while the host is responsible for their preparation. At each iteration, its dispatcher classifies a subgraph into either a high-value or low-value subgraph and sends it to its corresponding engine to facilitate value-driven differential scheduling. Both engines schedule their subgraphs for acceleration on GPU independently but concurrently.

Value-Driven Subgraph Dispatcher. Conceptually, the value of a subgraph at a given iteration is proportional to the amount of its UD and PUD. The key insight here is that, for a given subgraph, although accurately computing its PUD is difficult, its PUD size can be approximated based on the UD sizes in the current and past iterations. For a subgraph at a given iteration, Scaph's subgraph dispatcher (§4), classifies it adaptively as a high-value subgraph if it contains a sufficient amount of UD and PUD to justify its transfer in its entirety to GPU and a low-value subgraph to request only its UD to be transferred to GPU otherwise. This is done adaptively as the value of a subgraph changes as the iteration progresses.

Value-Driven Subgraph Scheduler. Scaph has two separate graph processing engines, described in §5, to process differentially high- and low-value subgraphs. For a high-value subgraph, we use a queue-assisted multi-round processing engine, which streams it entirely from the host to GPU (if it is not in GPU memory) and exploits both its UD and PUD adequately to enable faster convergence. For a low-value subgraph, Scaph relies on the graph processing engine given in Figure 3 but transfers only its UD to GPU, with the UD extracted in a NUMA-aware manner on the host.

Scaph is essentially a hybrid graph system that allows out-of-order computation of high-value subgraphs in each synchronous iteration. The use of asynchronous execution allows fast convergence but also changes the vertex scheduling priority of subgraphs. Therefore, a graph algorithm can use Scaph safely for preserving the convergence and the converged values, if it satisfies the correctness condition that the final vertex results are insensitive to the value propagation order.

4 Value-Driven Subgraph Dispatching

In Section 4.1, we quantify the value of a subgraph. In Section 4.2, we discuss how to estimate the value of a subgraph to support value-driven differential scheduling.

4.1 Quantifying the Value of a Subgraph

Graph computations proceed iteratively until convergence. Conceptually, the value of a subgraph $\tilde{G}$ can be measured in terms of its UD used in the current iteration and its PUD used in future iterations. Therefore, the *value* of $\tilde{G}$, denoted $Val(\tilde{G})$, from the current iteration Cur to the MAX-th iteration (beyond which $\tilde{G}$ is no longer active), is defined as:

$$Val(\tilde{G}) = \sum_{i=Cur}^{MAX} \sum_{v \in \tilde{G}.SetOfVertices} D(v) * A^i(v) \tag{1}$$

where $D(v)$ represents the number of out-going edges of vertex v restricted to $\tilde{G}$ and $A^i(v) \in \{0,1\}$ indicates that v is active (inactive) in the i-th iteration when $A^i(v) = 1$ ($A^i(v) = 0$). $Val(\tilde{G})$ represents the amount of computations arising from $\tilde{G}$ from the current iteration until convergence. According to Equation (1), the PUD of a subgraph is quantized by the number of its edges that will be used in future iterations.

The value of a subgraph depends upon its active vertices and their degrees. In the case of uniform degree distributions, the activation status of vertices can still differentiate the amount of UD, PUD, and NUD for a subgraph.

4.2 Value-Driven Differential Scheduling

Scaph emphasizes value-driven data transfers, which should directly reflect how the bandwidth is *effectively* utilized in order to enable faster convergence.

The intuition behind $Val(\tilde{G})$ is clear. If $Val(\tilde{G})$ is high, $\tilde{G}$ should be a high-value subgraph. Then we should transfer $\tilde{G}$ as a whole to GPU and also exploit its UD and PUD adequately by iterating over $\tilde{G}$ multiple times before it is removed from GPU memory. Otherwise, $\tilde{G}$ should be treated as a low-value subgraph. In this case, we will opt to transfer only its UD to GPU and just iterate over the resulting $\tilde{G}$ once.

If $\tilde{G}$ is a high-value subgraph, then the throughput of processing $\tilde{G}$ on GPU can be measured as follows:

$$T_{HV}(\tilde{G}) \quad = \quad \frac{|UD| + \lambda |PUD|}{|\tilde{G}|/BW + t_{barrier}} \tag{2}$$

The denominator $|\tilde{G}|/BW + t_{barrier}$, which represents the data transfer time for $\tilde{G}$, is used to approximate the time elapsed on processing $\tilde{G}$ by assuming a complete overlap between data transfers and computations on GPU. As $\tilde{G}$ is transferred in its entirety to GPU, $|\tilde{G}|$ denotes the amount of data thus transferred, BW represents the host-GPU bandwidth, and $T_{barrier}$ is the synchronization overhead for $\tilde{G}$ (amortized by the number of active subgraphs processed). The numerator $|UD| + \lambda * |PUD|$ represents the amount of UD and PUD accessed when $\tilde{G}$ is iterated over on GPU. We use a balancing factor λ to decay $|PUD|$, where $0 \leqslant \lambda \leqslant 1$, to signify the actual amount of PUD accessed.

If $\tilde{G}$ is a low-value subgraph, then we have:

$$T_{LV}(\tilde{G}) \quad = \quad \frac{|UD|}{|UD|/BW + t_{barrier}} \tag{3}$$

This time, only the UD of $\tilde{G}$ is streamed to GPU.

Now, $\tilde{G}$ is a high-value subgraph if $T_{HV}(\tilde{G}) \geqslant T_{LV}(\tilde{G})$ and a low-value subgraph otherwise. Thus, we need to analyze:

$$|UD| + \lambda |PUD| (1 + \frac{t_{barrier}}{|UD|/BW}) > |\tilde{G}| \tag{4}$$

To verify $T_{HV}(\tilde{G}) \geqslant T_{LV}(\tilde{G})$, the key lies in determining $|PUD|$, which is difficult to obtain directly. In fact, for a subgraph, its PUD is technically activated from its UD, motivating us to estimate the PUD of a subgraph heuristically based on the UD of the same subgraph. In this work, we consider a subgraph to have a high value if either of the following two conditions (which we found to work well across all of our applications, as confirmed in §6) holds to simplify Equation (4):

```
1  Procedure VDDSEngine(Graph $G$)
2      Distribute $G$'s subgraphs $\{\tilde{G}_1,\cdots,\tilde{G}_n\}$ to NUMA nodes
3      VertexInitialization($G$)
4      $\tilde{G}_{active} \leftarrow$ FindActiveSubgraph($G$)
5      Transfer VertexStates from GPU to CPU
6      while $\tilde{G}_{active} \neq \emptyset$ do
7          foreach $\tilde{G} \in \tilde{G}_{active}$ do
8              if Predictor( $\tilde{G}$) = "HIGH-VALUE" then
9                  Push(HVworklist, $\tilde{G}$)
10             else
11                 Push(LVworklist, $\tilde{G}$)
12         HVSPEngine(HVworklist)
13         LVSPEngine(LVworklist, VertexStates)
14         $\tilde{G}_{active} \leftarrow$ FindActiveSubgraph($G$)
15         Transfer VertexStates from GPU to CPU
```

Figure 8: Value-driven differential scheduling for high- and low-value subgraphs, with the calls in blue executed on GPU

- $|UD|/|\tilde{G})| > \alpha$. This indicates that UD is dominant among $\tilde{G}$. Intuitively, $\tilde{G}$ is a high-value subgraph.
- $|UD_{current}| - |UD_{last}| > 0$ and $|UD|/|\tilde{G}| > \beta$. UD remains a medium level and is also growing increasingly over iteration, indicating the potentially growing PUD. $\tilde{G}$ can be thus treated as a high-value subgraph.

When α is relatively large, which implies that the UD in a subgraph tends to be dominant, we can determine if it is a high-value subgraph by considering only its UD. β is needed to identify the high-value subgraphs where the amount of UD is relatively low and that of PUD is potentially high. Thus, β is often smaller than α. As shown in Table 1, considering both together is often more effective than considering either alone. In this work, α and β are set empirically as 50% and 30% to represent a nice point for yielding good results.

Figure 8 gives our value-driven differential scheduler, `VDDSEngine()`, for scheduling a graph G. Initially, G is partitioned into subgraphs, $\tilde{G}_1, \cdots, \tilde{G}_n$, at the host and distributed across its NUMA nodes (to facilitate their scheduling). Scaph uses two graph processing engines, as described in §5 below, `HVSPEngine()` for scheduling high-value subgraphs, and `LVSPEngine()` for scheduling low-value subgraphs. In line 8, Scaph uses the above heuristic predictor to estimate the value of an active subgraph. Note that both engines work independently but concurrently. `LVSPEngine()` needs *VertexStates* in order to perform UD extraction for the active vertices in each subgraph. The UD extraction can be overlapped effectively with the data transfers in `HVSPEngine()`. At the end of each iteration (line 15), Scaph will transfer back the updated vertices from the GPU to the CPU. Edges, which are not modified, are thus not transferred.

5 Value-Driven Subgraph Processing

Scaph has two graph processing engines. We describe the one for handling high-value subgraphs in §5.1 and the one for handling low-value subgraphs in §5.2.

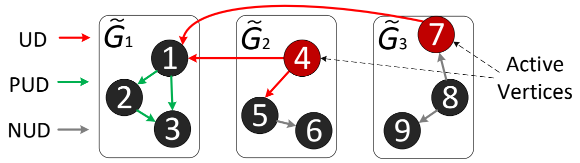

Figure 9: An example illustrating value propagation across the subgraphs, with ❶ activatable by ❹ and ❼. The PUD in $\tilde{G}_1$ can be exploited only if $\tilde{G}_2$ and/or $\tilde{G}_3$ are processed first.

5.1 High-Value Subgraph Processing

The key to extracting the most value out of high-value subgraphs lies in how to fully exploit their PUD. A useful idea of running each loaded subgraph multiple times is leveraged in the out-of-core settings [2, 53, 69] to exploit the *intrinsic value in a subgraph* for reducing the number of I/Os between memory and disk. However, under a GPU-accelerated heterogeneous architecture, subgraphs must often be small enough (in several tens of millions of bytes [17, 26]) against the ones in out-of-core settings, to enable fine-grained GPU scheduling. In this case, simply iterating over such a small-sized subgraph multiple times is often ineffective, since it can exploit only the PUD of its active vertices activated by its other active vertices but not active vertices from other subgraphs.

In Scaph, we improve the PUD exploitation significantly by enabling exploiting the *external value across the subgraphs*. Our key observation is that: *given a subgraph already available in GPU memory, scheduling it again* ***after a period of delay*** *can expose its PUD more fully than processing it repeatedly*. Figure 9 illustrates this with three subgraphs, exhibiting some complex inter-subgraph data dependencies (as is often the case in practice). We see that ❶ in $\tilde{G}_1$ can be activated by ❹ in $\tilde{G}_2$ and ❼ in $\tilde{G}_3$. Once ❶ in $\tilde{G}_1$ is activated, ❷ in $\tilde{G}_1$ may get activated (as shown). In this case, the edge data for ❶→❷, ❶→❸, and ❷→❸ are part of the PUD of $\tilde{G}_1$. By processing $\tilde{G}_1$ after $\tilde{G}_2$ or $\tilde{G}_3$ or both (even better), we can exploit such PUD to enable faster convergence. That is, repeatedly processing $\tilde{G}_1$ would not help.

Queue-Assisted Multi-Round Processing. The scheduling of high-value subgraphs at a given iteration is shown in Figure 10. We use a k-level priority queue ($PQ_1, \ldots, PQ_k$) to enable re-scheduling a GPU-resident subgraph after some delay, where k indicates the maximum number of times some subgraphs have been processed in the current iteration. Thus, k varies from iteration to iteration. Figure 11 shows a case.

In each differential scheduling iteration orchestrated by `VDDSEngine` (Figure 8), `HVSPEngine(worklist)` is invoked, where *worklist* contains all the high-value subgraphs in this iteration. During the pre-processing (lines 2–6), each subgraph $\tilde{G}_i$ in *worklist* is examined in turn. $\tilde{G}_i$ will be enqueued into PQ_1 (if not already there) if $\tilde{G}_i$ remains to be GPU-resident (i.e., in one of $\{PQ_1, \ldots, PQ_k\}$) from the previous iteration and inserted into *TransSet* (waiting to be streamed to GPU) otherwise. Thus, there are two concurrently executed modules,

```
1  Procedure HVSPEngine(worklist)
2      foreach $\tilde{G}_i \in$ worklist do
3          if $\tilde{G}_i$ is resident in GPU memory then
4              Push($PQ_1$, $i$)
5          else
6              Push(TransSet, $i$)
       /* Subgraph Transferring Module */
7      while $TransSet \neq \emptyset$ do
8          if copystream is available then
9              $i \leftarrow$ Pop(TransSet)
10             if GPU has available memory for one subgraph then
11                 $Gbuf \leftarrow$ AllocateDeviceMemory( )
12             else
13                 $j \leftarrow$ Pop($PQ_k$)
14                 $Gbuf \leftarrow$ GetGbuf($\tilde{G}_j$)
15             TransferData(copystream, Gbuf, $\tilde{G}_i$, CPU2GPU)
16             Push($PQ_1$, $i$)
       /* Subgraph Scheduling Module */
17     while $worklist \neq \emptyset$ do
18         if at least one stream in execstreams is available then
19             stream $\leftarrow$ Available(execstreams)
               /* Exploit the UD of a subgraph in $PQ_1$ */
20             if $PQ_1 \neq \emptyset$ then
21                 $i \leftarrow$ Pop($PQ_1$)
22                 Kernel(stream,$\tilde{G}_i$)
23                 Erase(worklist, $\tilde{G}_i$)
               /* Exploit the PUD of a subgraph in $PQ_i$, where $i \neq 1$ */
24             else
25                 for $p \leftarrow 2$ to $k$ do
26                     if $PQ_p \neq \emptyset$ then
27                         $i \leftarrow$ Pop($PQ_p$)
28                         Kernel(stream,$\tilde{G}_i$)
29                         break
30             priority $\leftarrow$ GetPriority($\tilde{G}_i$)
31             Push($PQ_{priority+1}$, $\tilde{G}_i$)
```

Figure 10: High-value subgraph processing in each iteration (called from Figure 8). The Kernel function is from Figure 3. The two colored code regions are executed in parallel.

Subgraph Transferring and Subgraph Scheduling.

The Subgraph Transferring module (lines 7 – 16) is responsible for streaming asynchronously the subgraphs in *TransSet* to GPU. This is done by using some free GPU memory whenever possible (line 11) or making some free by dequeuing a subgraph from the multi-level queue (lines 13 – 14). Due to lines 4 and 16, all subgraphs in *worklist* are initially enqueued into PQ_1, and thus assigned with the highest priority.

The Subgraph Scheduling module (lines 17 – 31) is responsible for scheduling the subgraphs in $PQ_1, \cdots, PQ_k$. The subgraphs in PQ_1 are processed first (for the first time in the current iteration) to exploit their UD (lines 21 – 23). If $PQ_1 = \emptyset$ (implying that some subgraphs are still being transferred to GPU asynchronously), the scheduler will dequeue a subgraph from a non-empty PQ_i, where i is the smallest, to exploit its PUD (lines 25 – 29), as this will be the i-th time that the subgraph is processed (in the i-th round) of the current iteration. Simultaneously, the data transfers for PQ_1 and the computations for $PQ_2, \cdots, PQ_k$ are maximally overlapped, too. In either case, the priority of a subgraph, once processed, drops by one (lines 30 – 31). This delayed re-scheduling attempts to maximize the PUD exploitation, by, e.g., increasing the chances for $\tilde{G}_1$ to be processed after $\tilde{G}_2$ and/or $\tilde{G}_3$ in Figure 9 (as motivated earlier). Consider $\tilde{G}_3$, which resides in PQ_1, in Figure 11. Once we have exploited its UD, we will move it to PQ_2 so that we can exploit its PUD after $\tilde{G}_7$, $\tilde{G}_4$, $\tilde{G}_8$, and $\tilde{G}_6$ have been processed.

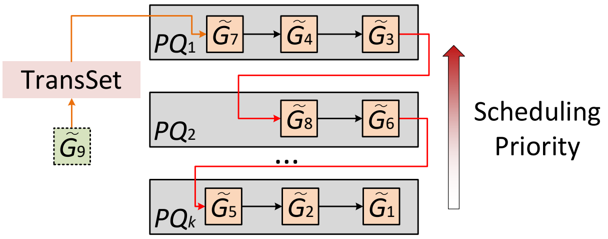

Figure 11: Subgraph processing with a k-level priority queue. PQ_i represents a queue PQ with the i-th priority. The smaller i is, the higher the priority is. All the subgraphs streamed from the host to GPU enter into PQ_1 initially.

Our scheduler with a multi-level priority queue guarantees that subgraphs are scheduled fairly, preventing them from bearing too many *useless computations* in the sense that the data of a vertex is computed but not updated.

Time and Space Complexity Analysis. k is expected to be bounded by $\frac{BW'}{BW}$ where BW' is the internal bandwidth of GPU and BW is the host-GPU bandwidth. In our computing platform, $BW' = 224$GB/s and $BW = 11.4$GB/s. Thus, $k \leqslant 20$ is typically expected.

As for the space complexity, a k-level priority queue is used to keep track of only the indices of the active subgraphs processed in an iteration. Thus, the worst complexity is $O(\frac{Mem_{GPU} \times \text{sizeof(SubgraphIndex)}}{|\tilde{G}|})$, where Mem_{GPU} is the global memory size and $|\tilde{G}|$ is the size of a subgraph $\tilde{G}$. In our computing platform, we have used $\frac{4\text{GB} \times 4\text{B}}{32\text{MB}} = 0.5$KB.

5.2 Low-Value Subgraph Processing

The key to exploiting the most value of low-value subgraphs is to extract their UD efficiently. We use multiple CPU cores at the host to parallelize the UD extraction. Due to *non-uniform memory access* (NUMA), however, scanning naively all the vertices in a subgraph to extract its UD can still be costly. In addition, different subgraphs exhibit different amounts of UD. Such scanning tasks are also prone to load imbalance.

Figure 12 gives our scheduler for low-value subgraphs. In each value-driven scheduling iteration orchestrated by `VDDSEngine()` in Figure 8, `LVSPEngine(worklist, VertexStates)` is invoked, where *worklist* contains all the low-value subgraphs that are active in this iteration, with their active vertices indicated in *VertexStates*. There are three modules, UD Extraction, Subgraph Transferring, and Subgraph Scheduling, which all execute concurrently. The major contribution here is a NUMA-aware parallel UD extraction.

UD Extraction. Initially, all the subgraphs partitioned from a graph are evenly distributed to different NUMA nodes,

```
1  Procedure LVSPEngine(worklist, VertexStates)
       /* UD Extraction Module */
2      para_for $\tilde{G}_i \in$ worklist do
3          $\tilde{G}'_i \leftarrow$ UDExtraction($\tilde{G}_i$, VertexStates)
4          Push(TransSet, i )
       /* Subgraph Transferring Module */
5      while TransSet $\neq \emptyset$ do
6          if copystream is available then
7              $i \leftarrow$ Pop(TransSet)
8              Gbuf $\leftarrow$ AllocateDeviceMemory()
9              TransferData(copystream, Gbuf, $\tilde{G}'_i$, CPU2GPU)
10             Push(ExecFIFO, i )
       /* Subgraph Scheduling Module */
11     while worklist $\neq \emptyset$ do
12         if at least one stream in execstreams is available then
13             stream $\leftarrow$ Available(execstreams)
14             $i \leftarrow$ Pop(ExecFIFO)
15             Kernel(stream, $\tilde{G}'_i$)
16             Erase(worklist, $\tilde{G}_i$)
   /* Extract UD on the host */
17 Procedure UDExtraction($\tilde{G}$, VertexStates)
18     $\tilde{G}' \leftarrow \emptyset$
19     Offset $\leftarrow 0$
20     while offset $\leqslant |\tilde{G}$.SetOfVertices$|$ do
21         WORD $\leftarrow$ Load(VertexStates($\tilde{G}$).bitmap, offset, 32)
22         if WORD $\neq 0$ then
23             foreach BYTE $\in$ WORD do
24                 if BYTE $\neq 0$ then
25                     foreach BIT $\in$ BYTE do
26                         if BIT = 1 then
27                             $v \leftarrow$ GetVert(offset, BYTE,
                                   BIT)
28                             $\tilde{G}' \leftarrow \tilde{G}' \bigcup v$.outedges
29         offset $\leftarrow$ offset + 32
30     return $\tilde{G}'$
```

Figure 12: Low-value subgraph processing in each iteration (called from Figure 8). The Kernel function is from Figure 3. The three shaded code regions are executed in parallel.

with a NUMA node consisting of a CPU socket and its own memory banks (line 2 in Figure 8). The UD extraction module is given in terms of lines 2 – 4 and lines 17 – 30. To boost performance and improve intra-node load balancing, the UD extraction for each subgraph is done in its own thread, which is bound to the NUMA node storing the subgraph (line 3). To improve inter-node load balancing (as a minor optimization), we also duplicate in a NUMA node an equal number of randomly selected subgraphs from the other nodes (if there is still some memory space available). We adopt a simple bitmap-based approach to extract the UD from a subgraph $\tilde{G}$ efficiently (lines 17–30). All its vertices are stored in a bitmap, $VertexStates(\tilde{G}).bitmap$, with 1 (0) indicating that the corresponding vertex in $\tilde{G}$ is active (inactive). To accelerate its construction, the total of active vertices is computed on GPU.

Unlike high-value subgraphs, which can each be stored in the same-sized chunk in GPU memory (§5.1), low-value subgraphs may give rise to UD-induced subgraphs of varying sizes. To reduce fragmentation, Scaph further divides each chunk for storing a subgraph into smaller tiles (totaling 32 in our implementation). To store a UD-induced subgraph in GPU memory, Scaph will try to find consecutive tiles first in a partially filled chunk and then in a vacant chunk.

Subgraph Transferring. As in the case of high-value subgraph streaming in Figure 10, this module proceeds similarly except that a multi-level queue is no longer used.

Subgraph Scheduling. As in the case of scheduling high-value subgraphs to GPU in Figure 10, this module schedules UD-induced subgraphs (without using a multi-level queue).

6 Evaluation

We evaluate the efficiency and scalability of Scaph by answering the following four research questions (RQs):

- ***RQ1:*** How much more efficient is Scaph over state-of-the-art heterogeneous graph systems?
- ***RQ2:*** How effective is Scaph's value-driven differential scheduling in helping it achieve the overall performance?
- ***RQ3:*** How well does Scaph scale?
- ***RQ4:*** How much runtime overhead does Scaph introduce?

6.1 Experimental Setup

We compare Scaph with the following three state-of-the-art CPU-GPU heterogeneous graph systems:

- Totem [14]. A graph is divided into two subgraphs, which are processed by CPU and GPU, respectively. At the end of each iteration, the states of the active vertices that are activated reciprocally by the two subgraphs are exchanged.
- *Graphie* [17]. Like Scaph, a graph is initially partitioned at the host CPU and the subgraphs are then streamed to GPU for graph processing. Unlike Scaph, however, all active subgraphs are transferred to GPU in their entirety.
- *Garaph* [34]. At an iteration, all the subgraphs that are partitioned from a graph are processed concurrently by both the host and GPU if the number of outgoing edges of all active vertices in the entire graph exceeds 50% of the total number of edges and on the host only otherwise.

Subgraph Size. For Totem, Graphie, and Garaph, the sizes of subgraphs are selected from their papers. In Scaph, a graph is partitioned into subgraphs of 32MB each for several reasons. First, the host-GPU bandwidth tends to be under utilized with smaller sizes. Second, subgraphs will be streamed to GPU more frequently with larger sizes, as they tend to contain active vertices for more iterations. Finally, the kernel launching overheads appear to be well hidden with 32MB.

Graph Applications. We consider the first three typical graph algorithms (from different categories) and the latter two actual graph workloads (with different complexities): (1) *Single-Source Shortest Path* (SSSP) [60]–Sequential traversal, (2) *Connected Components* (CC) [20]–Parallel traversal, (3) *Minimum Spanning Tree* (MST) [37]–Graph mutation, (4) *Neural Network Digit Recognition* (NNDR) [4], and (5) *Graph-based Circuit Simulation* (GCS) [25]. All these algorithms fit the correctness criteria discussed in §3, though NNDR and GCS are already typically executed in an asyn-

Table 2: Graph datasets. The graph size is evaluated in the weighted edgelist representation.

	Scaph	3.33	4.08	10.46	16.13	39.52	54.94

chronous way, while the other algorithms are typically run in a synchronous, iterative manner.

Graph Datasets. We use (1) 6 real-world graphs [6, 31]) for performance evaluation, and (2) 5 large synthesized graphs (generated by the RMAT tool [7]) for scalability evaluation. Table 2 gives all the graphs used. For SSSP and MST that work on the weighted graphs, we randomly assign each edge of an unweighted graph with a weight ranging from 1 to 100.

Computing Platform. We evaluate Scaph on a machine where the host is equipped with two Intel 14-core Xeon CPUs, E5-2680v4@2.40GHz with 512GB memory (256GB on each of the two NUMA nodes). The GPU is NVIDIA P100 (with 56 SMXs, 3584 cores, and 16GB memory), connected to the host via the PCI Express 3.0 at 16x. The host-GPU bandwidth is around 11.4GB/s. We use NVCC V8.0.61 and g++ V5.4.0 to compile all the applications under "-O3". The operating system is Ubuntu 14.04 with Linux kernel 4.13.

6.2 RQ1: Efficiency

To answer RQ1, we compare Scaph against Totem [14], Graphie [17], and Garaph [34]. Table 3 depicts the results.

Scaph vs. Totem. The speedup of Scaph over Totem ranges from 2.23× (for SSSP on SK) to 7.64× (for CC on TW) with an average of 4.12×. Totem's critical performance bottleneck lies in its severe load imbalance, as it partitions each graph into only two subgraphs, one for the host (with 512GB memory) and one for GPU (with only 16GB memory). As a result, Totem cannot tap GPU's processing power to exploit adequately the UD and PUD in a graph. Its bottleneck is to ask the CPU to process most of the graph data, which would have been processed more efficiently by the GPU otherwise. A typical measurement for FB is for the CPU to handle 358.1GB and the GPU to handle only 16GB. In contrast, Scaph streams all subgraphs dynamically to GPU with value-driven differential scheduling, thereby exploiting more adequately GPU's processing power, and consequently, the UD and PUD in all the subgraphs. In the case of CC operating on FR, SK, and UK, their GPU portions under Totem are 39.6%, 36.7%, and 19.1%, respectively. As a result, Scaph outperforms Totem by 5.51x (FR), 2.52x (SK), and 3.77x (UK).

Scaph vs. Graphie. Scaph is faster than Graphie by 8.93× on average, with its speedup ranging from 3.03× (for NNDR on TW) to 16.41× (for SSSP on SK). Both Graphie and Scaph process all subgraphs on GPU only. So Graphie can be understood as a version of Scaph, where every subgraph is treated as a high-value subgraph except that only its UD is used but its PUD is exploited rather inadequately. Graphie is inferior to Scaph for several reasons. First, Graphie transfers an active subgraph entirely to GPU even though it contains only a few active vertices (i.e., a lot of NUD), wasting the host-GPU bandwidth. Second, Graphie exploits the UD only but PUD inadequately in an active subgraph.

Let us examine SSSP on SK, where the speedup of Scaph over Graphie is the highest (at 16.41×). Graphie converges in 75 iterations, by transferring 18,019 subgraphs totaling 374.4GB data to GPU. In contrast, Scaph converges in 16 iterations, by transferring 9,897 subgraphs totaling only 19.6GB data, comprising 13.2GB for 798 high-value subgraphs and 6.4GB for 9,099 low-value subgraphs. For Scaph, its significantly improved utilization for the host-GPU bandwidth has resulted in its significantly improved overall performance.

Scaph vs. Garaph. Scaph is faster than Garaph by 3.71×, with an overall rang from 1.93× (for NNDR on TW) to 5.62× (for CC on FB). Unlike Scaph, Garaph processes all the subgraphs on both the host and GPU if the active vertices in the entire graph have a lot of outgoing edges and on the host only otherwise (§6.1). Despite this, Garaph cannot distinguish high-value from low-value subgraphs as Scaph does. While being more effective than Graphie in reducing the amount of NUD transferred, Garaph is inferior to Scaph as it still transfers more NUD to GPU and exploits PUD less adequately.

Let us examine CC on FB, where the speedup of Scaph over Garaph is the highest (at 5.62×). Garaph processes all the subgraphs on the host only (as the outgoing edges of FB's active vertices over the total is under 6.9% at any iteration), by

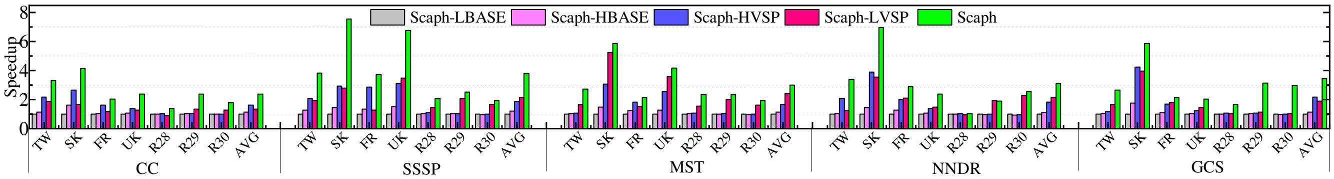

Figure 13: Speedup of Scaph, Scaph-HVSP, and Scaph-LVSP (normalized to Scaph-LBASE)

using a so-called notify-pull model. In contrast, Scaph uses a fine-grained value-driven differential scheduler to identify high-value and low-value subgraphs even though it has active vertices only in its local regions at any iteration, so that the GPU's processing power is adequately exploited.

6.3 RQ2: Effectiveness

To answer RQ2, we consider four variations of Scaph: (1) **Scaph-HVSP**, where all the low-value subgraphs can be understood as being misidentified as high-value subgraphs, (2) **Scaph-LVSP**, where all the high-value subgraphs can be understood as being misidentified as low-value subgraphs, (3) **Scaph-HBASE**, which applies the differential processing, but every subgraph transferred to the GPU has kept computation with a specific number of times (without using queue-based delayed scheduling), as used in CLIP [2], and (4) **Scaph-LBASE**, a variation of Scaph-LVSP except that every subgraph is streamed to GPU entirely (without UD extraction), as used in Graphie [17].

Figure 13 gives the results. We see that neither of Scaph-HVSP and Scaph-LVSP is always better than the other, and also Scaph is the best performer for all the algorithms on all the graphs. Thus, Scaph's value-driven differential scheduling with heuristic subgraph identification is highly effective.

Scaph-HVSP. Scaph-HVSP achieves better speedups for the graphs where algorithms take longer iterations to converge, as this allows it to exploit PUD more adequately and thus stream less redundant data to GPU. For example, each algorithm on SK has the longest number of iterations against on other graphs, thereby delivering considerable speedups. We also see that Scaph-HBASE is significantly inferior to Scaph-HVSP. This is because small subgraphs often contain very little PUD from themselves worthy of being exploited. Our queue-based scheduling allows the availability of PUD from other subgraphs via delayed scheduling. Thus, multi-time processing under Scaph-HVSP can expose significantly more PUD than that under Scaph-HBASE (i.e., by simply applying the idea from CLIP) for boosting performance.

Scaph-LVSP. Just like Scaph-HVSP, Scaph-LVSP can be quite effective in some cases. For example, the top two speedups achieved by Scaph-LVSP for MST are 5.26x and 3.58x on SK (14.8GB) and UK (27.61GB), respectively. The corresponding speedups from Scaph are 5.99x and 4.19x. However, Scaph-LVSP can be rather ineffective for the graphs that can nearly fit into the 16GB GPU memory, since Scaph-LBASE will then make GPU-resident for nearly all the subgraphs. For R28 with 16.78GB (unweighted) and 29.48GB (weighted), Scaph-LVSP offers little or even negative benefits for CC, NNDR, and GCS (on unweighted graphs) but positive ones for SSSP and MST (on weighted graphs).

Scaph. Scaph obtains the best of both worlds, Scaph-HVSP and Scaph-LVSP. For CC, SSSP, MST, NNDR, and GCS, the average speedups achieved by Scaph-HVSP (Scaph-LVSP) are 1.63x, 1.87x, 1.66x, 1.84, and 2.18x (1.33x, 2.12x, 2.41x, 2.15x, and 1.90x), respectively. As for Scaph, these average speedups are 2.38x, 3.79x, 3.01x, 3.12x, and 3.44x. Note that Scaph has the highest gain on SK, where Scaph-HVLP and Scaph-LVSP are also most effective.

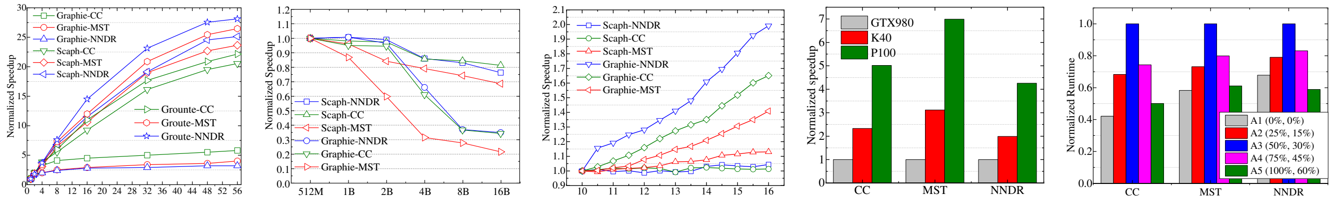
6.4 RQ3: Sensitivity Study

To answer RQ3, we investigate Scaph's scalability in terms of #SMXs, graph sizes, memory sizes, and GPU generations. We select Graphie as a reference on CC, MST, and NNDR.

#SMXs. Figure 14(a) compares Scaph and Graphie in terms of CC, MST, and NNDR on UK [6] for varying #SMXs by using all the 8GB GPU memory available. Scaph is significantly more scalable than Graphie for all the three graph algorithms, since Scaph can utilize the host-GPU bandwidth more effectively as already motivated earlier (Figures 1 and 4). For example, Graphie-MST reaches its plateau when #SMXs = 2, but Scaph-MST continues to offer a scalable performance improvement. CC and NNDR exhibit a similar trend.

However, Scaph's scalability degrades gradually as #SMXs increases, due to the integrated impacts of the intrinsic random accesses of graph processing on GPU [5, 25, 57] and the increasingly more SMXs competing for the memory bandwidth. As also shown in Figure 14(a), Groute [5], an in-memory graph system that can not handle over-subscription, on UK-2007@1M [6] (a sample graph with 1M vertices and 41M edges generated from UK), suffers from exactly the same scalability problem, which is beyond the scope of this work. We leave addressing this problem in future work.

Graph Sizes. Figure 14(b) compares Scaph and Graphie as the graph size increases. For CC and NNDR working on unweighted graphs, Scaph (Graphie) can store up to 4 billion (2 billion) edges in GPU memory. For MST working on the weighted graph, these edge counts drop to roughly 2 billion and 1 billion. Both Scaph and Graphie maintain their throughput well as the graph size increases but degrade visibly for the graphs that can no longer fit into GPU memory. However,



(a) #SMXs (b) Edge sizes (c) GPU memory (GB) (d) GPU generations (e) Varying α and β

Figure 14: Performance of Scaph and Graphie (including Groute for (a) only) in terms of varying (a) #SMXs: UK [6] and 8GB GPU memory, (b) graph sizes: R26–R30 [7] and 16GB GPU memory and #SMX=56, (c) GPU memory capacities: FB [31] and #SMX=56, (d) GPU genreations: FB [31], and (e) configurations of (α, β): FB [31], respectively. All results are normalized to the one obtained by itself with the smallest configuration.

Scaph has a slower performance reduction rate than Graphie, for two reasons. First, Scaph can better tap GPU's processing power due to its use of a multi-level priority queue for exploiting PUD more adequately and overlapping data transfers and GPU computation more effectively. Second, Scaph avoids transferring a large amount of NUD for low-value subgraphs.

GPU Memory Capacities. Figure 14(c) compares Scaph and Graphie for varying GPU memory sizes. Graphie is highly sensitive to the GPU memory capacity used, which determines directly how many subgraphs can be resident on GPU at an iteration and how many of these get re-processed in the ensuing iteration (before they are removed from GPU memory). In contrast, Scaph is nearly insensitive, since it exploits UD and PUD for high-value subgraphs and UD only for low-value subgraphs always. Note that Scaph is significantly faster than Graphie (Table 3). In Figure 14(c), Graphie improves over itself (normalized to 10GB) as the GPU memory size increases.

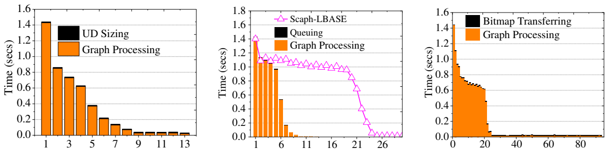
GPU Generations. Figure 14(d) characterizes the performance of Scaph on different GPU generations. Compared to Graphie that shows few speedups as shown in Figure 1, Scaph enables the significant speedups for K40 (1.99×∼3.12×) and P100 (4.26×∼5.02×) against that of GTX980.

Varying α and β. Figure 14(e) shows the sensitivity of the performance results of Scaph with respect to α and β. Here, A1 can be understood as Scaph-HVSP and A5 as Scaph-LVSP. Looking at A3, we see that increasing α and β causes more subgraphs to be mis-identified as low-value subgraphs (A4 and A5) and decreasing α and β causes more subgraphs to be mis-identified as high-value subgraphs (A1 and A2). Thus, A3 seems to represent a nice sweet spot for yielding good performance results. As for the problem of finding an optimal setting, we leave it as future work.

6.5 RQ4: Runtime Overhead

We discuss Scaph's overheads incurred in its *value-driven differential scheduling* (VDDS) given in Figure 8, *high-value subgraph processing* (HVSP) given in Figure 10, and *low-value subgraph processing* (LVSP) given in Figure 12.

VDDS. The cost of computing the subgraph value comes from computing the UD size for each iteration, on GPU, in line 8 of Figure 8. This is negligible, as shown in Figure 15(a).



(a) VDDS (b) HVSP (c) LVSP

Figure 15: Scaph's runtime overhead for running CC on UK [6] across the iterations

HVSP. The main overhead of HVSP lies in its queue management. In Figure 15(b), the cost incurred per iteration is small, representing an average of 0.79% of the total processing time. This small overhead is more than offset by the benefit reaped. In particular, the iteration count is reduced since most of the PUD can be computed ahead of schedule. The per-iteration time can be improved mainly because most of the NUD is discarded (rather than transferred expensively).

LVSP. The main overhead of LVSP lies in transfering a bitmap representation for all the active vertices in a subgraph from GPU to the host. As shown in Figure 15(c), the average cost incurred per iteration represents 4.3% of the total graph processing time. However, this cost increases relatively towards the last few iterations, reaching 57.4% at the end, where each subgraph has little UD to be acted upon.

6.6 Limitations

Graph Partition. Various partitions may show different value variations of subgraph at runtime. Scaph adopts a greedy vertex-cut partition [15] with the time taken depending on the number of partitions. It would be interesting future work to find a more reasonable partition method that can make most of UD and PUD exploited in the early stage of graph processing for faster convergence.

Disk-based Heterogeneous Graph Systems. The performance of Scaph is insensitive to the difference between CPU and GPU memory, given that the whole graph is assumed to fit into the CPU memory. To support even larger graphs on a single machine, using the disk (e.g., SSD) as secondary storage is promising. In this case, a new dimension of performance bottleneck will be the I/O inefficiency, which has been studied in prior work [2, 32, 35, 55]. We can combine Scaph with these past disk-based solutions to cooperatively handle graphs that cannot fit into the host memory.

Performance Profitability. Scaph delivers performance benefits by processing all the subgraphs differentially. Scaph is currently not expected to be applied to graph algorithms where the set of active vertices does not shrink as computation goes on. For example, all vertices in PageRank are active in every iteration. Thus, all the data of a subgraph can be regarded as UD without any PUD. In fact, we can extend Scaph to distinguish these all-active subgraphs further for PageRank by considering not only the degrees and the activation but also the state variation rate for each vertex, which is a potential direction of future work.

7 Related Work

Heterogeneous Graph Systems. Such systems have been studied on a range of heterogeneous architectures equipped with varying hardware resources [21, 35, 44]. Compared to GPU-accelerated solutions [43, 47], FPGA-accelerated alternatives are advantageous in energy-efficiency [10, 61]. In developing Scaph, we focus on improving host-accelerator bandwidth utilization. The basic idea behind can also be applied to improve the scalability of FPGA-accelerated heterogeneous graph systems with a few hardware specializations.

Distributed Graph Systems. The rationale is to aggregate multiple machines to enable processing large-scale graphs. The main challenge lies in obtaining good graph partitions [3, 8, 16, 48, 52] so as to minimize the communication overheads across the machines. Some recent studies take advantage of emerging high-speed networks (e.g., RDMA) to reduce communication overheads [49, 58]. Aspire [54] designs a relaxed consistency model to exploit asynchronous parallelism for iterative algorithms. Gemini [67] includes a series of adaptive runtime optimizations to enable obtaining an attractive scale-out efficiency.

Disk-based Graph Systems. Many disk-based graph systems [12, 45, 64, 65] exist for supporting large-scale graph processing. GraphChi [30] relies on parallel sliding windows to optimize disk accesses. GridGraph [68] uses 2-level hierarchical partitioning to reduce the I/O overhead. TurboGraph [18] applies a pin-and-slide model to exploit the multicore and I/O parallelism. Due to the low disk-to-memory bandwidth, disk-based graph systems are often at least two orders-of-magnitude slower than heterogeneous solutions.

Data Movement Reduction. Several previous studies leverage an analogous idea of running graph partitions multiple times for different purposes. CLIP [2] iterates over each loaded subgraph multiple times to squeeze out the value of each subgraph so that less amount of disk I/O is required. GraphQ [69] enables computing the local subgraphs multiple times in order to tolerate long latency across the compute nodes. Unlike these efforts, Scaph emphasizes on a GPU context that often requires small-size subgraphs to enable fine-grained scheduling. Thus, simply computing a subgraph multiple times is not sufficient to exploit its PUD fully. Scaph enables value exploitation not only within a subgraph but also *across the subgraphs* via a delayed scheduling mechanism.

In LUMOS [53], a subgraph in an iteration can be exploited asynchronously iff its updated values are independent of the subsequent iteration. This dependency-aware technique allows enjoying the efficiency of asynchronous execution while ensuring synchronous processing semantics. Applying this technique into Scaph can help identify the high-value subgraphs that contain across-iteration dependencies, so that Scaph can be extended to handle synchronous algorithms [22] safely by scheduling these high-value subgraphs once. However, the downside is that many dependency-free low-value subgraphs may also be allowed to be computed multiple times, wasting the GPU computational and storage resources.

Wonderland [63] uses graph abstraction as a bridge over on-disk subgraphs to speed up convergence. However, under the context of small-sized subgraphs, such a graph abstraction is often hard to keep concise, and extracting it from the whole graph is also non-trivial. PowerLayer [8] presents differentiated processing on high-degree and low-degree vertices to improve the trade-off between load balance and communication overheads in a distributed setting. However, applying the idea of PowerLayer cannot often identify the value of a subgraph accurately while Scaph does with a fine-grained solution. Mosaic [35] adopts a subgraph compression technique, which can be used to work together with Scaph to improve the bandwidth-efficiency of heterogeneous graph system further.

8 Conclusion

This paper tackles the challenge faced in achieving scale-up large-scale graph processing on a GPU-accelerated heterogeneous architecture. We introduce Scaph, a value-driven heterogeneous graph system that differentially schedules the subgraphs partitioned from a graph according to their values in order to improve the effective utilization of the host-GPU bandwidth. Scaph outperforms state of the art, as evaluated with representative graph algorithms operating on a range of graph datasets. In addition, these performance benefits scale up as more computing resources are available.

Abstract

The rapid development of scientific and industrial areas, which rely on time series data processing, raises the demand for storage that would be able to process tens and hundreds of terabytes of data efficiently. And by efficiency, one should understand not only the speed of data processing operations execution but also the volume of the data stored and operational costs when deploying the storage in a production environment such as cloud.

In this paper, we propose a concept for storing and indexing numeric time series that allows creating compact data representations optimized for cloud storages and perform typical operations – uploading, extracting, sampling, statistical aggregations, and transformations – at high speed. Our modular database that implements the proposed approach – Peregreen – can achieve a throughput of 3 million entries per second for uploading and 48 million entries per second for extraction in Amazon EC2 while having only Amazon S3 as storage backend for all the data.

1 Introduction

Time series data plays a very important role in the modern world. Many fields of science and industry rely on storing and processing large amounts of time series – economics and finances [6], medicine [7], Internet of Things [10], environmental protection [11], hardware monitoring [9] and many others. Growing industry demand for functional capabilities and processing speed led to the sharp rise of specialized time series databases TSDB [16] and development of custom TSDB solutions by large companies, e.g. Gorilla [18] by Facebook and Atlas by Netflix.

One of the most challenging applications of TSDBs, which becomes especially demanded by industrial companies like Siemens, is processing of long periods of historical time series data. Historical data can contain tens and hundreds terabytes of data thus making usage of in-memory databases too expensive. Standard solutions like relational databases or key-value storages struggle to efficiently process such large amounts of time series data [8, 23]. Thus it is very important for a TSDB to achieve the best balance between execution speed and operational cost.

A platform for historical time series analysis groups the data by sensors – modules responsible for capturing one specific phenomenon, e.g. tickers in stock market, temperature sensor for industrial machines or pulse sensor in a hospital equipment. There can be distinguished several typical scenarios of users interaction with the platform for historical data analysis. In the first case, user browses the whole dataset containing millions of sensors and years of data. User can select any sensor to investigate its behavior at any period of time. The platform must visualize the data for the user and allow to quickly zoom in and out, e.g. from years interval into months into days and hours and backwards. To successfully perform in this scenario, the underlying time series storage must provide fast access to any part of the data and be able to extract aggregated values when visualizing long time intervals.

In the second case, user analyzes a specific sensor and wants to look into time intervals, in which the value satisfies some condition, for example amplitude search or outliers search. For this user first searches for all time intervals meeting the condition and after that he or she selects the interval of interest and the platform visualizes the data for this interval. For this scenario the underlying time series storage must be able to perform fast search for time intervals in the whole volume of data and perform fast extraction – loading time series for a specified period – along with aggregation (e.g. average and standard deviation) and transformation (e.g. moving average).

Another important feature for any data processing system is an ability to use it in cloud platforms, like Amazon Web Services, Google Cloud or Microsoft Azure, since they allow the system to be globally available and increase the number of potential users and customers. Considering this the target TSDB must provide a good compression of the raw data along with the small internal footprint to minimize the cost of storing the data in cloud platform. Additional advantage for the target TSDB would be an integration with cheaper data storage cloud services, e.g. Amazon S3 or Google Storage.

Summarizing the above, we faced following challenging requirements for the target time series storage in the beginning of the joint project between Siemens and ITMO University:

1. Store terabytes of time series data for tens of years.
2. 1 second for conditional search in whole database.
3. Execution speed of 450,000 entries per second per node.
4. All data must be stored in Amazon S3.

To address described above requirements we propose an approach for storing numeric time series that is based on twofold split of the data into segments and blocks. Statistical information about segments and blocks is incorporated into three-tier indices, which are independent for every stored sensor. For building an internal data representation we use read-optimized series encoding that is based on delta encoding and Zstandard algorithm and achieves up to 6.5x compression ratio.

We also present design and implementation of the modular distributed database based on the proposed concept. The database is called Peregreen in honor of the fastest bird on Earth. In the experimental studies we demonstrate that Peregreen outperforms leading solutions – InfluxDB and ClickHouse – in the described above use cases. We also show that our solution is able to operate fast in the Amazon EC2 environment while storing all indices and data in Amazon S3 object storage.

Currently Peregreen is being integrated into internal projects of Siemens related to real-time analysis of historical data and development of complex workflows for processing long time series.

2 Proposed approach

The main challenge of development a database that would operate in a cloud environment and store its data solely in a remote object storage is minimizing network overheads. The first aspect of this problem is that there is no reasonable way to perform scans on database files to find appropriate data for the request. Because of that the index of the database has to contain metadata that would allow to navigate to exact parts of database files where the data is located. The second aspect is that we need to minimize the amount of network connections required for data uploading and extraction. For achieving this goal there is a need to develop a format for database files that would allow writing and reading all required data within one request. And the third aspect is minimizing sizes of both database and index files. The smaller files are the cheaper their storage is. And additional advantage of small index files is that more indices can be loaded into the RAM of the processing node.

In this section we give a detailed description of our approach for indexing and storing time series data for fast operation in cloud environments. Target use cases of the initial project included processing of numeric time series that means sequences of pairs *(timestamp,value)* without any tags. To achieve high speed of parallel uploads and ease of operation, every sensor has its own index and processed independently from others. Input time series data is indexed via three-tier data indexing mechanism and converted into the internal representation using read-optimized series encoding. Details on how this approach helps to optimize data processing and fit to the project requirements are given in Section 3.1.

2.1 Three-tier data indexing

The first part of the approach is a three-tier data indexing. Schema of the indexing is presented in Figure 1. At the first step the input data is divided into data chunks – subsets containing *(timestamp,value)* pairs. Time interval for data chunks split is a parameter called block interval. After that for every data chunk we create an index block that contains meta information required for data extraction and a set of metrics – aggregated statistics for the data chunk, e.g. minimum, maximum or average. Metrics are used for conditional search for time intervals in the index, details on it are given in Section 3.1. Block meta includes following fields: number of elements in the data chunk, length of the encoded representation (more details on it in Section 2.2), and a flag whether encoded representation is compressed.

Index blocks are incorporated into an index segment. Blocks in the segment are located in the chronological order, which allows fast calculation of required parts of the segment file as will be described further. During segment creation we initialize all the blocks in it empty, and all changes modify the existing blocks.

The time interval that every segment covers is set by a parameter called segment interval. Every segment has its meta information and a set of metrics. Segment meta contains a unique identifier (ID), start time, which is calculated during segment creation, and a version of the segment. Segment ID sets the name of the segment binary file in the storage backend. The presence of the segment start time makes possible fast and compact encoding of timestamps in blocks as described in Section 2.2.

The start time for a new segment is calculated according to the first timestamp of the indexed data chunk and existing segments in the index. If there are no segments in the index, the start time of the segment is set to the first timestamp of the data chunk. Otherwise, the start time of the segment is calculated so that it is separated by a multiple of the segment intervals from other segments and is as close as possible from the bottom to the first timestamp in the data chunk. The version of the segment is an integer number that increments every time the segment is changed.

Segment metrics are calculated by combining metrics of its blocks. There are two types of metrics – cumulative and non-cumulative. The difference between them is that for combining cumulative metrics there is no need to have all values

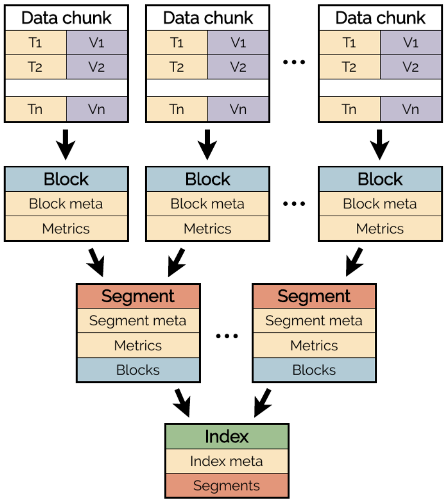

Figure 1: Schema of three-tier data indexing

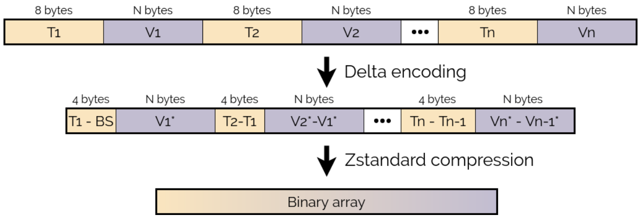

Figure 2: Schema of read-optimized series encoding

based on which these metrics were calculated. For example, minimum and maximum are cumulative metrics, and standard deviation and median are non-cumulative. For cumulative metrics combining function uses only their values while for non-cumulative metrics it uses all input values used to calculate these metrics. Metric instances of blocks and segments store input values during data uploading and delete them afterwards.

Segments are then incorporated into an index. Segments in the index are located in the chronological order. Index meta information includes unique identifier (name of the corresponding sensor), data type, segment interval, block interval and version. Data type determines the way how values are processed during data encoding. Supported data types are 8-bit integer, 16-bit integer, 32-bit integer, 64-bit integer, 32-bit float and 64-bit float. Block and segment intervals define time intervals for blocks and segments generation as it was discussed above. The version of the index is an integer number that increments every time the index is changed.

Indices are stored in the storage backend as individual files. File names for each individual index consist of index ID and index version.

2.2 Read-optimized series encoding

Since one of the most challenging requirements for our database was storing all data in Amazon S3, we needed an internal representation format that would allow performing data uploading and extraction in the best possible way. It is well known that one of the main factors that affect the speed of interaction with remote services is the network (connections instantiating, latency, etc.). That is why we aimed to create a format that would minimize the number of requests to the storage backend during extraction as much as possible.

The schema of the developed read-optimized encoding is presented in Figure 2. As the input we have a sequence of *(timestamp,value)* pairs from the data chunk. Timestamps are 64-bit integers and thus have the size of 8 bytes. The binary size of values **N** depends on the underlying data type and thus can be from 1 to 8.

The first part of the series processing is the delta encoding – instead of timestamps and values we store differences between current and previous items. It allows to reduce the amount of data required for storing timestamps from 8 to 4 bytes by assuming that difference between two consecutive timestamps would not be greater than ≈ 49 days ($(2^{32}-1)$ ms, maximum value of unsigned 32-bit integer). Delta for the first timestamp is calculated as a difference between the timestamp and block start (**BS** in the schema) that is calculated from the segment start time and the order of the block corresponding to the data chunk. The way how the algorithm generates stored differences for values depends on the processed data type: for integers diff is calculated as a subtraction of the next value from the previous one, and for floating point values a difference is generated as a difference between IEEE 754 binary representations of consecutive values, because such approach produces longer zero-filled bit sequences and can be compressed better.

At the second step calculated deltas are written in the same order as input values into the binary array (see Figure 2). At this point we already get some level of compression. And to get even more we use a high-performance algorithm Zstandard for compression of the obtained binary array. Our experiments shown that usage of the compression adds 10-15% overhead for data reading.

As a result we get a highly compressed representation of the input data chunk – data blocks. During uploading data blocks are written successively into a single array – data segment – that is written as a file into storage backend.

2.3 Discussion

It can be noted that the way of data organization in the presented approach resonates with columnar data formats, like Parquet and Apache ORC, or storage schema of other time series databases [12]. The most distinct and significant difference is that timestamps and values in our case are stored

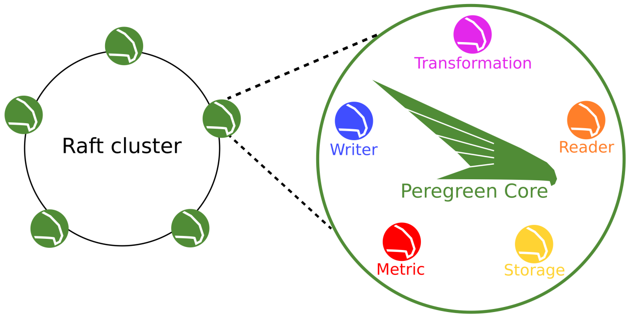

Figure 3: Overview schema of Peregreen. Every node in the Raft cluster includes Peregreen core and five modules.

not separately in different columns/series but together, one *(timestamp,value)* pair after another. This approach along with utilizing binary offsets allows the required parts of segment files to be extracted in a single I/O operation instead of many for other formats (timestamps reading and values reading). When using remote storage backends (Amazon S3 or HDFS) these additional I/O operations significantly decrease performance of data extraction. A possible logical drawback of our approach is a lower level of compression because of mixed sequences; however, experiments described in Section 4.1 show that read-optimized data encoding is more compact than in other solutions.

Another possibly questionable aspect of the proposed approach is the index organization when blocks in a segment and segments in an index are stored in the array rather than access-optimized data structures like trees. During development we experimented with different ways of organizing tiers in the index. We discovered that when having a reasonable number of blocks per segment and segment per index (up to 10,000) array-based index provides almost the same performance as B-tree-based index in terms of elements filtering. This is due to the simplistic logic of the array-based index and absence of recursion calls during the search.

3 Peregreen overview

Peregreen is a distributed modular database that was built to satisfy requirements described in Section 1. Peregreen was developed using Go programming language. Peregreen architecturally consists of three parts – core, modules, and cluster. This section describes these parts and gives information about limitations of the current implementation of the database. Overview schema of Peregreen is presented in Figure 3.

3.1 Peregreen core

Peregreen core is a backbone of the whole system. It implements concepts described in the previous section in a module responsible for the following CRUD operations.

Uploading. Data uploading procedure combines the three-tier indexing mechanism and read-optimized series encoding. At the first step input data is split into data chunks. If there is an existing data for the time interval covered by the new data, Peregreen core extracts it from the storage backend and combines new and existing data. After that the core goes through data chunks and simultaneously converts them into data blocks as described in Section 2.2 and creates index blocks as described in Section 2.1. The core then combines data blocks into segment files and index blocks into index segments. New version of the segment is embedded into the name of the segment file. After combining index segments into the index, segment files and the index are written to the storage backend.

Deletion. On deletion user specifies a time interval, in which the data must be deleted. Indexing engine extracts the data covering target interval from the storage backend, removes all entries that lie in between the start and finish timestamps, updates index and internal representation and loads them into the storage backend.

Search by value. This operation is designed to extract time intervals, values in which satisfy some conditions. Distinctive feature of search operation is that it does not access the data stored in the storage backend, but instead it works only with segments and blocks of the index. It allows to perform very fast search with complex queries over large amounts of loaded data. Time resolution of returned intervals equals to the block interval of the index.

During the search Peregreen core scans through segments of the index and checks whether they fall into the search interval. If a segment belongs to the search interval, indexer iterates over blocks of the segment and checks them for both matching to the search interval and to search query. Metrics available for search queries are all metrics that were computed during the uploading. If new metrics are added after the data was loaded, it is possible to recalculate new metrics for the existing data.

Peregreen provides an easy syntax for describing search queries. Queries consist of conditions combined by logical operators. Conditions have the following form:

```
metric operator value
```

where *metric* is a name of the metric in index blocks, *operator* is a conditional operator, and *value* is a value against which a value of the metric will be compared. Conditional operators used are very close to select operators in MongoDB – *lt* (lower than), *lte* (lower than or equal), *gt* (greater than), *gte* (greater than or equal) and *eq* (equal). Logical operators used for conditions combining include & (conjunction) and | (disjunction). For example, the following command: "min lte 200 & max gte 50 | avg eq 75" describes a query for searching time intervals where one of the following conditions is satisfied: (1) minimum metric is lower or equal to 200 and maximum metric is greater or equal to 50, (2) average metric is equal to 75.

Extraction. Peregreen provides a powerful extraction mechanism that allows performing a fast retrieval of large amounts of data along with data sampling, aggregations and transformations. For extraction, the user specifies sensor identifier, start and finish timestamps, partitioning time interval, and aggregation metrics or transformation functions. Four types of extraction are activated depending on these parameters:

1. Full extraction. This extraction is performed when the user does not specify partitioning time interval and aggregation metrics or transformation functions. In this case, the Peregreen core obtains all points from the storage backend.

2. Sampling. This extraction is performed when the user specifies a partitioning time interval and no aggregation metrics. Data sampling is the extraction of points, timestamps of which differ by user-specified interval, from the storage backend. This operation is useful in cases when the user wants to get a general picture of the data for some time interval. For sampling, the Peregreen core calculates time intervals according to start and finish timestamps, and extracts the first point for every time interval.

3. Aggregation. This extraction is performed when the user specifies a partitioning time interval and some aggregation metrics. This extraction provides the user with a deeper understanding of what is happening in the target time interval. For aggregation, the Peregreen core calculates time intervals according to start and finish timestamps, and generates a set of metrics for every time interval. Metrics available for aggregation include all metrics supported by Peregreen.

4. Transformation. This extraction is performed when the user specifies a partitioning time interval and some transformation functions. This extraction is useful when there is a need for modifying the initial form of the data, e.g. rolling average. For transformation, the Peregreen core applies specified transformation functions to values as they are retrieved.

For extracting values from the storage backend, Peregreen core utilizes meta information stored in all three tiers of the index. Based on start and finish timestamps the core calculates which segments have to be used. For this it uses segments' start times and segment interval from the index. For every segment the core then determines which blocks to extract using segment start time, block interval and blocks ordering. After that the core uses length of the encoded representation of blocks in the segment to calculate the range of bytes need to be extracted from the segment file. The core then extracts only the required part of the segment file, and for every data block of that part performs the actions of the encoding in the reverse order – decompress data with Zstandard, convert raw bytes to deltas and apply delta decoding for them. During decoding stage, Peregreen core applies required aggregations and transformations to the data if specified by user.

It can be seen that the way how internal representation in the Peregreen core is organized allows to achieve the optimal interaction with the storage backend by having only one read operation per segment file. This is the reason why the encoding is called read-optimized.

3.2 Peregreen modules

One of the most powerful features of Peregreen is its extensibility. This section describes five types of modules that allow to integrate various types of storage backends, aggregated statistics, transformations, input and output data types. In terms of implementation, modules are programming interfaces that provide a required set of methods.

Storage. *Storage* is a module, which is responsible for a proper integration of Peregreen with the storage backend. These methods include reading and writing indices, writing segment files and reading binary data for specified index blocks. Currently Peregreen contains three storage implementations out of the box – local file system, HDFS and Amazon S3. Local and HDFS storages allow to work with a data placed within a file system or HDFS respectively. They make use of file offsets for navigating in segment files and extracting only required data parts from them during data reading. S3 storage allows working with a data placed in the Amazon S3 object storage. It stores all data in one bucket specified in configuration file. S3 storage extracts only required data parts from segment files stored in S3 using HTTP bytes range headers.

Reader. *Reader* module is responsible for reading data elements from the input stream. It has only one method for reading a single data element. This is related to the internal mechanics of data reading in Peregreen – it creates data parts, which will be then converted into data blocks, on the fly to minimize memory consumption and total number of operations. That is why there is no need for a method to read all input data at once. The way how *Reader* will extract the data is defined by its implementation and two parameters – data type and format. Data type is a name of one of six supported data types – byte, short, integer, long, float and double. Depending on the data type the way of how *Reader* extracts element might slightly change. Format describes the rules of searching timestamps and values in the input stream. Lets examine how it works on the example of *Reader* implementation for CSV format, which is available in Peregreen by default. Its format definition looks as follows:

```
tsPos-valPos-sep
```

where *tsPos* is position of the timestamp in the string, *valPos* is position of the value in the string, and *sep* is a separator symbol. This simple notation allows to cover a wide range of CSV files layouts. Peregreen also supports JSON and MessagePack as input data formats.

Writer. There are four types of data that Peregreen can return on requests – search results, timestamp-value pairs, aggregations and transformations. *Writer* module describes methods for converting these types into desirable output format. At the moment Peregreen supports three types of output formats – CSV, MessagePack and JSON.

Metric. In order to provide a flexible search on the loaded data, Peregreen allows configuring and extending aggregated statistical characteristics calculated for the data with the help of *Metric* module. It describes three methods, by implementing which one can create new custom metric for the storage, – inserting a value to the metric, getting a value from the metric and combining two metrics into one. The latter method is used for creating metrics for long time intervals from metrics for short intervals. Currently Peregreen has implementations for count, minimum, maximum, average, standard deviation, median, percentile and mode metrics.

Transformation. Transformations allow to change the data as it is extracted. To do that the module provides a single method that converts input value in its new form. Specific implementations, like moving average, might have internal structures for storing intermediate values. Currently Peregreen has implementations for absolute value, difference, summation, subtraction, multiplication and moving average transformations.

3.3 Peregreen cluster

Peregreen cluster provides users horizontal scalability and fault tolerance. Our cluster operates over HashiCorp implementation[1] of the Raft consensus algorithm [17]. This algorithm provides consistency of a cluster. It is especially important for Peregreen because to eliminate the need to handle collisions only one sensor update at a time is allowed. That is why on every update we need to know where required indices are located in order to properly update them.

In Raft cluster write requests go through the leader node so Peregreen also has leader node in the cluster. All upload queries go through the leader node to get redirected to the node that will process uploading. Read requests are redirected directly to the responsible node by any of the cluster nodes. During the first start of the cluster, one node starts as a leader and all other nodes join to that node as followers.

Peregreen cluster state consists of three components:

1. List of nodes. It stores information required for nodes to connect with each other and with clients – node name, internal and external addresses and ports.

2. List of nodes per index. It stores information about mapping of indices onto cluster nodes. Every index is replicated to several nodes in runtime to achieve high availability. If the first node in the list is down, the second one will process the request, etc.

3. Number of indices per node. It stores information about how many indices are stored on every node of the cluster. This is required for the load balancing of the cluster.

Raft log in Peregreen stores information necessary for recreation of the cluster state when the node starts, i.e. information about the events that change the cluster state – addition of a new node, failure of a node, uploading of a new sensor and changing the replication factor.

3.4 Peregreen limitations

Since Peregreen and its underlying concepts are purposefully designed for storing large amounts of historical time series, it has a number of limitations when considering a general task of time series processing.

1. Preferably batch uploads. Although it is possible to load points one by one, it would be highly inefficient because on every such operation the whole data segment file will be downloaded from the storage backend and rebuilt. Even considering that every Peregreen node has a in-memory cache, loading single points brings too much overheads. But the main use case for Peregreen is loading large amounts of time series data at once and the longer input sequence, the better overall performance of Peregreen becomes.

2. One sensor update at a time. When leader receives an update request for a sensor, it locks index for that sensor until the request finishes. This approach was introduced into Peregreen architecture to eliminate the need for collision detection and resolution when more than one node modifies the data for some sensor. We will investigate the best practices for collisions resolution and address this limitation in the future.

3. No multi-sensor operations. All operations in Peregreen require the client to specify the target sensor in the request, and there are no options to specify several sensors. This comes from the fact that the project requirements specifically covered single-sensor operations. At the moment clients make several single-sensor requests for Peregreen and due to the high execution speed they still achieve good performance.

4. No SQL-like syntax. Peregreen has quite minimalistic REST API designed to execute CRUD operations as described in Section 3.1. We understand that supporting SQL would extend the number of use cases but integration of SQL into Peregreen would require significant changes to the architecture of the database.

4 Experimental evaluation

This section describes two series of experiments that were conducted to check different aspects of Peregreen performance in a range of conditions. The first experiment was performed in an on-premise environment on a rack of blade servers, whereas the second experiment was set in the Amazon AWS cloud. Data used in experiments was generated based on a sample of real data with a frequency about 1 Hz. We generated 1 year of data for 1000 sensors that resulted in 31.5 billion records and the total volume of 750 GB.

[1] https://github.com/hashicorp/raft

4.1 On-premise experiment

In order to check the performance of Peregreen compared to existing databases, we performed a detailed experimental evaluation of various data processing operations for Peregreen and two other solutions widely used for time series storage – InfluxDB and ClickHouse. InfluxDB [13] is an open-core time series data store that provides high throughput of ingest, compression and real-time querying. As of November 2018 it is the most popular time series storage [15]. ClickHouse [25] is an open source distributed column-oriented DBMS that provides a rich set of features to its users. Due to the MergeTree table engine and time oriented functions, ClickHouse has proven to be efficient for working with time series data [5,20].

Hardware setup for the first experiment consists of IBM blade servers, each of which has the following characteristics: 2x Intel Xeon 8C E7-2830 (32 vCPUs), 128 GB RAM, 100GB SSD local storage and 2000 GB attached storage from IBM Storwise V3700 storage system connected via fiber channel. All databases were deployed at the local storage whereas the data was stored in the attached storage. In our experiments we used 1, 4 and 7 instances of blade servers.

InfluxDB configuration. In our experiment we used default configuration of InfluxDB provided by its developers with two minor changes. The first is that limit on maximum size of the client request was disabled to upload historical data split by months. And the second, to perform search by values in more equal conditions we created additional aggregation table, which contained 1 hour time intervals and minimum and maximum values for these intervals. Schema of both main and aggregation tables can be found in the listing[2].

When performing several SELECT requests for different time intervals there are two options for InfluxDB – several individual requests or one request with subrequests. Our empirical study[3] shown that making several simultaneous requests is faster than one request with the same number of subrequests. That is why in our experiments we abandoned usage of subrequests.

It must also be mentioned that the trial enterprise version of InfluxDB cluster we used in experiments could not be deployed on 7 instances and because of that experiments for InfluxDB were conducted only for 1 and 4 instances.

ClickHouse configuration. ClickHouse was configured to use the following table schema: date Date, timestamp UInt64, sensorId UInt16, value Float64. Partitioning for the table was set by year and month using toYYYYMM function by date column. The primary key and thus physical order of the records was formed by sensorId and timestamp fields. Table for time series indexing was created as a materialized view of the previous table using 'group by' aggregation by date, sensorId, floor(divide(timestamp, <tdisr>)), where 'tdisr' is a block interval equal to 3600000 ms (1 hour).

Table 1: Data upload time for on-premise experiment, minutes

	1 instance	4 instances	7 instances
Peregreen	891	243	150
ClickHouse	530	193	83
InfluxDB	1847	583	n/a

Table 2: Total stored data volume, GB

Peregreen	ClickHouse	InfluxDB
172	301	272

The materialized view had the following schema: date, sensorId, min(timestamp) AS mnts, max(timestamp) as mxts, min(value) AS mnval, max(value) AS mxval. The primary key of the materialized view was formed by sensorId, mnval and mxval fields. For both tables we used MergeTree engine, which provides the best combination of scan performance, data insertion speed and storing reliability.

These two tables were created on each node due to master-master architecture of ClickHouse. Materialized view tables are updated automatically upon insertion into the main tables. Compression method was changed to Zstandard for all nodes. Index granularity of raw tables was left 8192 as it does not contribute significantly to the increase of data size stored on the disk but allows to position more precisely for 1 hour interval queries. Max thread setting was set to 16 for queries with a single client using SET instruction supported by SQL dialect of the ClickHouse. Other settings were left at their default values. To perform queries to ClickHouse, its native tool called clickhouse-client was used. In experiments with multiple clients, multiple processes were spawned each sending its own SQL query. Native format was used by clickhouse-client to retrieve data.

Peregreen configuration. For all experiments Peregreen was configured as follows: block interval was set to 3,600,000 ms (1 hour), segment interval was set to 31,622,400,000 ms (366 days), compression was enabled. With these settings an average block size was 15 KB, and the segment size was about 130 MB.

Data uploading. In this experiment data uploading requests were sent to storages from all instances of the cluster. It means that for setup with 1 instance it sent all 1000 sensors, with 4 instances each instance sent 250 sensors, and with 7 instances each sent 142-143 sensors. It allows to check scalability of the databases in terms of data uploading.

Results of data uploading time for different sets of nodes are presented in Table 1. It can be seen that ClickHouse provides the highest speed of uploading with the rate of 8 GB per minute on 7 instances. InfluxDB uploading speed was slightly less than two other solutions, but on 4 nodes it demonstrated the uploading rate of ~900,000 records per second, which is quite close to the InfluxData official benchmarks [8].

Table 2 shows the total volume of internal data representa-

[2] https://bit.ly/2P8d4B7
[3] https://bit.ly/2KIKTrG

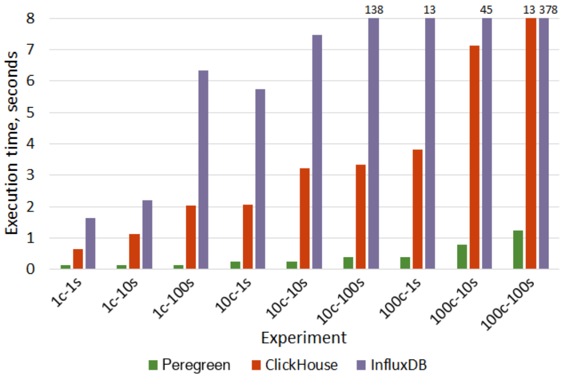

Figure 4: Values search execution time for 4 instances

tion stored by three solutions. With the help of delta encoding and Zstandard compression Peregreen is able to compress the raw data 4 times to 172 GB from 750 GB. Other storages also provide quite high compression rates – 2.5x for ClickHouse and 2.7x for InfluxDB. Despite using Zstandard algorithm, compression rate for ClickHouse is lower than demonstrated in other benchmarks [1]. But compressibility heavily depends on the data characteristics (schema, frequency, etc.) and thus direct comparison of two benchmarks for different datasets would be far from the mark.

It also should be mentioned that indices for all 1000 sensors in Peregreen have the total size of 110 MB, 110 KB per sensor. Such small size ensures minimal footprint of the system and allows to store all indices in the memory in the runtime.

Values range search. In this series of experiments we simulated behavior of clients who try to perform various search by values requests. Number of clients varied in range $[1,10,100]$, number of sensors for which search requests were made by each client varied in range $[1,10,100]$. Every request was amplitude search, where minimum and maximum values cover all values in the dataset, so all solutions had to perform full scan of their storages. In Figure 4 results of this experiment for 4 instances are presented. Columns captions encode experiment types – c stands for the number of clients, s stands for the number of sensors per client. From the figure we can clearly see that Peregreen significantly outperforms two other solutions in all scenarios. This is related to the fact that search operations in Peregreen are performed using only indices, which are stored in the memory, whereas ClickHouse and InfluxDB select results from the tables that are stored on the disk.

Data extraction. These experiments were designed to investigate how well target storages can handle data extraction workloads of various sizes. Number of clients for this series varied in range $[1,10,100]$, number of sensors for which extraction requests were made by each client varied in range $[1,10,100]$, time interval for extraction varied in range $[1,24,240]$ hours. The largest case – 100 clients, 100 sensors per client, 240 hours – is a very extreme scenario that involves extraction of 8.6 billion records.

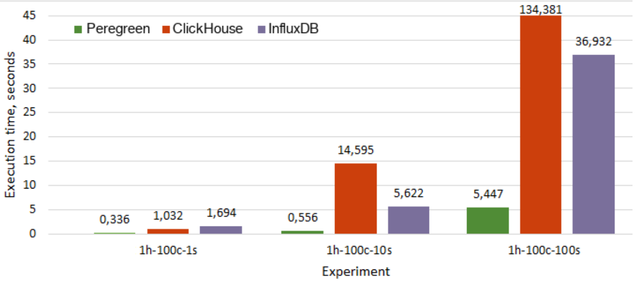

Figure 5: Data extraction time for small requests on 1 instance

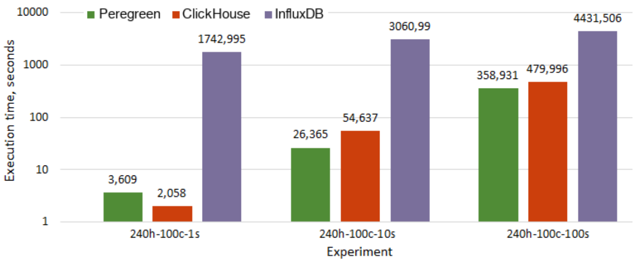

Figure 6: Data extraction time for large requests on 1 instance, logarithmic time scale

Sample results for small requests (1 hour, 100 clients, 1, 10, 100 sensors per client) execution on 1 instance are presented in Figure 5. Columns captions encode experiment types – h stands for the extracted time interval, c stands for the number of clients, s stands for the number of sensors per client. Execution time for Peregreen is much lower than for other systems, because it quickly navigates in segment files using the index and extract only required data blocks (no more than two for these experiments). InfluxDB in these experiments significantly outperformed ClickHouse, which is expected because InfluxDB is designed for working with short time series.

But the situation dramatically changes if we try to extract a lot of long time intervals. In Figure 6 results for large requests (1 hour, 100 clients, 1, 10, 100 sensors per client) are presented. Plots were generated using logarithmic time scale because results differ by orders of magnitude. InfluxDB demonstrates very low extraction speed, since extraction of this many long time intervals is far from its standard use case. ClickHouse, on the other hand, is very good at reading long sequences of data and because of that it demonstrates impressive results of 43,000,000 records per second for the scenario 240h-100c-1s. Although Peregreen performs almost twice slower in this scenario, with increase of parallel requests it starts to outperform ClickHouse and for the hardest case it demonstrates execution speed of 24,000,000 records per second against 18,000,000 for ClickHouse.

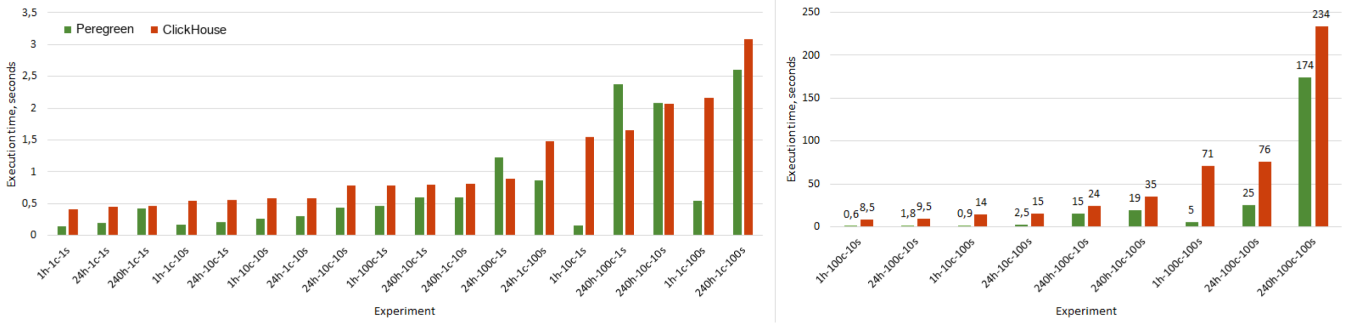

Figure 7: Data extraction time for 7 instances

In Figure 7 experimental results for all types of requests are presented. These experiments were conducted on 7 instances and because of that there are no results for InfluxDB. For relatively small requests, which are shown on the left plot, Peregreen and ClickHouse demonstrate comparable performance. But as the workload grows transcendence of Peregreen also grows. In the hardest scenario 240h-100c-100s Peregreen achieves the speed of 49,500,000 records per second. The speed of ClickHouse is slightly lower, but also very high – 37,000,000 records per second. Difference in the processing speed can be explained by following factors: (1) ClickHouse has lower compression rate (difference in blocks organization and no delta encoding) and because of that has to read more data from the disk during extraction; (2) data parts in ClickHouse are organized by size, not by time, that is why ClickHouse has to read some unnecessary data during extraction by time intervals; (3) ClickHouse creates large number of files with data parts and during extraction it has to read from a lot of files, which increases a number of random reads from disk, whereas Peregreen reads from very small number of segment files.

4.2 EC2 experiment

The second series of experiments was aimed to evaluate performance of Peregreen in a cloud environment for two types of storage backend – local file system and Amazon S3.

Hardware setup for this experiment consists of Amazon EC2 instances of c5.4xlarge type with 16 vCPUs, 32 GB RAM, 8 GB internal SSD storage and 500 GB attached EBS storage. All instances were localed in us-east-1 region. Peregreen was deployed on the local storage whereas the data was stored in the attached storage. Testbed contained 1, 4 and 7 instances.

Benchmarking utility was deployed on a dedicated instance to avoid its influence at performance of Peregreen nodes.

Data uploading. This experiment was designed the same way as in Section 4.1 – data is loaded from all instances of the cluster. Experimental results are presented in Table 3. We can see that in all cases uploading to the cluster with EBS storage backend is faster than to the one with S3 storage backend. It is expected because in the second case segment files are uploaded into remote web service. Nevertheless, both storages provide high uploading rates, 21-23 MB/s per node for EBS storage and 17-18 MB/s per node for S3 storage. Also, both storages demonstrate close to linear change in uploading time with increasing in number of instances, which is very important for the solution deployment on a large scale.

Table 3: Data uploading time for EC2 experiment, minutes

	1 instance	4 instances	7 instances
EBS backend	573	122	75
S3 backend	702	175	97

Search by values. In this series of experiments we performed various amount of parallel search by values requests. Number of parallel requests varied in range $[1, 10, 100, 1000, 10000]$. Since search by values request does not depend on storage backend, we did not compare setups with different backends, and only checked how well Peregreen handles increasing load. In order to make Peregreen process all segments and blocks, we used the following condition in search requests:

```
min lte 500 & max gte -200
```

Due to the fact that searching through indices located in RAM is a very lightweight operation, results for setups with 1, 4 and 7 did not differ significantly. In Figure 8 experimental results for 4 instances are presented. It is clear that search request scales very well and provides a sub-second execution time even for 10000 simultaneous requests.

Data extraction. In this series of experiments we investigated, how well can Peregreen with different storage backends perform under wide range of data extraction requests, and whether usage S3 as a persistent storage of large amounts of time series data can bring performance comparable to the EBS storage. For this we varied number of concurrent requests made to the manager node in range $[1, 10, 100, 1000, 10000]$ and extracted time interval in range $[1, 6, 24, 240]$ hours. Due to the extremely large memory requirements and limited

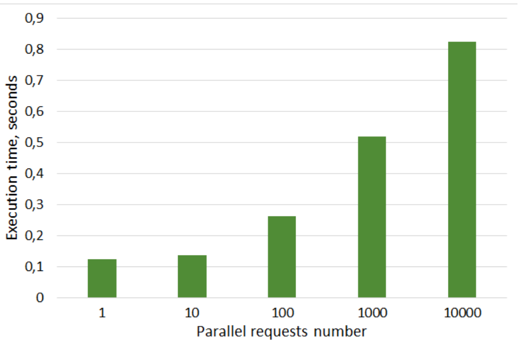

Figure 8: Data search execution time for 4 instances in EC2

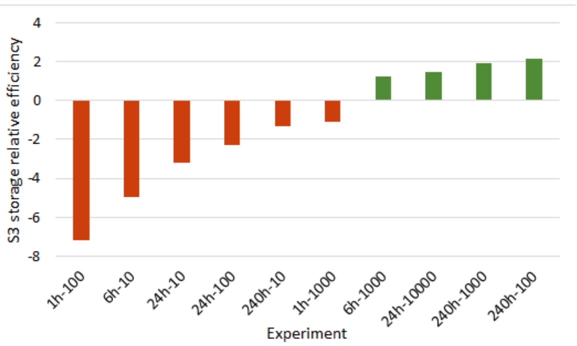

Figure 9: Efficiency of S3 storage backend with regard to EBS storage backend for 4 nodes in EC2

amount of RAM on EC2 instances (320 GB in total) maximal request (10000 requests for 240 hours each) could not be executed, but all other requests completed successfully. All requests were performed 10 times to downplay possible network and hardware effects.

To compare performance of Peregreen with S3 storage backend and with EBSstorage backend we performed all described above experiments in both settings and calculated relative efficiency of S3 as a ratio of execution time with S3 backend to execution time with EBS backend. In Figure 9 S3 relative efficiency plot is presented. Experiment with 100 parallel extraction requests for 1 hour shows the worst S3 efficiency – 49 ms for EBS backend and 351 ms for S3 backend. But as the load (number of parallel requests and interval length) grows, S3 relative efficiency increases, and starting from 1000 requests for 6 hours S3 becomes more efficient than EBS (1320 ms for S3 and 1605 ms for EBS). Maximal loads (100 and 1000 requests for 240 hours) demonstrate two times lower execution time for S3 storage backend – 35096 ms for EBS backend and 18156 ms for S3 backend for 1000 requests. Such difference can be explained by the fact that EBS volumes have limits on a throughput and number of I/O operations per second [2]. S3, on the other hand, does not have such limitations [3], which allows it to scale better under the high workload.

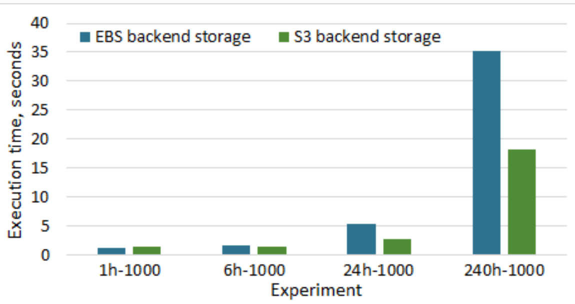

Figure 10: Data extraction results for 4 instances in EC2

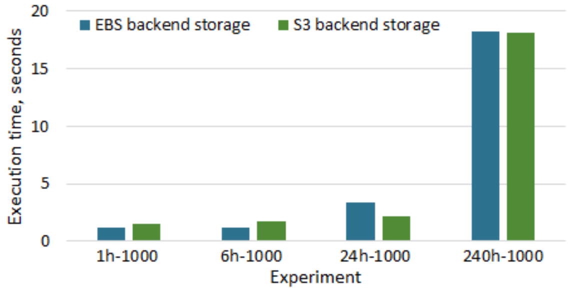

Figure 11: Data extraction results for 7 instances in EC2

In order to further investigate scaling of two storage backends, we analyzed performance of the same set of requests for different sets of nodes. In Figures 10 and 11 we present experimental results for 1000 parallel requests for extraction of 1, 6, 24 and 240 hours on 4 and 7 instances respectively. It is interesting to mention that for 6h-1000 scenario on 4 instances S3 storage backend is slightly more efficient than EBS (1320 ms and 1605 ms), whereas in case of 7 instances EBS backend provides smaller execution time (1233 ms and 1782 ms). But the most important observation is in the 240h-1000 scenario. When Peregreen deployed on 4 instances S3 provides twice faster execution, but for 7 nodes EBS storage demonstrates the same result as S3 storage, and execution time for S3 storage does not change. The reason why this scenario cannot be finished in less than 18 seconds is a network bandwidth limitations – this request generates 864 million data records with the volume of almost 18 GB. Even with a very high EC2 inter-instance throughput [4] it takes a fair amount of time to transfer such data volume to the testing instance.

5 Alternatives comparison

Today there are plenty of time series oriented databases and storages. In this section, we give a brief description of the most popular and mature solutions, which are used for storing time series data, and investigate how they compare against Peregreen. Comparison criteria are based on requirements

Table 4: Comparison of databases for storing time series

	InfluxDB	ClickHouse	Kudu	Cassandra	Gorilla	Gnocchi	TimescaleDB	OpenTSDB	Snowflake	Prometheus	Peregreen
Index type	sparse	controlled sparse	precise	precise	sparse	external	various	sparse	no	sparse	controlled sparse
Internal data structures	LSM+ MVCC	LSM	LSM+ MVCC	LSM+ MVCC	PSP	n/a	B-tree+ MVCC	n/a	tables	custom	custom
Data layout	column	column	column	row-wise	ts-specific	n/a	row-wise	column	column	ts-specific	ts-specific
TS-specific compression	yes	no	no	no	yes	n/a	yes	yes	no	yes	yes
Values-based index	mat. view	mat. view	no	special index	no	no	special index	no	no	special index	special index
Aggregations	yes	yes	no	no	no	yes	yes	yes	yes	yes	yes
SQL-like query syntax	yes	yes	no	yes	no	no	yes	no	yes	no	no
In-memory	no	yes	no	no	yes	no	no	no	no	yes	no
Low-cost object storage	no	no	no	no	no	yes	no	no	partly	no	yes

from Section 1 and common use cases of working with time series. Results of the comparison are presented in Table 4.

InfluxDB is an open-core time series data store that provides high throughput of ingest, compression and real-time querying. As of November 2018 it is the most popular time series storage [15]. ClickHouse is an open source distributed column-oriented DBMS that provides a rich set of features to its users. Due to the MergeTree table engine and time oriented functions, ClickHouse has proven to be efficient for working with time series data [5, 20]. TimescaleDB is an open-source extension of PostgreSQL designed to overcome limitations of PostgreSQL when it comes to working with time series. TimescaleDB introduces hypertable – an entity, which has the same interface for the user as a simple table, but internally is an abstraction consisting of many tables called chunks. This mechanism allows avoiding slow disk operations by storing in memory only the chunk of the latest period. Apache Kudu [14] is a column-oriented data store that enables fast analytics in the Hadoop ecosystem. Apache Cassandra is a general-purpose distributed NoSQL storage, the main aims of which are to provide linear scalability and fault tolerance. Gorilla [18] is a fast in-memory time series database developed by Facebook. Gnocchi is an open-source TSDB that aims to handle large amounts of aggregated data. OpenTSDBis an open-source scalable, distributed time series database written in Java and built on top of HBase. Snowflake is an analytic data warehouse provided as Software-as-a-Service (SaaS). It uses custom SQL database engine with a unique architecture designed for the cloud. Prometheus is an open-source systems monitoring and alerting toolkit that has a powerful time series storage engine.

The first criterion for the comparison is an index type. Precise indices in Kudu and Cassandra make possible fast search of exact data entries, but they generally do not increase the speed of long continuous time series extraction compared to sparse indices in other solutions, and moreover, index sizes in Kudu and Cassandra are very large. A sparse index is much more suitable for the extraction of long time series, and control over the sparsity of the index is an additional advantage. Gnocchi relies on external indexing by PostgreSQL or

MySQL. The interesting fact about Snowflake is that it does not have indices and instead relies on data micro-partitioning and clustering [22] that have proven to be very effective on a large scale.

In terms of internal data structures, log-structured merge-tree (LSM) is the most widespread way to store the data. But InfluxDB, Kudu and Cassandra also use multiversion concurrency control (MVCC) to handle concurrent data modifications. And when using MVCC there can exist several versions of the data, and if these versions were not merged into one during the reading operation, the storage will have to merge versions upon reading, which decreases the overall performance. On the other hand, plain sorted partitions (PSP) used in Gorilla, make possible fast navigation and extraction of large amounts of data. OpenTSDB relies on the backend storage, usually HBase, for storing the actual data. Snowflake tables are the part of the proprietary platform thus no detailed information on them is available. The schema of storing the data in Prometheus includes custom data format for chunks and write ahead logs that are optimized for reading. Peregreen also has a custom format based on read-optimized series encoding.

The next criterion is an internal data layout. Row-wise store data layout of Cassandra and TimescaleDB can be efficient for sequential reads only when there are no other columns except timestamp and value. InfluxDB stores timestamps and values as two separate sequences in its blocks and in that sense its layout is also columnar. OpenTSDB stores the data in columnar storages, like HBase or Bigtable, and because of that provides good speed of data extraction. Prometheus [19] as well as Peregreen has time series specific data layout format. Regarding the time series specific compression, general purpose databases do not have special methods for efficient time series compression, like delta or delta-of-deltas compression. It is worth mentioning that TimescaleDB allows to compress the data by chunks but compressed chunks cannot be updated [24].

The next criteria are related to search by values and data aggregations. The best way to perform a fast search based on values conditions is to have some sort of values-based index. ClickHouse and InfuxDB provide such functionality through materialized views and continuous queries. Cassandra and TimescaleDB can easily create a secondary index over the values column and thus provide very fast search. Snowflake relies on clustering and intelligent query optimization for providing high speed of searching across values conditions. Prometheus allows querying the data based on values of the tags. Index of Peregreen stores aggregated metrics for blocks and segments that makes possible fast search in the large data volumes. All solutions except for Kudu, Cassandra and Gorilla, support data aggregation during extraction.

SQL-like query syntax is a great feature for any database since SQL is familiar to many developers and analysts. Prometheus provides a query language called PromQL that lets users select and aggregate time series data. It should also be noted that Peregreen has no support for SQL syntax and has a set of purposefully built operations available through API.

The last set of features is related to the support of various storage backends. Only ClickHouse, Gorilla and Prometheus can store the data in memory to provide the maximal speed of data access. The most interesting criterion is the ability of the storage to use low-cost object storages, like Amazon S3 or Google Cloud, because it is a very important advantage in terms of cost of usage. Apart from Peregreen only Gnocchi support such functionality. Snowflake supports integration with Amazon S3 but in order to efficiently perform operations over the data it have to be loaded into Snowflake tables [21].

As can be seen from the presented comparison, modern databases provide users with great functionality when speaking about working with time series. Nevertheless, Peregreen provides a unique set of features – high performance along with cloud object storage integration – for working with large volumes of historical time series.

6 Conclusion

In this paper we presented Peregreen – high performance storage for numeric time series. Peregreen is based on a three-tier indexing mechanism and read-optimized series encoding, which allows it to achieve high compression rate, small index size and high execution speed of data processing operations. Experimental results show that Peregreen performs better than InfluxDB and ClickHouse in operations of data search and extraction over large amounts of historical time series data. Peregreen also provides integration with Amazon S3 as a backend data storage out of the box, which means that it can greatly reduce the cost of data storing while increasing the overall efficiency compared to storing the data in EBS, as our experiments demonstrate.

AC-Key: Adaptive Caching for LSM-based Key-Value Stores

Fenggang Wu Ming-Hong Yang Baoquan Zhang David H.C. Du
University of Minnesota, Twin Cities

Abstract

Read performance of LSM-tree-based Key-Value Stores suffers from serious read amplification caused by the leveled structure used to improve write performance. Caching is one of the main techniques to improve the performance of read operations. Designing an efficient caching algorithm is challenging because the leveled structure obscures the cost and benefit of caching a particular key, and the trade-off between point lookup and range query operations further complicates the cache replacement decisions.

We propose AC-Key, an Adaptive Caching enabled Key-Value Store to address these challenges. AC-Key manages three different caching components, namely key-value cache, key-pointer cache, and block cache, and adjust their sizes according to the workload. AC-Key leverages a novel caching efficiency factor to capture the heterogeneity of the caching costs and benefits of cached entries. We implement AC-Key by modifying RocksDB. The evaluation results show that the performance of AC-Key is higher than that of RocksDB in various workloads and is even better than the best offline fix-sized caching scheme in phase-change workloads.

1 Introduction

The persistent Key-Value Store (KVS) has become an indispensable storage engine in many applications [1–4] for its flexibility and scalability. Existing KVSs, e.g., LevelDB [5], RocksDB [6], Cassandra [7], etc., use a Log-Structured Merge (LSM) tree [8] to improve the performance of write operations. However, their read performance is sacrificed because of the log-structured nature of LSM trees, where finding a key by searching several levels could incur multiple storage I/Os [9–11].

Caching is one of the main techniques to improve read performance since workloads usually demonstrate certain amounts of access locality. Studies show that read operations exhibit "hot spots" in enterprise workloads on LSM-tree-based KVSs (LSM-KVS) for both point lookups [12–14] and range queries [15, 16]. In Facebook, some large-scale production use cases of RocksDB exhibit good locality [17]: fewer than 3% of the keys were accessed during a 24-hour UDB workload; in the ZippyDB workload about 1% of the KV-pairs are accountable for 50% of the total Gets.

There are two major unique challenges in designing an efficient caching scheme for LSM-KVS. First, LSM has a multi-level design where the storage I/O saved by each cached key-value pair (*caching benefit*) could be different. The deeper the level where the KV pair resides, the more storage I/Os can be saved if it is cached. Additionally, the DRAM caching size taken by one key-value pair (*caching cost*) is also different with different key and value sizes. It is challenging for the caching scheme to estimate the cost and benefit and make replacement decisions accordingly. Second, the two types of read operations, namely point lookup and range query, exhibit quite different caching requirements. Point lookup prefers caching an individual key-value pair (KV) for space efficiency [6, 7]. If the value is large, another alternative is to cache a key-pointer pair (KP, where the pointer refers to the location of the value in storage) [7]. In contrast, a range query cannot be served by caching sporadic individual keys, so people resort to caching blocks to support range queries [5, 6]. It is difficult to disentangle the trade-offs among caching KV, KP, and blocks, as each of them has certain types of favorable workloads. Additionally, designing an adaptive caching scheme that can deal with dynamic workloads is more challenging.

Existing caching schemes [5–7, 18, 19] only consider one or two types of entries to cache among KV, KP, and block, and they have a fixed allocated cache budget for one type of entry. Therefore, they cannot leverage all of their merits to cope with various workload scenarios, and cannot adjust the caching space when the workload changes. Besides, to the best of our knowledge, there is no existing work addressing the heterogeneous caching costs and benefits in the unique LSM-KVS scenario.

We comprehensively study the trade-offs among caching KV, KP, and blocks, and propose AC-Key, Adaptive Caching for LSM-based Key-Value Stores, to combine their advantages in handling different workloads. AC-Key uses one designated caching component for each type of the entries (KV, KP, and block). The size of each caching component is dynamically adjusted by the proposed *hierarchical adaptive caching* algorithm that uses *ghost caches* to guide the size adjustment. AC-Key leverages a novel *caching efficiency factor* that quantifies the different caching costs and benefits to aid the boundary adjustment among the caching components as well as the replacement decision within each caching component.

We implement AC-Key based on RocksDB [6]. Our benchmark evaluations show that the read performance of AC-Key is higher than that of the default RocksDB by up to 57.1%. In the phase-change workloads, AC-Key can achieve even better performance than the best offline fix-sized caching scheme. We also evaluate AC-Key using YCSB [15] where AC-Key outperforms the default RocksDB by up to 59.9%.

The rest of the paper is organized as follows. We first provide the background and motivation in §2 and §3, respectively. Then we present the design of AC-Key in §4 and analyze the performance of AC-Key in §5. §6 concludes the paper.

2 Background and Related Work

2.1 LSM-Tree-Based Key-Value Store

Popular implementations of LSM-tree-based Key-value stores (LSM-KVSs), such as LevelDB [5] and RocksDB [6], consist of two parts, a memory component and a storage component. The memory component, or *MemTable*, is typically implemented using in-place sorted data structures such as skip-list or B+ tree. The storage component is implemented as levels of files storing sorted runs of key-value pairs compactly. As shown in Fig. 1, one level is partitioned into multiple *sorted string table* files, or *SSTs*. Each SST has a configurable size limit, typically 2MB~64MB.

When the MemTable is full, it will be formatted into an SST and written to the storage component. This procedure is called the *flush* operation. Each level in the storage component has an exponentially increasing size limit (by default 10 times larger than the previous level). Therefore, larger levels will have more SSTs. L_0 SSTs will be merged with the L_1 SSTs when the specified size limit is reached. After that, L_1 SSTs will then be merged with L_2 SSTs, so on and so forth. This is called the *compaction* operation.

Every level is a single sorted run (except L_0) where the SSTs have disjoint key ranges. The sorted run of key-value pairs of an SST are divided into multiple *data blocks*, and the boundary keys between every two adjacent data blocks are stored in an *index block* with the corresponding data block offset within the SST. Besides, SST also contains a bloom filter block (BF block) to determine the existence of a key in this SST hence to save unnecessary storage I/Os. Block is the basic storage I/O unit in LSM-KVS.

There are two types of read operations in LSM-based key-value stores, namely *point-lookup* (or `Get`) and *range query* (or `Scan`). `Get` is to retrieve the value of a specific key in the following sequence: MemTable, every SST in L_0 from the youngest to the oldest, then L_1 to L_N. If the key is found in the MemTable, it will return with the value without any storage access. Otherwise, the key-value store will search the SSTs in the storage component. It will first check the bloom filter of one SST and skip the SST if the bloom filter indicates that the key does not exist. Otherwise, the index block will be read to locate the corresponding data block. Finally, the data block is retrieved and searched for the key. Therefore, a key-value store needs at most three storage I/Os when searching an SST for a specific key.

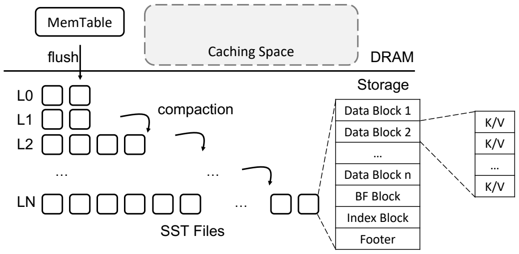

Figure 1: LSM-based Key-value Store (LSM-KVS).

LSM-KVS performs a range query using a starting key and an ending key or a number specifying how many key-value pairs to return. To execute a range query, the KVS uses a `Seek()` function to construct a merging iterator that can iterate through the MemTable, all SSTs in L_0, and one SST in each of the larger levels at the same time. Then, the KVS will call a `Next()` function to return the next larger key. When the key returned by the `Next()` function is larger than the ending key, or the number of the returned key-value pairs has reached the specified number, the range query will be terminated.

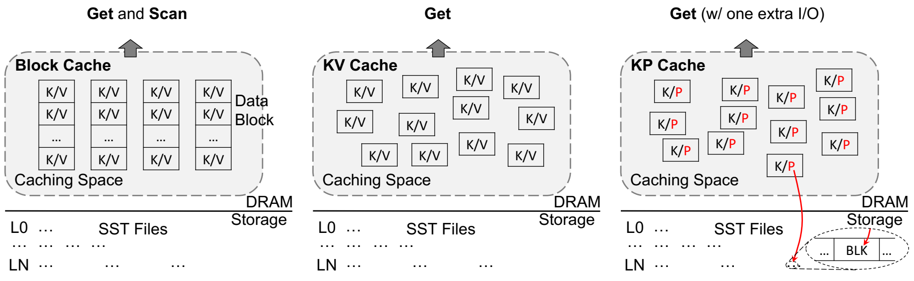
2.2 Related Work

2.2.1 Caching Schemes in LSM-KVS

There are three type of entries that can be cached in LSM-KVS: block, KV, and KP (Fig. 2).

LevelDB [5] only adopts the Block Cache (Fig. 2a), where the blocks could be data block, index block, or Bloom Filter (BF) block. The blocks in the Block Cache are indexed using the SST file ID and the block offset (`<SstID|BlockOffset>`). Block Cache can be beneficial for both point lookup and range query operations. Storage I/Os can be saved as long as the target block is cached. However, Block Cache is not space-efficient to serve point lookup, as the whole block has to be cached even though only a small portion of the keys in the block are accessed frequently.

RocksDB [6] has both Block Cache (Fig. 2a) and KV Cache (Fig. 2b). The KV Cache stores KV pairs that can serve point lookup. However, the sizes of the Block and KV Caches in RocksDB are predefined and fixed. When the KV cache is enabled, point lookup will first consult the KV cache if the write buffer does not contain the key. If the key was not cached in the KV Cache, RocksDB will follow the normal read process using Block Cache as LevelDB does, and insert



(a) Block Cache

(b) KV Cache

(c) KP Cache

Figure 2: Three Types of Entries to Cache in LSM-KVS.

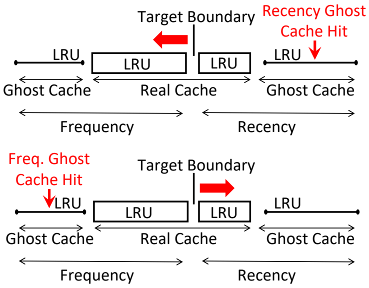


Figure 3: ARC Algorithm.

the KV pair into the KV cache afterwards. Range queries are supported by the Block Cache.

Cassandra [7] does not have a Block Cache but has both KV Cache (Fig. 2b) and KP Cache (Fig. 2c. In the KP Cache, the locations of the values in the storage are cached in memory as pointers). On a hit in the KP Cache, one point lookup can be served with only one storage I/O, skipping all the shallower levels in the storage component. Compared with KV Cache, KP Cache is more space-efficient for large value sizes at a price of one extra storage I/O. Similar to KV Cache, KP Cache cannot handle range queries. When promoting a key from KP Cache to KV Cache, Cassandra does not remove the KP entry.

zExpander [18] is a KVS caching scheme which caches key-value pairs only. It partitions caching space into a compressed zone (Z-zone) and an uncompressed zone (N-zone) and can adapt the boundary between them. LSbM [19] has a small on-disk *compaction buffer* that keeps old, but hot data from being deleted during compaction to reduce the block cache invalidation due to compaction. It needs extra storage space for compaction buffer, and does not take advantage of the more efficient KV or KP Cache to support point lookup.

2.2.2 General Caching Algorithms

The page cache replacement problem has been studied for decades [20]. Adaptive Replacement Cache (ARC) [21] is a dynamic page replacement algorithm designed for managing the page cache in DRAM. As shown in Fig. 3, ARC divides the caching space into two parts, the *recency cache* and the *frequency cache*, each of which is an LRU cache. A page is brought into the recency cache when first encountered. If the page gets a second access before being evicted, it is considered a frequently accessed page and will be migrated to the frequency cache.

The space distribution between the recency cache and the frequency cache is dynamic. ARC uses two *ghost caches* to store metadata of evicted pages (page number) from the recency and frequency cache respectively. The pages stored in the ghost cache will be a future reference for adjusting the allocated space for each part. Compared with the *real cache*, i.e., the cache stores the actual page contents, the size of the ghost cache is negligible since they only store page numbers.

A hit on the recency ghost cache indicates the recency cache should have been larger, so the target boundary will be moved leftwards (top figure in Fig. 3) and vice versa (bottom figure in Fig. 3). As a result, the size of the corresponding real cache will be increased or decreased according to the workload.

CAR [22] also maintains a dynamic partition between the recency and frequency cache using ghost caches, but it uses CLOCK instead of LRU to manage each caching component to reduce overhead. H-ARC [23] uses Non-Volatile Memory (NVM) to cache both clean and dirty pages and propose a hierarchical algorithm to adaptively handle the page replacement.

Such page-based caching algorithms (e.g. ARC [21], CAR [22], H-ARC [23]) do not fit LSM-KVS well because they are based on identical page sizes and caching benefits (i.e. storage I/Os saved by caching an entry), whereas the entry sizes and caching benefits in LSM-KVS are no longer uniform. Similarly, pure frequency-based cache eviction algorithms (e.g. WLFU [24]) and admission policies (e.g. TinyLFU [25]) assume homogeneous entry size and caching benefit too and make replacement decisions solely based on the access frequency. However, in LSM-KVS, the difference in entry size and caching benefit should also be considered along with frequency. Web caching algorithms often take into account the entry size information [26]. In LSM-KVS, however, besides entry size, the caching benefit for different entries is also diverse. For example, caching a KV from a deeper level will save more storage I/Os than caching one from a shallower level. Such special knowledge of the leveled structure of LSM-tree should be exploited to aid caching decisions in LSM-KVS.

3 Motivation

3.1 Unique Challenges in Caching for LSM

Comparing with the page cache replacement problem [20–23], where the pages have identical sizes, keys and values in the LSM tree do not necessarily have the same size. The caching algorithm in LSM should also take the size difference into consideration when designing the replacement algorithm.

Hash-based KVS [27, 28] does not support range queries. In contrast, LSM-KVS has two distinct read operations, point

Table 1: LSM-KVS Caching Scheme Comparison

Cached Entry	Space Efficiency	Extra I/O	Get Existing	Get Missing	Scan	Compaction	Flush	Favorite Workload
Block	Low	No	Helpful	Helpful (BF block)	Helpful	Affected	Not Affected	Scan / Get (missing)
KV	High	No	Helpful	Not Helpful	Not Helpful	Not Affected	Affected	Get (hot/small value)
KP	High	Yes	Helpful	Not Helpful	Not Helpful	Affected	Affected	Get (warm/large value)

lookup and range query, that exhibit quite different caching requirements, and brings additional challenges in the design of LSM caching algorithms.

B+ tree-based KVS [29] supports both point lookup and range query. LSM-KVS is different as it has a leveled structure that diversifies the caching benefit of KV pairs on different levels. The deeper level the KV resides, the more storage I/O can be saved by caching this KV pair. Besides, native operations in LSM-KVS such as compaction and flush do not exist in B+ tree-based KVS, but they will invalidate cached entries and need special treatment in the design.

To motivate our design, we discuss two key question about the LSM-KVS caching: *what to cache*, and *how to perform replacement*, while summarizing the lesson learned.

3.2 What to Cache in LSM-KVS

For point lookup which retrieves the value for a given key, it's natural to directly cache the hot KV pairs in the DRAM cache. However, when the value size is large, and/or the access is less frequent, another alternative is to cache a pointer referring to the location of the value on the storage component. When looking for this key, the value can be fetched using one storage I/O instead of performing multiple I/Os along every SST from L_0 down to the level where the KV resides. By storing a smaller pointer instead of the original larger value, KP Cache can hold more entries. The hit ratio of KP Cache will be higher than that of a KV Cache and can potentially save more I/Os. Comparing KV with KP entry, a hit on a KV entry can save more storage I/Os since a KP hit still needs one storage I/O to get the value. On the other hand, caching KP entries is more space-efficient in the case of relatively large value sizes.

Lesson 1: The merits of caching KV and KP entries should be combined to efficiently serve point lookups.

Unfortunately, cached KV and KP entries cannot help with range queries. Given the staring key of a range query, the next larger key cannot be determined by only examining the sporadic cached KV or KP entries. Therefore, some LSM-KVS implementations such as LevelDB [5] and RocksDB [6] cache data blocks for range queries.

Cached data blocks can serve point lookup too. However, retaining a whole block for point lookup is not space-efficient as it keeps a whole block in the DRAM even only a few keys are frequently looked up. Beside data blocks, frequently accessed index blocks and bloom filter blocks (BF blocks) are also cached in Block Cache.

Lesson 2: Cached blocks and KV/KP entries each have their advantage to support range query and point lookup.

3.3 How to Perform Replacement

From the discussion above, we reach to the conclusion that caching KV, KP, and block each has its own favorable workload scenario. We have a comprehensive comparison summarized in Table 1. However, designing the replacement algorithm for a cache that consists of all these three different entries is challenging.

A straightforward approach is to treat all the cached entries (KP entries, KP entries, or blocks) equally and borrow existing replacing schemes, such as LRU (Least Recently Used) or LFU (Least Frequently Used), to manage the cache. Each entry is inserted or evicted according to the corresponding eviction policy. Therefore, the number of cached entries among the cached KV entries, KP entries, and blocks are solely determined by the access pattern. However, this "unified" caching approach is too simplified and cannot distinguish the differences between these cached entries. First, different cached entries have different sizes. For example, one cached block may take up the DRAM space which can hold tens or hundreds of KV/KP entries. Second, different cached entries have different numbers of saved storage I/Os. For example, one cached block saves one I/O if hit, but one cached KV entry could save multiple storage I/Os for all the SSTs to be accessed for a point lookup. Besides, KV/KP entries on different levels will have different numbers of storage I/O saved too. General cost-aware caching schemes [30, 31] does not have special analysis on the caching cost and benefit in this LSM-KVS scenario either. Third, if there is a single-pass large range query, the fetched blocks will evict useful entries out of cache without bringing any benefit.

Lesson 3: The caching algorithm should consider the difference of DRAM size taken and number of storage I/O saved among different cached entries, respecting the unique leveled structure of LSM-KVS.

Another approach is to have designated fix-sized KV Cache, KP Cache, and Block Cache for the corresponding entries, and perform independent eviction decisions based on popular caching algorithms, such as LRU or LFU. In this case, the cache is resilient to the large single-pass range query (as mentioned before) because the each caching component has a bounded capacity and will not influence the other caching components. However, this fix-sized approach has some problems. First, it is difficult to get the size distribution right in the first place. Second, even if we could have a favorable fix-size configuration at the beginning, it might not be suitable later on as the access pattern of workloads could change over time. For example, a workload has a phase change from range query

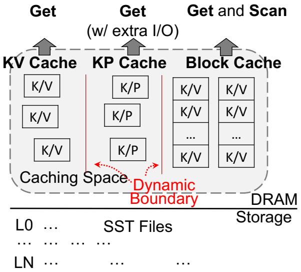

Figure 4: AC-Key Caching Components

dominant into point lookup dominant. If the fixed configuration is good for the range query at first, i.e., majority of the cache space is used as Block Cache, in the point lookup phase, it is clearly not efficient.

Lesson 4: The caching algorithm should be adaptive to the workload changes.

4 AC-Key Design

AC-Key (Fig. 4) caches all three types of entries – KV, KP, and block – with designated caching components for each of the three. Different from the fix-sized scheme described in the previous section, AC-Key has *dynamic* sizes for each of the caching components. The sizes are adjusted by the proposed *hierarchical adaptive caching* algorithm. Considering the heterogeneous costs and benefits of different cached entries and the unique leveled structure of LSM-KVS, AC-Key uses the proposed *caching efficiency factor* to quantitatively guide the size adjustment among the caching components as well as the replacement policy within each caching component.

4.1 AC-Key Caching Components

The AC-Key system architecture is depicted in Fig. 4. The storage component is identical to popular LSM implementations (§2). The DRAM caching space has three components: the *KV Cache*, the *KP Cache*, and the *Block Cache*. The Block, KP, and KV Caches are managed by E-LRU, an improved LRU with cache efficiency factor based eviction (see §4.2).

KV cache stores the key-value pairs directly. KP Cache holds keys with pointers, where the pointers are in a format of `<SstID|BlockOffset>`. When a KP Cache entry is hit, it takes only one storage I/O for the KVS to fetch the data block which contains the target key-value pair. Block Cache stores frequently accessed blocks, which can be either a data block, an index block, or a Bloom Filter (BF) block.

Remarks on the KV and KP Cache. In a point lookup operation, if a *lookup-key* is accessed for the first time, it will be brought to the KP Cache. A key cached in KP cache is called a *warm key*. If a warm key in KP cache is hit again, we consider the key as a *hot key*. We anticipate that it has a higher probability to be accessed again in the future. Therefore, we "promote" the key to KV Cache to potentially save more I/Os from the future accesses. Different from the existing solution in [7] that still keeps key in the KP Cache, AC-Key removes the key from KP Cache to avoid the duplicity and achieve better space-efficiency.

In our current design, we will not "demote" a hot key from KV Cache to KP Cache since we no longer have the pointer information. Another design alternative is to have both the pointer and value stored in KV Cache. However, the accompanying pointer will occupy extra cache space of the KV Cache hence we do not take this approach. As an optimization, if the value size of a KV pair is smaller than the pointer size (implementation-dependent, 24 B in our case), we will cache the *value* with the key into the KP Cache instead of the *pointer* to save the extra I/O without paying more DRAM caching space. This entry still needs another hit to be promoted to the KV Cache. AC-Key does not directly insert this KV entry to the KV cache. The reason is that if this key is not "hot" enough, i.e., having less chance to be hit again, it will evict other "hot" entries from the KV Cache. For example, the workload at a certain time starts to access through a substantial number of keys with small values without a second hit, those keys will occupy the whole KV cache, kicking out useful KV pairs without bringing any benefit.

4.1.1 `Get` Handling

`Get` Existing Key. Denote K as the key to search. First, the MemTable is searched for K as it potentially has the latest version of the value. If not found, then the KV and KP Cache is searched for the key. One of the following cases will happen.

- *Case I*: **Hit in KV Cache**. The value is returned without any I/O incurred.
- *Case II*: **Miss in KV Cache but hit in KP Cache**. Using the cached pointer (`<SstID|BlockOffset>`) as block handle, AC-Key will check whether the data block is already cached in the Block Cache. If not, AC-Key will load the data block into the Block Cache. Using binary search, AC-Key locates the KV pair in the data block and then serves the `Get` request. Besides, the key will be migrated to the KV Cache, promoting the cached entry from key-pointer format to key-value format.
- *Case III*: **Miss both in KV Cache and KP Cache**. AC-Key will examine every sorted run level by level, identifying each SST that has a key range overlaps K, from the youngest to the oldest. Once the key is found in a certain SST, AC-Key will stop searching and return the result directly. Besides, the location of the KV pair, i.e., the pointer, will be recorded and cached in the KP Cache indexed by the key.

In case III, when searching one SST, AC-Key first consults the BF block of this SST. If the BF block is not in the Block Cache, it will be fetched from the storage and inserted into the Block Cache. If the BF block indicates the key is not in the SST, AC-Key will skip this SST and proceed to the next SST. Otherwise, AC-Key will access the index block to narrow down the scope and pinpoint which data block to search. The index block and data block will be fetched from storage and inserted to the Block Cache if not already cached. The BF block, index block, and data block share the Block Cache similar to RocksDB [6].

`Get` Missing Key. When looking up a missing key K in AC-Key, Case I and II of §4.1.1 will not happen as there will be cache miss in both KV and KP Caches.

Similarly, in Case III, the Block Cache will be searched for the corresponding BF block and one storage I/O will be saved if hit. Getting missing keys is the "worst" case where all the overlapping SSTs will be checked. However, by using the cached BF blocks in the Block Cache, multiple storage I/Os can be saved.

4.1.2 `Flush` Handling

`Flush` will dump the MemTable that contains the latest version of the values into the storage component as an L_0 SST. It is possible that a key inserted to the MemTable is already cached in either KV or KP cache. Insertions (also called `Put` operations) to the MemTable will obsolete the corresponding cached entries. As long as the new version of value is still in MemTable, obsolete entries in the caches do not matter because point lookup operation will always consult the MemTable first. However, the cached KV and KP entries must be synced before the keys is flushed to the storage to avoid returning stale results.

We have two alternatives of the timing of the sync: during `Put` or during `Flush`. If during `Put`, the KV and KP Caches will be checked for potential obsolete entries in each `Put` and update the KV entry or delete the KP entry accordingly. Note that during `Put`, AC-Key cannot update the KP entry since the latest value of such key has not been written into an SST yet, hence there is no way to know where the pointer should point to. This approach introduces significant performance overhead because of the extra checking during *every* `Put` operation. Besides, if a key gets multiple updates before flushed from MemTable, we have to repeatedly check both KV and KP Cache for it, which further increases the sync overhead.

Therefore, AC-Key takes another alternative to sync the caches only during `Flush` time. It can accumulate multiple updates to the same key and only sync the KV or KP cache once for each key. Besides, during `Flush` time, AC-Key can figure out the new pointers of keys in the KP Cache and update them accordingly.

4.1.3 `Compaction` Handling

Compaction will affect KP and Block Caches since it creates new SSTs and delete old ones. The old SSTs deleted during compaction may contain blocks that are already cached in the Block Cache. Such deleted SSTs may also contain data blocks being referenced by the pointers cached in the KP Cache. However, it will not affect the entries in KV Cache because compaction reorders and consolidates old KV pairs instead of inserting new ones. AC-Key updates KP and block Caches when compaction affects any of cached KP entries or blocks.

For the KP Cache, during the compaction, AC-Key identifies affected KP entries in the KP-Cache and update the pointers to point to the new data blocks that contain the keys. For the Block Cache, if one cached data block is to be invalidated during compaction, AC-Key will replace the invalidated data block with one new data block generated by compaction to avoid the invalidated block wasting the Block Cache's capacity. The key range of the newly generated data block may not be exactly the same as the old one. AC-Key chooses the block that has the largest overlap with the old cached block and repopulates it back to the Block Cache. Similarly, invalidated cached BF blocks and index blocks are also replaced by the new ones with the most overlapping key ranges. Such block replacement does not incur extra I/O, as the new blocks are generated in memory during compaction.

4.2 Caching Efficiency Factor

To quantitatively analyze the trade-off between the costs and benefits of the cache entries, we propose the novel *caching efficiency factor* that takes into account the unique level structure of LSM-KVS. Using this caching efficiency factor, AC-Key improves LRU into *E-LRU* to manage cache evictions within each caching component, and modifies ARC into *E-ARC* to adjust the size of each caching component. We introduce the caching efficiency factor and E-LRU in this section, and discuss E-ARC in the next section.

We define the *caching efficiency factor E* (E standing for Efficiency) for one cached entry as the following equation. The meaning of this caching efficiency factor is "the number of saved I/O per byte of DRAM caching space".

$$E = \frac{b}{s}, \tag{1}$$

where: E = caching efficiency factor of one cached entry,
b = number of saved storage I/O if cached,
s = caching space taken by this entry.

For example, one typical cached KV entry will take one or several hundreds of bytes, one KP entry will normally take less than one hundred bytes, and one cached block will take 4~16KB. b denotes the number of I/O being saved if this entry is cached. It is given by:

$$b = \begin{cases} 1 & \text{if block,} \\ f(m) & \text{if KV entry,} \\ f(m) - 1 & \text{if KP entry.} \end{cases} \tag{2}$$

where: m = number of SSTs to search for the key,
$f(m)$ = number I/Os to get a key. It is a function of m.

The function $f(m)$ depends on the LSM-KVS implementation. Typically, $f(m) = m+2$, where we have to read m bloom filters each from one SST along the searching path, as well as one index block and one data block in the SST that contains the lookup-key. The number of SSTs to search, m, is estimated by the level l where the key resides:

$$m = \begin{cases} n_0/2 & \text{if } l = 0, \\ l + n_0 & \text{if } l >= 1. \end{cases} \quad (3)$$

where: n_0 = max number of SSTs L_0 can hold,
l = the level where the key resides.

If $l = 0$, the key is in L_0. AC-Key assumes $m = n_0/2$ as an estimate of the average number of SST to search for a key in L_0. If the lookup key resides in levels greater than L_0, potentially every SST in level L_0 will be checked. So, AC-Key uses n_0, the max number of files in L_0, to estimate m.

E-LRU. Traditional LRU only considers the access pattern without taking care of the different benefits and costs of the cached entry. We develop E-LRU, the efficiency-based LRU, to address this issue. E-LRU checks the least used a cached entries and evict one with the least caching efficiency E. The value of a depends on the variance of the caching efficiency factor E of the cached entries. It is given by $a = e^v$, where v is the standard deviation of the caching efficiency factor E of sampled entries in the caching component. When $v = 0$, meaning cached entries has identical efficiency, then $a = 1$, and E-LRU degenerates to the original LRU algorithm that evicts the last one entry from the list. The larger v, the more variance of the efficiency E, the greater a should be used to select a better candidate to evict. In the current implementation, we have a cap on a to avoid AC-Key checking too many entries when making eviction decision. We use E-LRU for simplicity, yet other cost-aware caching schemes [30, 31] can be adapted here using our proposed caching efficiency factor.

4.3 HAC: Hierarchical Adaptive Caching

Hierarchical Adaptive Caching (HAC) has a two-level hierarchy to manage different caching components (Fig. 5). On the upper level, the cache is divided into two components: the Point Cache and the Block Cache. The boundary between the Point Cache and the Block Cache is dynamically adjusted. On the lower level, the Point Cache is further divided into KV Cache and KP Cache with an adjustable boundary too. HAC maintains *ghost caches* to keep a record of the evicted entries from the KV, KP, and Block Cache. On the upper level, there are two ghost caches for the Point Cache and the Block Cache respectively, while in the lower level, there are two ghost caches each for the KV and KP Cache. Opposed to ghost caches, the original KV, KP, and Block Caches are called *real caches*. Here the KV and KP Real Caches collectively make up the Point Real Cache. The ghost caches do not hold the real entry, but only metadata of the evicted entries. A hit in the ghost cache means it could have been a real cache hit if the corresponding real cache was larger. By using ghost cache with the caching efficiency factor, we design E-ARC (caching Efficiency enabled ARC) to adjust the size of the corresponding real cache.

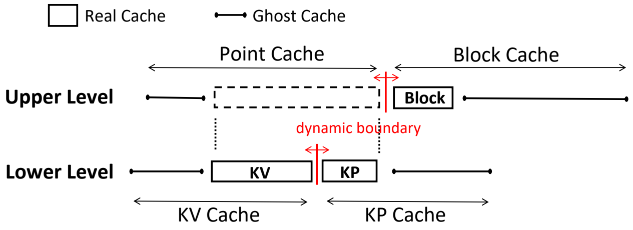

Figure 5: Hierarchical Adaptive Caching (HAC) Algorithm.

4.3.1 Lower-Level HAC

AC-Key uses E-ARC, or efficiency based ARC, to manage the lower-level HAC. On the lower-level HAC, the Point Cache is divided into the KV Real Cache (R_{kv}) and KP Real Cache (R_{kp}). That is: $|R_{kv}| + |R_{kp}| = S_{point}$, where $|\cdot|$ means size, and S_{point} denotes the Point Cache size. AC-Key maintains the KV Ghost Cache as if the KV Real Cache R_{kv} plus the KV Ghost Cache G_{kv} equals to the total size of the Point Cache. Note that the KV Ghost Cache only holds the metadata of the keys evicted from the KV Cache. Denote $|G_{kv}|$ as the size if they were storing the whole KV pair, then $|R_{kv}| + |G_{kv}| = S_{point}$. Similarly, with G_{kp} denoting the KP Ghost Cache, we have $|R_{kp}| + |G_{kp}| = S_{point}$.

Therefore, the following equation is always maintained:

$$S_{point} = |R_{kv}| + |R_{kp}| = |R_{kv}| + |G_{kv}| = |R_{kp}| + |G_{kp}|. \quad (4)$$

We show how E-ARC handles cache hits and misses in the following cases:

- Case I: **Real Cache Hit**. Cache hits on R_{kv} or R_{kp}. Move the hit entry to the MRU end of R_{kv}. Especially, if the hit happens on R_{kp}, AC-Key needs one storage I/O to get the value. Then the key and value is inserted into R_{kv} (promotion).

- Case II: **KV Ghost Cache Hit**. Cache hits on G_{kv} means the size of R_{kv} should have been larger. Shift the target boundary towards the KP Cache end by $\delta = kE$, where E is the caching efficiency factor of the hit entry on G_{kv}. Here k is a configurable learning rate. After fetching from storage, insert the fetched KV to the MRU end of R_{kv}. To make room for this KV entry, evict from R_{kv} (resp. R_{kp}) if the target boundary is within R_{kv} (resp. R_{kp}), meaning that the target size of R_{kv} (resp. R_{kp}) is smaller than its actual size.

- Case III: **KP Ghost Cache Hit**. Cache hits on G_{kp} means the size of R_{kp} should have been larger. Shift the target boundary towards the KV Cache end by $\delta = kE$.

E is the caching efficiency factor of the hit entry on G_{kp}. After fetching from storage, insert the fetched KV to the MRU end of R_{kv}. To make room for this KV entry, evict from R_{kv} (resp. R_{kp}) if the target boundary is within R_{kv} (resp. R_{kp}), similar to Case II.

- Case IV: **Cache Miss**. Retrieve the entry from storage and cache to R_{kp} in KP format. To make room for this KP entry, if the target boundary is within KV cache, evict from R_{kv}. Otherwise evict from R_{kp}.

The target boundary between the KV Real Cache R_{kv} and KP Real Cache R_{kp} indicates the direction the actual boundary should move. The actual boundary will normally lag behind the target boundary. The high level sequence of operations is as follows: 1) ghost hit adjusts the target boundary; 2) entry insertion or promotion shifts the actual boundary towards the target boundary, and as a result, real cache sizes $|R_{kv}|$ and $|R_{kp}|$ are updated; 3) ghost cache sizes are adjusted based on the new real cache sizes using the Eqn. 4; and 4) real and ghost caches perform eviction if necessary to fit the updated sizes using E-LRU (§4.2).

Remarks on E-ARC. Although we follow a similar logic of the canonical ARC algorithm, the original ARC does not have the size and cost differences. In the original ARC, the saved block access b and space cost s for each entry are always the same. E-ARC's definition of $\delta = kE = k\frac{b}{s}$ is a generalization of that of the canonical ARC, and the ARC's definition of the adjustment is a special case of E-ARC's formula where $\frac{b}{s} = 1$.

4.3.2 Upper-Level HAC

On the upper level of HAC, we re-apply the E-ARC scheme to adjust the boundary between Point Cache and Block Cache. Block Cache and Point Cache each has a real cache (R_{block} and R_{point}) and a ghost cache (G_{block} and G_{point}). R_{kv} and R_{kp} collectively forms R_{point}. Blocks evicted from R_{block} enter G_{block}. On the other hand, entries evicted from R_{point} (R_{kv} or R_{kp}) will be inserted to G_{point}. Note that the evicted entry will also be inserted to the corresponding KV or KP Ghost Caches (G_{kv} or G_{kp}) in the lower level (§4.3.1). Similarly to the low level of HAC, the sum of the virtual "size" of the real cache and ghost cache of the Block Cache (resp. Point Cache) will be the total available cache size:

$$\begin{aligned} S_{total} = & \quad |R_{block}| + |R_{point}| \\ = & \quad |R_{block}| + |G_{block}| = \quad |R_{point}| + |G_{point}|. \end{aligned} \tag{5}$$

Target Boundary Adjustment. A ghost hit on G_{block} will move the target boundary between R_{point} and R_{block} toward R_{point} by $\Delta = kE$, where E is the caching efficiency factor of the entry on G_{block} being hit, and k is the learning rate as defined earlier. As a result, the target size of R_{point} will be reduced by Δ. Then, in the lower level, the amount of the adjustment will be distributed between the target size of R_{kv} and R_{kp} proportionally to their current target size ratio. In this example, target size of R_{point} is shrinking by Δ. Denoting the current target size of R_{kv} as $|R^*_{kv}|$ and the target size R_{kp} as $|R^*_{kp}|$, they will be updated as follows: $|R^*_{kv}| \leftarrow |R^*_{kv}| - \Delta\frac{|R^*_{kv}|}{|R^*_{kv}|+|R^*_{kp}|}$, and $|R^*_{kp}| \leftarrow |R^*_{kp}| - \Delta\frac{|R^*_{kp}|}{|R^*_{kv}|+|R^*_{kp}|}$.

On the other hand, a ghost hit on G_{point} will move the target boundary toward R_{block}, i.e., making the target size of R_{block} smaller and that of R_{point} larger. The adjustment amount is also $\Delta = kE$. The caching efficiency factor E of an entry in G_{point} will normally be larger that that in G_{block}, as a Point Cache entry (either KV or KP entry) takes less DRAM caching space and save a greater number of storage I/Os than one Block entry. While there is a ghost hit on G_{point} on the upper level, normally there will be a ghost hit in the lower level too, either in G_{kv} or G_{kp}. In this case, the lower level target boundary will be adjusted first, then that of the upper level. For example, if the ghost hit happens both in the KV Ghost Cache G_{kv} and the Point Ghost Cache G_{point}, the target size of R_{kv} and R_{kp} will first be updated as described in §4.3.1), then increment of Δ is distributed proportionally to the new target size of R_{kv} and R_{kp} accordingly.

Actual Boundary Adjustment. On a block miss when this block needs to be inserted to the Block Cache, if the current Block Cache size plus the new block is greater than the target block size, the Block Cache will not grow. It will evict one block from itself to make space for the new-coming block. Otherwise, if the current Block Cache size plus the new block is within the target Block Cache size, the Block Cache will expand by inserting the new block, and the Point Cache will shrink to make room for the growth of the Block Cache. Typically, more than one KV and KP entries will be evicted because a block is normally larger than cached KV and KP entries. The number of KV or KP entries to be evicted will be based on current target size of the KV and KP Real Caches.

On the other hand, when the Point Cache demands more capacity, (i.e., when new KP entry is inserted to the KP Cache, or when a KP entry is promoted to KV Cache and takes more space), HAC estimates the new Point Cache size after the growth and compares it with the target Point Cache. If the estimated new Point Cache size is within the target Point Cache, one block from the Block Cache will be evicted to make the room for the Point Cache to grow. On the other hand, if the estimated new Point Cache size is above the target Point Cache size, Point Cache will not expand, and the eviction will happen within the Point Cache, following the current target KV and KP Real Cache sizes. One problem is that increasing the size of Point Cache by small amount may result in a whole block evicted from the Block Cache. To address this, not until the target boundary is within the Block Cache for at least one block's size (typically 4KB or 16KB) does HAC evict blocks from the Block Cache. In other words, the size of the Point Cache will grow at the expense of evicting from the Block Cache only when the target Point Cache size is greater by the current actual Point Cache by a whole block size.

4.3.3 Reduce Ghost Cache Size

In the ARC design [21], when a page is evicted from the real cache, the page content is dropped, and only the page number is retained in the ghost cache. The size of the page number is negligible compared to the page content. Similarly, in AC-Key, the ghost cache for the Block Cache G_{block} only stores the block handle in the format of `<SstID|BlockOffset>` (24 B in our implementation) which is also negligible compared to the cache block contents (typically 4~16 KB). However, the ghost caches of G_{point}, G_{kv}, and G_{kp} have significant overhead that can no longer be ignored. For example, assuming a key size of 16 B and the value size of 100 B, one real KV entry takes 116 B. When this entry is evicted from the real cache, the value is dropped, and the key is inserted into the KV ghost cache which still takes 16 B. As the key size is no longer negligible when comparing to the value size and pointer size, a ghost cache potentially occupies a substantial portion of the limited caching space, impair the caching efficiency.

We propose two ways to reduce the space overhead of the ghost caches. First, instead of using the original key of the evicted KV or KP entries, AC-Key only stores a hash value of the evicted key as a "fingerprint". In this way, AC-Key reduces the ghost cache size overhead while sacrificing the ghost cache hit accuracy. Hash collision will cause false-positive ghost hits, resulting in imprecise adjustment decisions. In our implementation, we found a hash value of 4 B shows a good trade-off between the ghost cache overhead and accuracy.

Although using a hash-based fingerprint to replace the key in ghost cache reduces the overhead, a hash value (for example, 4 B) is still taking significant space compared with the real KV and KP Caches. We further propose another optimization to eliminate such ghost cache overhead by disabling ghost cache when the adaptive scheme settles to a favorable capacity distribution among the KV, KP, and Block Cache. If the changes of hit ratios of all the caching components remains within a threshold θ (called *ghost cache turnoff threshold*, 5% by default), the ghost cache mechanism will be turned off, and the space taken by the ghost caches will be reclaimed for real caches. The size of the real caches will be proportionally scaled up to use all the available cache capacity when the ghost cache's space is released. Later, when the access pattern switches and the current size distribution is not favorable, the change in the hit ratio will flag the phase transition. When the hit ratio fluctuates beyond the threshold of θ, the AC-Key will turn the ghost cache mechanism back on until the hit ratio converges again (fluctuating within the threshold θ).

5 Evaluation

5.1 Implementation and Setup

We implement AC-Key based on RocksDB `version 6.2` with roughly 5.6K lines of change in `C++` code. We carry out our experiment on a Dell PowerEdge R430 1U Server. It has two six-core Intel Xeon E5-2620 v3 @ 2.40 GHz processors and 64 GB of DDR3 memory. The operating system is Ubuntu LTS 18.04 with Linux kernel version 4.15.0. The storage device is a 372 GB Intel DC P3700 PCIe SSD formatted as `xfs`.

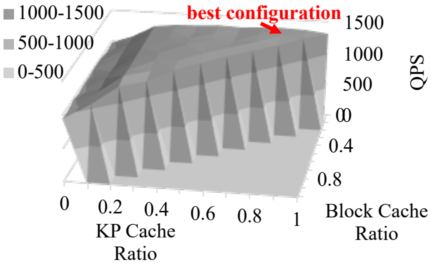

Figure 6: The `offline` scheme tries out on different configurations (at a smallest granularity of 1/10 of the cache size) and select the fix-sized configuration with the best result.

We load a 100GB database with randomly generated keys [9, 11]. The default key size is 16 B and value size is 100 B, which is the default value of RocksDB [32]. The length of range scans is set as 100, which is close to the length used in literature [15, 33–35]. The default point lookup to range query ratio is set to 1:1. We use the existing exponential function based workload generator in RocksDB [32] to generate workloads with different skewness of hot keys (point lookup key and scan starting key). In our experiments, we take the default skewness as the hottest 1% keys taking up the 99% of the accesses (including both the key for point lookup and the starting key for range query). The default learning rate k is 100K (see §4.3) and default ghost cache turnoff threshold θ is 5%. Data compression is disabled to rule out unrelated performance interference and simplify the analysis as in literature [9, 36]. We specify identical cache sizes in the configuration files of RocksDB and YCSB to ensure the same amount of caching budget is used in competing schemes. Page-based direct I/O [37] is enabled to rule out the interference of the OS buffer cache, similar to [38, 39].

The following schemes are compared.

- `pure-kv`: The whole caching space is used as KV Cache.
- `pure-kp`: The whole caching space is used as KP Cache.
- `rocksdb`: Off-the-shelf RocksDB with default setting. Note that RocksDB disables KV cache by default and the whole caching space is used as Block Cache.
- `offline`: We try combinations of different component size with the granularity of 1/10 of the cache size and select the best fix-sized configuration. Note that such best configuration is determined offline, and is not applicable in a real-time caching system (Fig. 6).
- `ac-key`: Our AC-Key scheme.

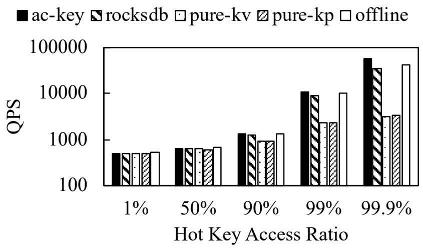

Figure 8: Varying Skewness.

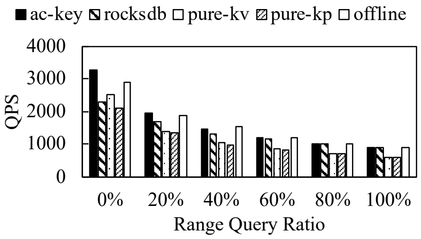

Figure 9: Varying Range Query Ratio.

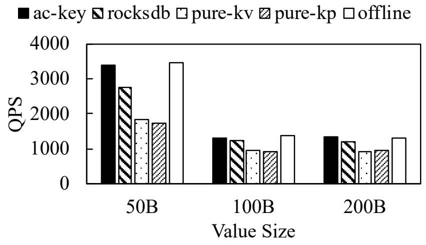

Figure 10: Varying Value Size.

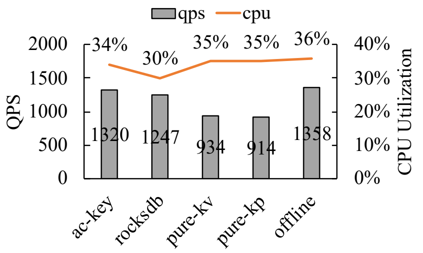

Figure 11: CPU Utilization Comparison.

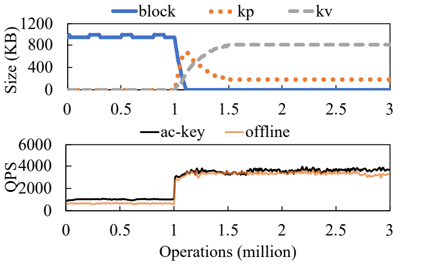

Figure 12: Adaptive Adjustment in AC-Key.

5.2 Micro-benchmark

Varying cache size. We vary the cache size from 1 MB to 10 GB, collect the Query Per Second (QPS) and plot them in Fig. 7. As the cache size increases, the QPS also increases for `ac-key`, `rocksdb`, and `offline`, as larger cache can potentially cache more entries, hence results in less cache misses. In contrast, `pure-kv` and `pure-kp` do not improve much because they do not support range queries, and therefore the range queries will cause many storage I/Os. `ac-key` outperforms other caching schemes that have only a single type of caching component (better than `rocksdb` by 5.0%~9.1%, `pure-kv` by 47.1%~97.7%, and `pure-kp` by 52.8%~104.5%) since they cannot serve both point lookups and range queries efficiently. Comparing with `offline`, `ac-key` performs close to or even better than `offline` because of the ability to adaptively configure the size of each caching component. The reason for the better performance of `ac-key` in some cases is because `offline` cannot exhaust all the possibilities of configurations as `offline` only tries out the cache size at a granularity of one-tenth of the total cache size (Fig. 6).

Varying skewness. We vary the access skewness of the point lookup and the range query using RocksDB's native benchmark tool [32]. In Fig. 8, x-axis shows the access ratio of the hottest 1% ranges from 1% (no skew, uniform distribution) to 99.9% (very skewed). Note that the y-axis is set to log-scale to enhance readability. We can see that when the access is uniformly distributed (left-most cluster of bars) over all the keys, the QPS is similarly low for all the caching schemes. This is because in a uniform-distributed workload, every caching scheme has hardly any hit. In contrast, as the access becomes increasingly skewed, the performance of all the schemes rises, and `ac-key` outperforms `rocksdb` by 3.6%~57.1%, `pure-kv` by 5%~17.6×, and `pure-kp` by 7%~16.5×.

Varying range query ratio. We change the ratio of the point lookup and range query in the workload, ranging the range query ratio from 0% (pure point lookup) to 100% (pure range query) to create Fig. 9. In this figure, we see that as the range query ratio increases, the QPS decreases. This is because a range query has more potential storage I/Os and occupies more caching space. `ac-key` has similar result as `offline` and is better than `rocksdb` (by 1.1%~42.6%), `pure-kv` (by 30.4%~54.7%), and `pure-kp` (by 43.0%~52.8%).

When increasing the range query ratio from 0% to 20%, the performance of `rocksdb` becomes better and exceeds `pure-kv`. This is because KV Cache cannot serve range queries. In contrast, Block Cache supports both point lookups and range queries. However, the space efficiency of Block Cache is low which misses the opportunity to cache more useful entries. `ac-key` adaptively combines Block Cache, KV Cache, and KP Cache and delivers the best performance.

Varying value size. We try different value sizes ranging from 50B to 200B (Fig. 10). As the value size increases, the performance of all caching schemes decreases. This is because larger value size incurs more storage I/O overhead per each key being read. `pure-kv` performs better than `pure-kp` at small value but is exceeded by `pure-kp` as the value size increases. This is because the total number of keys can be cached for `pure-kv` decreases as the value size increases, hence the performance of `pure-kv` becomes not as good as that of `pure-kp`. `rocksdb` still performs better than `pure-kv` and `pure-kp`, as half of the requests are range queries that cannot be served by the KV or KP Caches. `ac-key` performs close to `offline`, and constantly better than `rocksdb` (by 5.9%~22.4%), `pure-kv` (by 41.4%~83.6%), and `pure-kp` (by 44.5%~96.0%) because of the use of the hierarchical adaptive caching in adjusting the size of each component.

CPU Utilization Comparison. With the default settings (§5.1), we record the CPU utilization by the Linux native `time` command and plot them in Fig. 11. The QPS is also plotted to better illustrate the trade-off. We can see that `rocksdb` consumes less CPU resource than the other schemes (`ac-key`, `pure-kv`, `pure-kp`, and `offline`) because they all use Point Cache and thus need to calculate the hash value of *every* key inserted to check if they were cached. We can also observe that although `ac-key` has extra operations to adapt the size of caching components, the CPU utilization is not increased significantly comparing with `pure-kv`, `pure-kp`, and `offline`. Besides, `ac-key` performs close to `offline` and is better than `rocksdb`, `pure-kv`, and `pure-kp`.

5.3 Adaptive Adjustment in AC-Key

To verify the adaptive adjustment process of AC-Key, we construct a workload with two phases: 1 million range queries with random starting key, then 2 million random point lookups. We plot the size of the caching components – Block, KV, and KP Caches – to show the direct evidence of the adaptation process (Fig. 12 top figure). Besides, we also compare the real-time QPS of `ac-key` and `offline` (Fig. 12 bottom figure).

We can see from the top figure of Fig. 12 that during the first 1 million queries, the sizes of the KV and KP Cache are reduced to zero to maximize the Block Cache since they cannot serve range queries. When the workload changes from pure range query to pure point lookup after the first 1 million queries, the Block Cache shrinks sharply, and the KV and KP Cache start to grow. This is because Point Cache (KV and KP Cache) are more space-efficient in caching point lookups, so the HAC algorithm adjusts in favor of the Point Cache (including both the KV and KP Caches). The KP Cache grows faster than the KV Cache at the beginning because every entry is first cached in the KP Cache, and only a small amount of "hot" KVs with a second access will be migrated to the KV Cache. At the beginning of the second phase, both KV and KP Cache grow as they are "stealing" space from the Block Cache. After the size of the Block Cache declines to almost zero, the KV and KP Cache start to compete with each other for space, and it is when KP Cache starts to shrink. The size of the KP and KV Cache finally converges to 19% and 80% of the total cache size. In different workload settings, the Block, KP, and KV Cache will stabilize into different ratio.

`ac-key` is adaptive and can adjust the size of the caching components based on the workload. We also run the `offline` scheme, which tries to find the best fix-sized configuration. However, such one-size-fit-all configuration is not tailored for the special workload of each phase, thus has inferior performance than `ac-key` in each phase: `ac-key` is 32%~66% better in the range query phase, and 2%~20% better in the point lookup phase after convergence (bottom figure in Fig. 12).

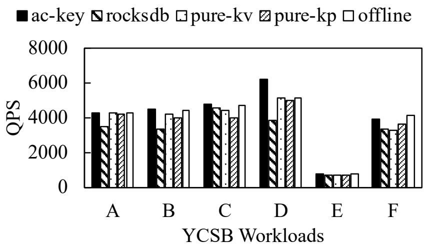

Figure 13: Macro-benchmark YCSB Evaluation.

Table 2: Average Write Latency (μs) and Regression.

Workload	A	B	C	D	E	F
RocksDB	242.8	238.0	N/A	21.7	32.8	28.6
AC-Key	241.1	241.4	N/A	22.7	33.5	26.7
Regression	-0.7%	1.4%	N/A	$\boxed{4.9\%}$	2.0%	-6.8%

5.4 Macro-benchmark YCSB Evaluation

We also use six workloads in YCSB [15] to further verify the performance of our design in near-production workloads. As can be seen in Fig. 13, the overall QPS of `ac-key` is higher than `rocksdb` (by 3.6%~59.9%), `pure-kv` (by 0.1%~20.7%), and `pure-kp` (by 1.2%~25.2%).

We also measure the regression of write performance of AC-Key from RocksDB (Table 2) and find the regression is below 5%. This shows that `ac-key` does not incur significant overhead on the write operations while improving the overall performance.

5.5 Sensitivity on Parameters

Using the default setting in §5.1, we range the learning rate k in the adaptive algorithm (see §4.3) from 1K to 10M, i.e. (1K, 10K, 100K, 1M, 10M). The fluctuation of the QPS is within 3.9%, ranging from 1461 to 1520 operation/s. We also test the ghost cache turnoff threshold θ (§4.3.3) from 0%, 5% , $\cdots$, 30%, and the QPS stays nearly constant (1418~1459, varying within 2.8%). As the two parameters do not have a significant impact on the result, we set their default values as $k = 100K$ and $\theta = 5\%$.

6 Conclusion

Caching is one of the essential techniques to improve the read performance of LSM-tree-based key-value stores. We investigate three different types of entries being cached, namely block, KV, and KP, and incorporate them into one integrated cache. We propose a Hierarchical Adaptive Caching (HAC) scheme to dynamically adjust the size of the block, KV, and KP caching components. To deal with the heterogeneous costs and benefits of the cached entries, we leverage a novel caching efficiency factor to aid the size adjustment among caching components and the eviction decisions within each caching component. We implement the proposed AC-Key by modifying RocksDB. Evaluations show that AC-Key improves the read performance of default RocksDB by up to 57.1% without significant impact on write performance.

POSH: A Data-Aware Shell

Deepti Raghavan Sadjad Fouladi Philip Levis Matei Zaharia
Stanford University

Abstract

We present POSH, a framework that accelerates shell applications with I/O-heavy components, such as data analytics with command-line utilities. Remote storage such as networked filesystems can severely limit the performance of these applications: data makes a round trip over the network for relatively little computation at the client. Reducing the data movement by moving the code to the data can improve performance.

POSH automatically optimizes *unmodified* I/O-intensive shell applications running over remote storage by offloading the I/O-intensive portions to proxy servers closer to the data. A proxy can run directly on a storage server, or on a machine closer to the storage layer than the client. POSH intercepts shell pipelines and uses metadata called *annotations* to decide where to run each command within the pipeline. We address three principal challenges that arise: an annotation language that allows POSH to understand which files a command will access, a scheduling algorithm that places commands to minimize data movement, and a system runtime to execute a distributed schedule but retain local semantics.

We benchmark POSH on real shell pipelines such as image processing, network security analysis, log analysis, distributed system debugging, and `git`. We find that POSH provides speedups ranging from 1.6× to 15× compared to NFS, without requiring any modifications to the applications.

1 Introduction

The UNIX shell is a linchpin in computing systems and workflows. Developers use many tools at the command-line level for data processing [33], from core `bash` utilities, including `sort`, `head`, `cat` and `grep` to more complicated programs such as `git` [22], ImageMagick [30] and FFmpeg [4]. Network security engineers use shell pipelines to find potential patterns in gigabytes of logs. The shell's continued importance over many decades and generations of computing systems shows just how flexible and powerful a tool it is.

The UNIX shell, however, was designed in a time dominated by local and then LAN storage, when file access was limited by disk access times, such that the overhead of network storage was an acceptable trade-off. Today, however, solid-state disks have reduced access times by orders of magnitude. At the same time, networked attached storage, especially for the enterprise, remains extremely popular [9, 57, 60]. Mounting filesystems across the wide area could incur tens of milliseconds of latency. Furthermore, many applications use wide area storage systems, via cloud blob storage [25, 54] or cloud-backed filesystems [7, 48, 50, 51, 58].

Running I/O-intensive shell pipelines over the network requires transferring huge amounts of data for little computation. For example, consider generating a `tar` archive on NFS. The `tar` utility effectively copies the source files and adds a small amount of metadata: the server reads blocks and sends them over a network to a client, who shifts their offsets slightly and sends them back. NFS mitigates this problem by offering compound operations [29] and server-side support for primitive commands such as `cp` [41]. However, something as simple as `tar` requires large network transfers.

The result of these changing performance trends is that network transfer is an increasingly large overhead on shell scripts. For example, unzipping a dataset of size 0.5 GB with `tar -x` over NFS within a cloud datacenter takes 7× longer than on a local disk. While intra-datacenter networking is fast, it is not as fast as a local flash drive. Some workflows are so slow over the network that they are effectively unusable: running `git status` on the Chromium repository [24] takes 2 seconds locally, but if the repository is stored in a nearby datacenter, it takes over 20 minutes.

The underlying performance problem of using the shell with remote data is locality: because the shell executes locally, it must move large amounts of data to and from remote servers. Data movement is usually the most expensive (time and energy) part of a computation and shell workloads are no exception. Near-data processing [1, 5, 14, 47, 52, 59] can reduce data movement overheads. Data-parallel processing systems such as Spark [61], stored procedures in SQL databases [43, 44], and native data structures in key-value stores such as Redis [40] all bring computation closer to the data. However, many of these systems require applications to use their APIs: they can supplement, but not replace shell pipelines.

To address the shell performance problem of data locality, this paper proposes POSH, the "Process Offload Shell", a system that offloads portions of *unmodified* shell commands to *proxy servers* closer to the data. A proxy server can run on the actual remote fileserver storing the data, or on a different node that is much closer to the data (e.g., within the same datacenter) than the client. POSH improves shell-based I/O workloads through three techniques. First, it identifies parts of complex pipelines that can be safely offloaded to a proxy server. Second, it selects which candidates run on a proxy, in order to minimize network data movement. Finally, it executes the pipeline across an underlying runtime, stitching together the distributed computations while maintaining the exact output semantics expected by a local program. Correctly and efficiently implementing these three techniques has three principal challenges:

1. Correctly understanding the semantics of shell command-line invocations in order to deduce which files each command in the pipeline accesses and determine which

commands can be offloaded.

2. Distributing the entire pipeline across different machines to minimize overall data movement, based on the "closest" execution environment (client or proxy) for each command and its file dependencies.
3. Automatically parallelizing pipelines that access many files while ensuring the output maintains a sequential execution order.

In order to address the challenge of understanding the semantics of shell command-line invocations, POSH uses *annotations*. POSH's key insight is that many shell applications only read and write to files specified in their command-line invocation, so POSH can deduce which files a command accesses from a model of the application's argument structure. Annotations store a model of each command's (e.g., `cat`'s or `grep`'s) semantics and arguments, stored locally at the client's shell. These annotations, inspired by recent proposals to annotate library function calls for automatic pipelining and parallelization [46], assign *types* to the possible arguments of command-line applications. At runtime, POSH can parse which arguments are files and use the underlying storage configuration to determine where those files are located.

Next, POSH must schedule the entire pipeline across the execution engine in a way that reduces data movement as much as possible. However, POSH does not know explicitly how much data is transferred across each pipe in the entire pipeline. If the output of `grep` or `awk` is piped to another command, POSH cannot know how much data will travel over the pipe without running the command. POSH constructs a DAG representation of the entire command and associated metadata and applies a greedy algorithm, that estimates how much data travels across each pipe, to determine the best way to schedule the DAG.

Finally, POSH further improves performance when it knows it can split commands into multiple data-parallel processes. POSH ensures that each split parallel invocation retains the same argument structure as the original command and that the output is stitched together in the correct order. It does so by using information about each argument stored in the annotation to safely split the command. POSH's execution engine serializes output from any parallel processes in the correct order, before writing to the final destination (e.g., client `stdout`).

This paper makes the following contributions:

1. **An expressive annotation language for shell commands**: Annotations capture the dominant grammar of most shell commands and summarize which inputs to command invocations are files as well as semantics to safely split command invocations across inputs.
2. **A greedy scheduling algorithm that reduces data movement for unmodified shell pipelines**: POSH's scheduling mechanism decides which parts of pipelines can be offloaded to proxy servers closer to the data and which parts of pipelines can be parallelized, while preserving the correctness of the output.

We evaluate POSH on a variety of workloads, including an image processing pipeline that creates thumbnails, a `git` command workflow on the Chromium repository, and log processing pipelines from research project analysis. On one hand, for a more compute-heavy log analysis application that includes a data transfer of one large file, POSH provides a 1.6× speedup over running `bash` over NFS. In the best case, for a `git` command workflow, POSH provides a 10-15× speedup over running `bash` over NFS, even when the client and the server are in the same datacenter. Section 8 contains the set of full results.

2 RELATED WORK

Near-data computing (NDP). POSH draws upon previous work that "ships computation closer to the data." Previous approaches to NDP, surveyed in [5], focus on two paradigms: PIM (processing in-memory), where compute is co-located with memory [28, 45, 47], or ISC (in-storage computing), where processors or accelerators are co-located with persistent memory or storage [1, 14, 52, 55, 59]. POSH follows the second approach and pushes portions of arbitrary shell applications to *proxy servers*, compute units running on general-purpose servers, either co-located with storage devices or closer to storage devices than the client.

Barbalace et al. [5] propose an entire operating system architecture for NDP with features such as locality-driven scheduling. Various systems focus on offloading database query computation into smart SSDs [14] or FPGA accelerators [32, 52, 59]. The Metal FS framework [52] allows users to run reusable compute kernels, that perform operations such as encryption or filtering, on FPGA accelerators near the storage. They can be programmed with standard shell syntax such as pipes to chain many near-data operations together. Seshadri et al. [55] propose an extensible programmable SSD interface where users can push specific pieces of functionality, e.g., to run filesystem appends, to the SSD. Finally, many databases allow users to write SQL queries to run as stored procedures [43, 44]. Similarly, many key-value stores, such as Redis [40], Splinter [39] and Comet [21] support extensibility with user-defined functions. POSH, in contrast, focuses just on a locality-aware shell, to enable the extensibility of remote filesystems. POSH pushes computation to proxy servers (that do not require custom hardware), without forcing the user to explicitly decide which operations should be offloaded.

NFS Optimizations and filesystems. NFS, starting in version 4.2 [29], offers support for some server-side operations, such as server-side copy [41]; however, NFS does not have support for offloading arbitrary programs. NFS allows batching operations via compound operations [29]; Juszczak [37] describes techniques to batch writes. vNFS [10] offers a new API for NFS that supports batching and vectorizing filesystem operations. This technique reduces the latency of running commands such as `tar` over NFS, but still requires moving the data across the network, instead of pushing the computation to the data. CA-NFS [6] attempts to improve application performance in a multi-tenant scenario by adaptively scheduling certain client operations to run asynchronously during periods of high system load. POSH currently does not handle multi-tenancy, but could use similar methods to factor system load to adapt scheduling decisions. BlueSky [58] proposes running proxy servers in the cloud that serve data from slower blob storage; these proxy servers can expose NFS access to the data. POSH, in contrast, uses proxy servers to push application code.

Distributed execution engines. Distributed cluster computation systems such as Spark [61], MapReduce [13], Dryad [31], Hadoop [19] also automatically parallelize computation on large datasets, but require that users follow a specific API. Systems such as gg [17] and UCop [15] take "everyday applications," such as software compilation, unit testing and video encoding, and automatically parallelize them in the cloud. These systems focus on compute-intensive workloads, not I/O-intensive, and do not necessarily make decisions about scheduling computation to preserve data locality, unlike POSH.

Code offloading and type systems. Many systems enable *code offloading*, to implement distributed applications on many mobile devices that can benefit from computation on nearby servers [8, 26, 35]. Some of these systems require specific programming language constructs to offload processes and partition programs [8, 27, 34–36]. Recently, Pyxis [11] optimizes database applications by *automatically* offloading procedures to run at the database server. It uses program analysis to determine what to offload, while POSH uses per-command annotations. Split Annotations [46] proposes using per-function annotations to determine how to split and pipeline function calls in data analytics workloads, to enable cross-function cache pipelining and parallelization. These annotations are fundamentally different from POSH's shell annotations: POSH's annotations attempt to understand the command-line semantics of shell commands, which tend to have a much more varied structure than function calls.

Command-line tools. Many command-line tools allow users to automatically parallelize and execute shell commands remotely. `rsh` [3] enables remote execution of shell commands. `pssh` [12] allows users to execute commands over SSH in parallel on other machines. GNU Parallel [56] splits input arguments and executes jobs over these inputs in parallel across one or more machines. POSH also parallelizes commands on remote machines, but *automatically* decides how to offload and schedule commands so users do not need to explicitly program when to offload code. POSH does not rely on SSH access to the storage servers and can be used on top of a service such as NFS, where remote shell access may be prohibited.

3 SYSTEM OVERVIEW

POSH consists of three main components: a shell annotation interface (§4), a parser and scheduler (§5), and an execution engine (§6). This section briefly describes each component and how they link together, pictured in Figure 1.

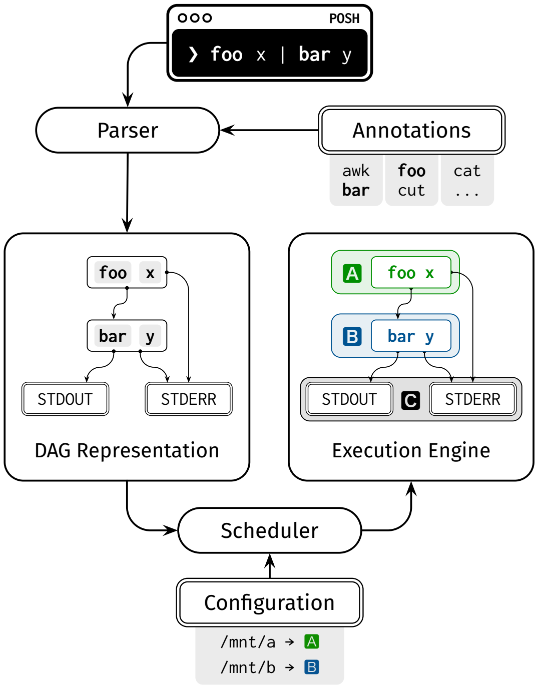

Figure 1: In POSH's main workflow, a shell command is passed to the parser, which uses the annotations to generate and schedule a DAG representation of the command. The DAG includes which machine to run each command on, A, B, or C (client) here. The execution engine finally runs the resulting DAG.

Annotation interface. POSH, on bootup, requires users to provide a file containing a list of annotations for any commands they want POSH to consider offloading. Annotations are written *once per command*, e.g., once for `grep` or once for `awk`, so POSH can then accelerate shell pipelines that combine these commands with standard constructs, such as anonymous pipes. We envision that developers can share annotations for popular programs, so users do not necessarily need to write their own annotations; crowdsourcing annotations has seen success with TypeScript [2, 42, 49].

Parser and scheduler. Given a shell program, the POSH parser turns each pipeline (each line of the program, potentially consisting of several commands combined by pipes and redirects) into a directed acyclic graph (DAG). This graph represents the input-output relationship between commands, the standard I/O streams (`stdin`, `stdout` and `stderr`) and redirection targets, as shown in Figure 1. POSH then parses each individual command and its arguments using the corresponding annotation and completes the DAG by including additional input and output dependencies of the pipeline.

The parser finally runs a scheduling algorithm on the DAG and assigns an execution location to each command in the pipeline. In order to do this, the parser requires extra *configuration information* that specifies a mapping between each mounted client directory and the address for a machine running a proxy server for the corresponding directory (if any).

Execution engine. After POSH has parsed and scheduled a shell pipeline, it executes the command across the underlying execution engine. The execution engine consists of one or more proxy servers, each associated with a specific remote client mount, either at the storage server, or in a nearby node with access to the same data. Additionally, one "proxy server" runs at the client to execute any local computation. POSH ensures that the entire command looks like it has been running locally, even if processes had been offloaded to proxy servers.

4 Shell Annotations

POSH must correctly understand the semantics of shell commands, which can be challenging because of the wide range of syntax allowed by command lines. In this section, we discuss the motivation and design of POSH's shell annotation layer.

4.1 Motivation for Shell Annotations

In order to schedule and execute shell pipelines in a way that minimizes data movement, POSH must understand the semantics of command-line pipelines. Concretely, annotations must reveal enough information that allows POSH to determine:

1. Which commands can be safely offloaded to proxy servers.
2. If any commands in the pipeline filter their input.
3. If any commands can be split in a data-parallel way into multiple processes.

Consider a simple pipeline: `cat A B C D | grep "foo" | tee local_file.txt`. POSH could try to offload any of the three commands: `cat`, `grep`, or `tee`. To determine which commands are safe to offload, POSH must understand which files (if any) `cat`, `grep` and `tee` access, and where these files live. Therefore, POSH must determine which arguments to the three commands represent file paths. However, outside of the program, all of these arguments are seen as generic strings. For example, consider the following four commands:

```
cat A B C D | grep "foo"
tar -cvf output.tar.gz input/
tar -xvf input.tar.gz
git status
```

The `cat` command takes in four input files, while the argument to `grep` is a string. The second command, `tar -cvf`, takes an output file argument followed by `-f`, followed by an input file argument (not preceded by a short option). The third command, also `tar`, takes an input file argument followed by `-f` and implicitly takes its output argument as the current directory. Finally, `git` also implicitly relies on the current directory as a dependency. Without a formal way to model the argument structure for each command, POSH could not determine the file dependencies for each command.

Secondly, in order to produce an execution schedule that reduces data movement, POSH needs to know the relationship between the inputs and outputs of a command. In the `cat | grep` example, if the file argument to `cat` is remote, to minimize data movement, POSH cannot *just* offload the `cat` command. Since `cat` usually produces the same amount of output as input, but `grep` usually filters its input, POSH must also offload `grep`.

Finally, suppose `cat` had multiple file arguments, but these files lived on different mounts (e.g., a pipeline that processes logs from different servers). POSH could not safely offload this command to a single proxy server, as the proxy server may not have access to all the mounts. However, many command-line programs perform map functions over each line in the file in sequence. For example, `cat` prints all lines to the output, and `grep` filters the input line by line. Therefore, these commands can be split into processes across their input files and then offloaded to different proxy servers. However, parallelization is not safe for all commands: `wc`, for example, "reduces" the input. Without a formal model for the command's semantics, POSH could not make optimal scheduling decisions.

4.2 Annotation Interface

Annotations need enough information to allow POSH to deconstruct, parse and schedule each command. Annotations contain two types of information: argument-specific and command-specific information. First, they contain a list of arguments along with a type assignment for each argument. Second, they contain information relevant to parsing the entire command line, either semantic information relevant to scheduling, or custom parsing options. The annotation interface is inspired by the POSIX conventions for command-line arguments and their GNU extensions [23], which are followed by a multitude of UNIX utilities. If a program does not follow these conventions, POSH may not be able to determine how to accelerate it. We describe both parts of the annotation in turn.

4.2.1 Argument-Specific Information

POSH supports the following classes of command-line arguments:

1. A single option with no arguments (e.g., `-d` or `--debug`).
2. An option, followed by one or more parameters (e.g. `-f <file>`).
3. A parameter without a preceding option (e.g. the arguments in `cat A B C D`).

The annotations must specify the following information for each argument that has associated parameters:

1. The **`short`** or **`long`** option name: This is only relevant for arguments preceded by options.
2. The **`type`**: `input_file`, `output_file`, or `string`.
3. The **`size`**: `1`, `specific_size(x)`, or `list` (for variable size).
4. If the argument is **`splittable`**: If an argument has multiple parameters, the **`splittable`** keyword specifies that the command can be split in a data-parallel way across this argument (this is only allowed for up to a single argument).

The above format applies to many popular UNIX commands and core utilities. For example, the annotation for `cat` may look like:

```
cat:
  - PARAMS:
    - type:input_file,splittable,size:list
```

This specifies that `cat` takes in one or more input files, and it can be split across its inputs.

4.2.2 Command-Specific Information

Annotations contain information relevant to the semantics of the entire command, specified by the following keywords:

- **`needs_current_dir`**: Whether the command implicitly relies on the current directory.
- **`splittable_across_input`**: Whether the command can be split *across its standard input*. In the example pipeline, if the `cat` is split into separate `cats`, POSH would also need to split the `grep` command into separate commands to truly take advantage of parallelism.
- **`filters_input`**: Whether the command is *likely* to have a smaller output than input.
- **`long_arg_single_dash`**: Most programs use double dashes before long arguments (e.g. `--debug`), but some programs require long arguments be preceded by a single dash. (e.g. `-debug`).

4.2.3 Annotation Conflicts

Some commands can be invoked with flags whose behavior changes depending on which other flags are present. For example, the annotation for a `tar` invocation used to *create* an archive could be:

```
tar: [filters_input]
  - FLAGS:
    - short:c
    - short:z
  - OPTPARAMS:
    - short:f,type:output_file,size:1
  - PARAMS:
    - type:input_file,size:list
```

However, developers commonly invoke both `tar -x` and `tar -c`, to extract and create a tarball, respectively. The assignment for the `-f` flag conflicts; it would be an `input_file` in the `-x` case, but an `output_file` in the `-c` case. POSH supports this by allowing multiple annotations per command. In particular, a client can include one annotation *per type of invocation* for every binary, and POSH will try all annotations until it finds one that fits the current invocation.

4.3 Correctness and Coverage

Potential mistakes. POSH depends on correct annotations for optimal execution: if the annotations are incorrect in some way, POSH does not make guarantees about the correctness or the performance of the resulting execution. Annotations with incorrect type semantics (assigning an argument with `str` instead of `input_file`) or parallelization semantics (specifying a command is **`splittable`** when the command needs all input files concurrently) could cause execution errors. POSH might schedule the command on a machine without access to a necessary file, or incorrectly try to split the command into parallel workers. Annotations might not include potential optimization information, by omitting that a command filters its input or it can be parallelized. In this case POSH might not make the optimal scheduling decision, but execution will still be correct.

Finally, a command, such as `awk`, could either filter or increase its input depending on its invocation. `awk` could include multiple annotations for each separate program string, which separately specify or omit the **`filters_input`** keyword.

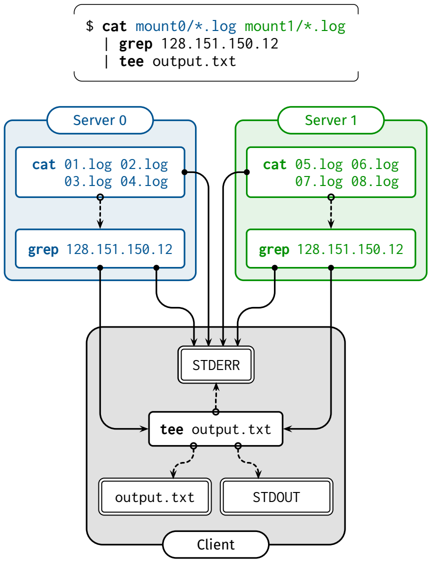
Mitigations. In practice, we expect that a community of developers would maintain and crowdsource a set of "verified" annotations; other annotation-based systems such as Typescript [42] make this assumption. To prevent incorrect type semantics, POSH could use a sandbox on top of the filesystem interface that checks if the program only reads and writes to files specified by the annotation, and crash the execution if the program accesses a file outside of its dependency list [17, 20]. Finally, future work could explore profiling commands to automatically deduce whether command invocations produce less, more or the same amount of input data as output data.

Coverage. The POSH interface covers the command-line syntax for a wide range of command line programs, as specified by the GNU command-line standard syntax and extensions [23]. Along with the source code of POSH, we provide annotations for 21 different commands, which cover a wide range of unmodified shell applications used in our evaluation (§7).

However, POSH will not cover *all* parsing options for all programs. While POSH can interpret wildcards ("*") when listing file paths, it will not do any custom parsing to list paths. For example, `ffmpeg` allows users to provide input files (input frames) based on a pattern, such as "`%04d.jpg`", which corresponds to all files between `0000-9999.jpg`. POSH will not parse commands whose file dependencies are specified *dynamically*, via a pipe: e.g., "`find . -type -iname "*.jpg" | xargs -i mogrify -resize 100x100`" could be used to dynamically list all `jpg` files and resize them with `ImageMagick`. Since POSH does not know what the file inputs to the `mogrify` command are upfront, it cannot decide whether to offload the `mogrify` command or not.

5 POSH's Parser and Scheduler

This section discusses how POSH solves two challenges in executing shell commands efficiently across a set of proxy servers: (1) scheduling pipelines to minimize data movement (§5.2) and (2) correctly parallelizing pipelines (§5.3). We begin by discussing how POSH constructs an intermediate program representation of the command that allows it to



```
$ cat mount0/*.log mount1/*.log
  | grep 128.151.150.12
  | tee output.txt
```

Figure 2: DAG representation of a simple shell program that uses `cat` and `grep` to analyze logs across different mounts. POSH uses its scheduling and parallelization mechanisms to offload the `cat` and `grep` to each server.

effectively solve these two problems.

5.1 POSH's Program Representation

POSH needs a program representation that allows the runtime to see every data source (file that is read), data sink (output file that is written to), and flow (pipe) that connects two commands within the pipeline. Understanding which files commands read and write allows POSH to determine the execution location closest to the data for each command. Understanding the connections in the pipeline allows POSH to see how data flows between commands and allows POSH to preserve dependencies when parallelizing nodes.

POSH represents parsed shell pipelines as directed acyclic graphs (DAGs), which contain *nodes* and *streams*. Nodes represent single commands (command nodes) along with each of their arguments, and parsed annotation metadata (argument types, if it is **`splittable`**, and if it filters its input). Nodes also represent sources and sinks in the entire pipeline: reading from `stdin` (read nodes) or writing to `stdout` or a file (write nodes). Streams represent the data flows in and out of these nodes.

Given a shell pipeline, POSH constructs a DAG that models the dependencies between commands (UNIX pipes) and standard I/O streams (`stdin`, `stdout` and `stderr`). POSH then builds a custom argument parser for each command from the annotations, to determine which arguments actually appear in each command's invocation and what their corresponding types are. For example, if a `tar -c` invocation contained the `-f` argument, POSH knows the string following `-f` is an `output_file`.

Figure 2 shows an example DAG generated for the simple program discussed in §4.1, that runs `cat` and `grep` on files stored in different mounts and pipes the final output to `tee`.

Algorithm 1 POSH Scheduling Algorithm

```
function SCHEDULE(dag)
  for node ∈ dag.GETNODES do
    if CONSTRAINT(node) != NULL then
      node.location ← CONSTRAINT(node)
  for source_node ∈ dag.GETSOURCES do
    path ← GETPATHTOSINK(dag,source_node)
    sink_node ← path[path.length() - 1]
    if source_node.location == sink_node.location then
      for node ∈ path do
        if node.location == NULL then
          node.location ← source_node.location
    else
      $min\_weight \leftarrow 1$
      edges ← { }
      for (node,next) ∈ path do
        if ISFILTERNODE(node) then
          $min\_weight \leftarrow min\_weight/2$
        edges[(node.id,next.id)] = $min\_weight$
      for (node,next) ∈ path do
        if node.location == NULL then
          if edges[(node.id,next.id)] ≥ $min\_weight$ then
            node.location ← source_node.location
          else
            node.location ← sink_node.location
        else if node.location != CONSTRAINT(node) then
          node.location ← CLIENT
```

POSH schedules and parallelizes the workload by first splitting the command into separate `cat` and `grep` commands that run at each proxy server and then merging the outputs at the client. Sections 5.2 and 5.3 discuss these steps in turn.

5.2 Scheduling

POSH's scheduling algorithm seeks to minimize data movement, as it assumes that in scenarios where the computation is I/O bound rather than CPU bound, minimizing data movement will reduce end-to-end latency. However, POSH does not know how much data a command will produce prior to execution. We describe the exact setup of the problem and POSH's greedy algorithm that uses information from POSH's annotations to estimate how to minimize data movement.

Problem setup. The POSH scheduling algorithm, summarized in Algorithm 1, takes the DAG representation of the command discussed in §5.1 and assigns an execution location to each node. POSH must pay attention to two concerns: *constraints* on where certain nodes can execute and the *number of bytes transferred across edges* in the DAG. The first concern arises because certain proxy servers might not be able to execute certain nodes as they do not have access to all the necessary files. The second concern arises because POSH seeks to minimize the number of bytes transferred between two locations across the network. Concretely, consider a `cat` node (operating on a remote file) that pipes its output to a `grep` node, that filters

Algorithm 2 POSH Scheduling Algorithm Helper Functions

```
 1: /* Returns constrained location assignment for node, if any. */
 2: function CONSTRAINT(node)
 3:   loc ← NULL
 4:   if ISREADNODE(node) then
 5:     loc ← GETREADLOC(node)
 6:   else if ISWRITENODE(node) then
 7:     loc ← GETWRITELOC(node)
 8:   else if ISCMDNODE(node) then
 9:     deps ← Set()

```

its input, which in turn writes its output to `stdout` on the client. To schedule the least data movement across the network, POSH should offload both the `cat` and `grep` commands: in the path through the `cat`, `grep` and the `stdout` nodes, the minimum cut (edge with least data transferred) occurs after `grep`.

Step 1: Resolving constraints on each node. Algorithm 2 summarizes the helper functions for the scheduling algorithm, including a function, `Constraint`, that determines whether a node in the DAG has any constraints on execution location (lines 1-16). Read and write nodes are assigned to the location of their input or output data streams (lines 4-7). Command nodes that access files on a single mount are greedily assigned to execute on the proxy server corresponding to that mount (lines 14-15). Finally, command nodes that access files from multiple different mounts are always assigned to execute on the client (lines 12-13). Only the client has access to all mounts; by default, proxy servers only serve requests for a single mount. We discuss an optimization to this decision in §5.3, for special cases where the command can be parallelized.

Step 2: Minimizing data transfer. In Algorithm 1, after assigning locations to nodes with constraints (lines 1-4), POSH assigns locations for the remaining command nodes. POSH first iterates through all the source nodes of the graph, traces the path from each source to a sink node with the `GetPathToSink` helper function defined in lines 18-19 of Algorithm 2, and considers each path individually. Each path is guaranteed to be linear because each node in the graph effectively has one child. POSH assumes most data transfer occurs along `stdout` streams: even though command nodes have two children (one edge to `stdout` and one to `stderr`), POSH only pays attention to `stdout` connections. Read nodes can have one child by definition, and write nodes are sinks, so have no children.

Within a path, when the source and sink nodes have the same location, scheduling is simple: all nodes along the path from the source to the sink are assigned that location (lines 8-11). However, when the source and sink have different locations, the scheduler must find the edge along which cross-location data transfer should occur: to minimize data transfer, this should be the edge where the *least* data flows. POSH first iterates along each edge in a path and assigns relative weights according to heuristics (lines 13-18). POSH assumes nodes produce the same amount of output as input, or filters input by half (lines 16-18). The helper function `IsFilterNode` called on line 16 returns true for commands whose annotations indicate that they filter their input from the **`filters_input`** keyword. This heuristic, that filter commands halve their input, obviously does not fit all cases. Some filters, such as `wc`, usually produce much less than half the input. To find the minimum cut, only the relative ordering of edges matters, rather than the absolute weight values.

POSH then iterates along each path and schedules each unassigned node's location to be either the source location or the sink location, depending on if the node is before or after the minimum cut edge. For example, if a path contains `cat`, `grep`, and `cut`, and writes to `stdout` on the client, POSH determines the minimum weight edge is in between `cut` and the `stdout` write node. When there are conflicting assignments from nodes appearing in two different paths, POSH schedules the node on the client (lines 25-26).

5.3 Parallelization

The second challenge POSH resolves is determining when commands are safe to parallelize and then guaranteeing correct execution while parallelizing nodes. After determining a command is safe to split, correctly executing the command in a data-parallel way requires: (1) splitting the command only across the argument that can be split while preserving the other arguments and (2) stitching the outputs of the command back together in the correct order.

Determining which nodes to parallelize. POSH can automatically parallelize nodes that are safe to parallelize across the files they access, or across their input edges. In the first case, to parallelize the command `cat -n A.txt B.txt C.txt`, POSH needs to know that the file arguments are `A.txt, B.txt` and `C.txt`, and that the "-n" flag must be preserved. POSH uses the per-argument **`splittable`** keyword in an annotation, which indicates that the command can be split across a particular argument (here, the file argument). In the above example, POSH would replace the single node for `cat` with three nodes, each with the `-n` flag and one of `A.txt, B.txt` or `C.txt`.

In the second case, POSH allows nodes to also be parallelized *across their input streams*. Concretely, if the `cat` above piped its output to `grep`, there would not be much performance benefit to parallelizing `cat`, unless POSH also split `grep` across the three input `cat` nodes. POSH determines which commands this parallelization is safe for via the **`splittable_across_input`** keyword. The annotation for `grep` would include this keyword, so POSH would replace the `grep` node with three `grep` nodes for each `cat` node. This is not safe for commands that reduce or merge the input such as word count (`wc`): since the annotation for `wc` would not include this keyword, POSH would ensure that the output of the prior commands are merged before executing `wc`.

Splitting across mounts. When POSH splits nodes that can be parallelized, it will inherently split commands that read and write to *different mounts*. This allows the scheduler to bypass the restriction in Algorithm 2, lines 12-13. If a single command accesses files in different mounts, but the command can be split, instead of assigning this node to run at the client, POSH will split it into multiple workers that run in parallel on different proxies. POSH by default parallelizes commands across machines, but within a single machine, the *maximum splitting factor* parameter determines the degree to which to split further. The default value is 1, but increasing the splitting factor to a value $s > 1$ causes POSH to split a command into s commands that each operate on $\frac{n}{s}$ sized chunks of the input files, where n is the number of files that the node accesses on a single machine.

Correctly preserving output order. In order to ensure that the output of the entire pipeline is correct, when POSH splits a command in parallel, it must ensure that any node that reads the output of this node now reads the output of the replacement nodes *in sequence*. When nodes execute, they process their inputs in sequential order, guaranteeing correct output order.

6 POSH CONFIGURATION AND EXECUTION

In this section, we discuss how to configure POSH and how POSH executes programs.

6.1 POSH Configuration

To understand how to setup and configure POSH, consider a client that has access to folders on two NFS servers, within a nearby datacenter. Each NFS administrator has agreed to allow a separate proxy server, that resides within the same datacenter, to access the same mounts on behalf of the client (via NFS).[1] To use POSH, each of the two proxy servers must run the POSH *server* program, which is configured with a list of client credentials mapped to the folder paths each client has access to (which the proxy servers themselves access via NFS). The client must run the POSH *client* program, which takes in a file containing the shell annotations, and a configuration file that specifies a mapping from locally mounted folders, to the addresses for proxy servers for those mounts. In the previous example, the client's configuration file would map each of the two mounted folders to the corresponding proxy server. Together, the client and the two proxy servers make up POSH*'s execution engine*, which can be used to execute any schedules POSH's parser creates.

6.2 Execution Engine

After the client schedules a shell pipeline, the execution engine can execute the DAG.

Setup Phase. First, the client divides the DAG into subgraphs that need to execute on different machines (including a subgraph that will execute on the client itself). The client handles setting up persistent connections with proxy servers for any pipes between DAG nodes assigned to two different machines. Finally, when all pipes are setup, the client sends a request to each proxy server to start executing their portion of the DAG.

Execution Phase. Once each proxy server receives a request to execute a subprogram DAG, it will first spawn all the nodes in the DAG corresponding to processes that need to be executed (e.g., `cat` or `grep`). To redirect I/O between processes, POSH spawns a thread for each redirection that needs to occur and copies the output from each node to the correct pipe, TCP stream or file. For nodes that have multiple inputs, nodes process these inputs sequentially. Nodes that send output to nodes with multiple inputs buffer the content until the receiver starts processing that node's output.

6.3 Implementation

POSH is implemented in about 12,400 lines of Rust code. POSH uses Rust's CLAP library [38] to build custom parsers for each command, based on the command's annotation, to find out which arguments are actually present in an invocation.[2]

7 METHODOLOGY

We evaluate POSH by measuring its performance impact over five unmodified I/O-intensive shell applications. This section describes our evaluation methodology: the applications, why they cover a broad range of I/O-intensive shell applications, and our experimental setups.

7.1 Applications

For each application, in our evaluation setting, we assume that all input data files and intermediate files live on a remote NFS mount, so POSH accelerates these applications by preventing unnecessary data movement. Some applications require writing the final output to `stdout` or a file on the client; we specify this on a per-application basis.

Ray-tracing log analysis. The first application represents a best-case workload for POSH: it is computationally light, can be parallelized, and its output is a tiny fraction of the data it reads. The application analyzes logs of a massively distributed research ray-tracing (computer graphics) system [18], to track a

[1] The remote fileserver itself can also run the POSH server program and act as a proxy server.

[2] The implementation of POSH is available at https://github.com/deeptir18/posh.

task (a simulated ray of light) through the path of workers it traversed. The analysis first cleans and aggregates each worker's log into one file with `cat`, `grep`, `head` and `cut`. It then runs `sed` to search for the path of a single ray (e.g., a straggler) across all the workers and stores the final output on a file at the client.

Thumbnail generation. The next application is CPU-intensive, but still produces output that is a tiny fraction of its input, and is highly parallelizable. The application uses ImageMagick [30] to generate thumbnails of size 10 KB for each image in a folder of about 1090 images, each about 4 MB large; the output thumbnails are also written to the remote mount.

Port scan analysis. The third application is computationally heavy, but not parallelizable, and involves data transfers of large files. ZMap [16] is a network scanning tool that performs Internet-wide scans of the public IPv4 address space. Network security researchers run the following shell application to analyze 40 GB subset of a full Internet scan of port `80`; the final output file is stored in the remote mount.

1. Clean the raw data with a program called `zannotate`.
2. Use a JSON processing tool, `jq`, to isolate the *IP* and *AS ID#* (Autonomous System ID) columns.
3. Use `pr` to merge the columns together.
4. Use `awk` to count the number of IPs per AS.

Distributed log analysis. The next application is a synthetic benchmark that models system administrators running analysis on logs across *different storage servers*, to search for an IP address within the access logs stored across different machines. It is computationally light, highly parallelizable, and the output is a tiny fraction of the input. This workload runs `cat` over all of the files and then filters for a particular IP with `grep` and writes the results back to the file stored locally at the client. Each of five storage servers contains approximately 15 GB of logs from the SEC's EDGAR Log File Data Set [53].

Git workflow. The final application, a `git` pipeline on the Chromium [24] repository, attempts to imitate a developer's `git` workflow and is extremely *metadata-heavy*. After rolling back the repository by 20 commits and saving each commit's patch, the workload successively applies each patch and runs three `git` commands: `git status`, `git add .`, and `git commit -m`.

7.2 Setup and Baselines

Baselines. For all workloads, we compare POSH to two NFS configurations, one with with synchronous operations (`rw,sync,no_subtree_check`) and the other with asynchronous operations (`rw,async,no_subtree_check`).

POSH configuration. For all experiments, unless otherwise specified, the POSH proxy runs on the same machine as the NFS server. The POSH client also mounts the NFS folder locally in case some computations must run on the client. Section 8.2.1 evaluates the impact of placing the proxy directly at the storage server versus on another machine.

Network settings. We focus on two network scenarios:

1. Client and server in the same Google Compute Platform (GCP) region (`us-west2`). The RTT and throughput between the two machines are 0.5 ms and 5-10 Gbps, as measured by `ping` and `iperf`.
2. Client in a university network (at Stanford) and server in a nearby GCP region (`us-west2`). The RTT and throughput between the client and server are approximately 20 ms and 600 Mbps.

Setup. GCP client, proxy, and storage machines are configured with 4 vCPUs, 15 GB of memory, and 10 Gbps egress network bandwidth (`n1-standard-4`); they run Ubuntu 19.04. The client at Stanford runs Ubuntu 18.04. All storage servers store data on regional persistent SSDs.

8 EVALUATION

Our evaluation seeks to answer several questions: *(1)* Can POSH accelerate end-to-end pipelines that use many different command-line tools to access remote data over NFS (§8.1)? *(2)* What is the best way to configure POSH (§8.2)? *(3)* Where do performance benefits come from (§8.3)?

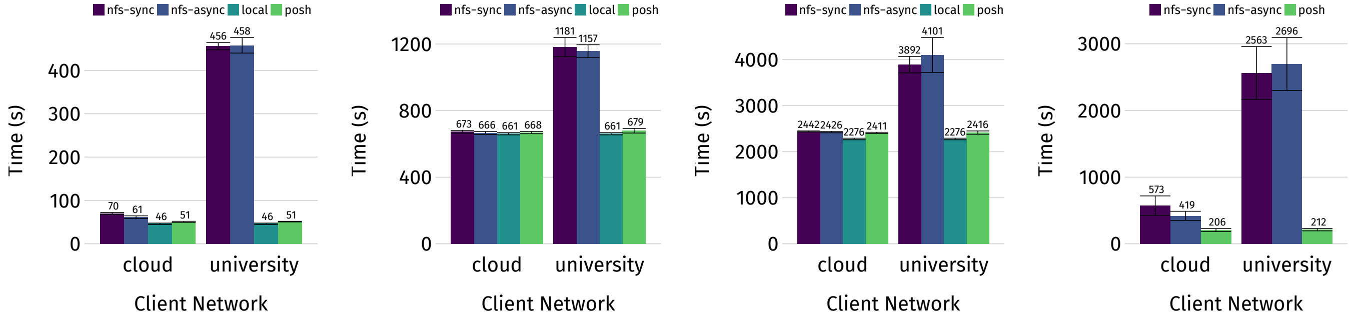
8.1 End-to-End Application Performance

For each workload described in §7.1, Figures 3 and 4 show the performance of POSH compared to `bash` over NFS for two network settings: one where the client is in the same GCP region as the storage server ("cloud") and one where the client is in a university network outside the datacenter ("university"). For `git`, Figure 4 only shows results for a client in the same datacenter.

Summary of all results. On the university-to-cloud network, POSH performs 8× better than `bash` over NFS on the ray-tracing workload, 1-2× better on the thumbnail generation and port scan analysis workloads, and 12.7× better on the distributed log analysis workload. On the cloud-to-cloud network, POSH outperforms `bash` over NFS for the `git` workload and distributed log analysis workload; however, POSH does not outperform `bash` over NFS on the other three applications, partially because these applications are more bandwidth than latency sensitive. We discuss each set of applications below.

Ray-tracing log analysis. This workload sees an 8× improvement on the university-to-cloud network and no improvement on the cloud-to-cloud network. The workload reads 6 GB of input from about 2000 files over NFS, and aggregates them into one 4 GB file, which is written back to NFS. The final output of `sed` on the aggregated file is much smaller (20 lines). POSH prevents 10 GB of data from being copied across the network unnecessarily. On the cloud-to-cloud network, both the overheads of separate filesystem requests (to open and read 2000 files) and the overheads of transferring data to the client are not as large.

Thumbnail generation. This workload sees a 1.7× improvement in the university-to-cloud setting and no improve-



(a) Ray-Tracing Log Analysis **(b)** Thumbnail Generation **(c)** Port Scan Analysis **(d)** Distributed Log Analysis

Figure 3: End to end latency of POSH on four applications, compared to NFS sync, NFS async and local execution time for two networks: one where the client is in a university network and one where the client is in the same GCP region as the storage server. The POSH proxy runs directly on the NFS server. POSH provides between 1.6-12.7× speedups in the university-to-cloud network compared to NFS. Using POSH from a client outside the datacenter results in about same latency as a client inside the datacenter using NFS, with barely any overhead over local execution.

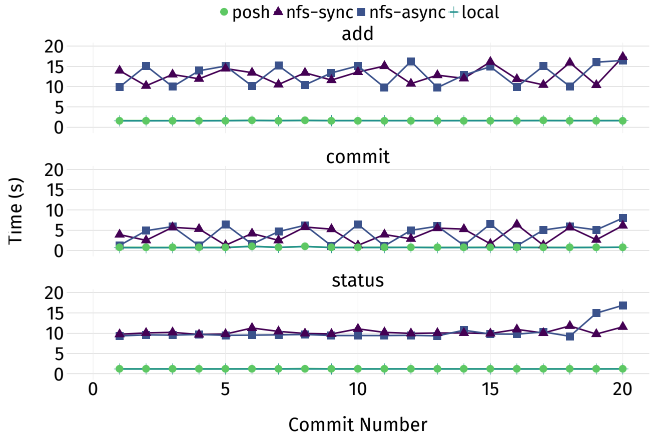


Figure 4: Average latency of 20 `git status`, `git add`, and `git commit` commands run on `Chromium` repo, of POSH compared to NFS and local execution, for a client in the same cloud datacenter as the storage server. POSH provides up to 10-15× speedups by preventing round trips for filesystem metadata calls.

ment in the cloud-to-cloud setting. Generating thumbnails with ImageMagick is computationally heavy: it takes 12 minutes to finish when running locally. While generating thumbnails produces a smaller input (12 MB of thumbnails vs. 15 GB of input images), in the cloud network, transferring 15 GB of data to the client will take about 12 seconds on a 10 Gbps connection. However, in the university-to-cloud setting, POSH attenuates the added delay from transferring data over a slower network.

Port scan analysis. The scanning analysis workload sees a 1.6× benefit with POSH in the university-to-cloud setting, but no benefit in the cloud-to-cloud setting. The scanning workload starts by processing one large 40 GB file with `zannotate` and writing the result back to NFS. This is more bandwidth than latency sensitive, as the application makes fewer filesystem requests across the network than the ray-tracing or thumbnail generation workloads. In addition, `zannotate` is CPU-intensive as it must parse each line of JSON in the input file.

Distributed log analysis. This workload sees a 12.7× improvement in the university-to-cloud setting, because POSH is able to *parallelize* the computation across the five different mounts and only aggregate the result locally. Both offloading the computation in order to prevent data movement as well as running the work on each machine in parallel, instead of sequentially, reduces latency. Even in the cloud-to-cloud setting, this results in a 2× speedup.

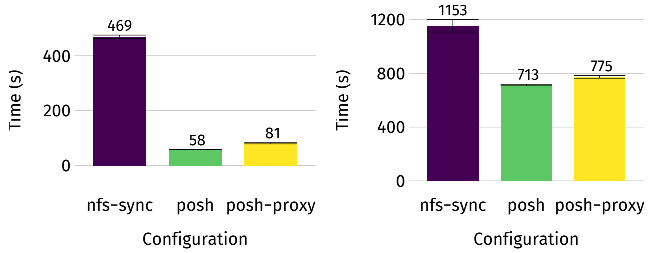
Git workflow. POSH sees the greatest performance benefit, a 10-15× latency improvement, when running `git` commands over NFS. Figure 4 shows the time for each `git status`, `git add`, and `git commit` commands for 20 commits, in the cloud-to-cloud network. We did not perform this full analysis for the university-to-cloud network, because the time to run a single `add` was up to two hours. `git` repositories typically contain many small files; commands like `status` and `add` check the status of every file in the folders to see if it has been modified. This results in NFS making filesystem requests such as `stat` for every file. As a comparison, the ray-tracing log analysis workload makes around 2,500 `open()` calls and 2,500 `stat()` class. For a `git add` in this workload, these numbers are 34,000 and 340,000, respectively, measured by `strace`. By offloading these commands to the server, POSH avoids many unnecessary roundtrips.

8.2 POSH Configuration

We evaluate two aspects of POSH's configuration: placement of proxy servers and maximum parallelization factor within a single machine.

8.2.1 Proxy Placement

Figures 5 and 6 shows the cost of placing the proxy server on a different machine from the storage server, within the same datacenter, for the client at Stanford, for three applications: ray-tracing, thumbnail generation, and `git`. The proxy server is closer to the data than the client; it has both a higher bandwidth



(a) Ray-Tracing Log Analysis **(b)** Thumbnail Generation

Figure 5: Cost of running the POSH proxy on a separate server from the storage server, for a client outside the datacenter ("POSH-proxy", versus POSH where the proxy is at the storage server ("POSH"), and the baseline NFS sync execution time. POSH-proxy has a low overhead over POSH because there is not much overhead to running NFS between two machines in the datacenter.

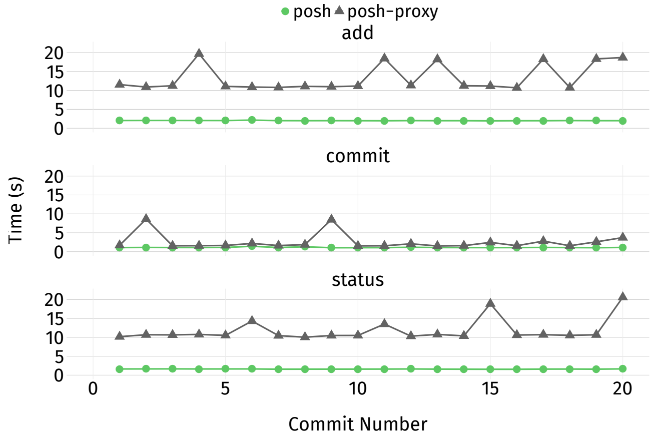


Figure 6: Cost of running the POSH proxy on a separate server from the storage server for a client outside the datacenter for the `git` workload. There is a 10-15x slowdown over POSH running directly at the storage server because running bash over NFS for this workload results in a 10-15x slowdown, due to filesystem metadata calls.

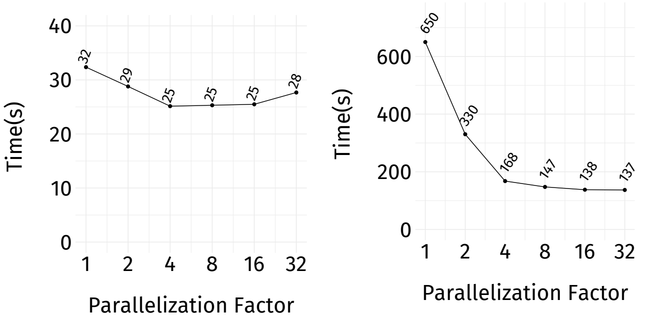
(10 Gbps vs. 600 Mbps) as well as lower latency (0.5 ms vs. 20 ms) connection to the storage server. However, in this setting, the proxy server will have at least the same latency as `bash` over NFS for the cloud-to-cloud setting. The proxy still must perform remote filesystem requests and transfer all the necessary data within the datacenter, because it mounts the data over NFS as well. `bash` over NFS does not have much overhead for the ray-tracing and thumbnail generation workloads, but has a 10-15× overhead for the `git` workload, due to many filesystem metadata calls. However, running `git` at the client outside the datacenter over NFS would have taken on the order of *hours*; POSH merely takes seconds.

8.2.2 Parallelization on a Single Machine

For a 16-core machine, Figure 7 shows the effects of varying the maximum splitting factor for the ray-tracing and thumbnail generation workload. The latency of the ray-tracing workload decreases until $s = 4$ processes and the latency of the thumbnail



(a) Ray-Tracing Parallelization **(b)** Thumbnail Generation Parallelization

Figure 7: Latency improvements from using POSH to parallelize pipelines within a single machine, for the ray tracing and thumbnail generation workloads.

Application	NFS	POSH
Ray-Tracing Log Analysis	10 GB	3 KB
Thumbnail Generation	15 GB	0
Port Scan Analysis	175 GB	0
Distributed Log Analysis	80 GB	76.3 KB

Table 1: Bytes transferred over the network. Data movements are significantly reduced by POSH.

Application	Setup Time
Ray-Tracing Log Analysis	50 ms
Thumbnail Generation	30 ms
Port Scan Analysis	10 ms
Distributed Log Analysis	10 ms
`git status`	0 ms

Table 2: Median setup time.

generation workload decreases until $s = 16$ processes. The limit at 16 is expected for a machine that only has 16 cores. In addition, with higher splitting factors, there is a higher overhead to spawning more threads and context switching. The ray-tracing workload does not benefit from parallelism past 4 threads because it already consists of multiple processes running in parallel, as the workload has many commands (`cat`, `grep`, `cut`, `head`): splitting this further does not provide further benefit.

8.3 Performance Improvements Analysis

Data movement reductions. For each of the log analysis applications and the thumbnail generation application, Table 1 reports the number of bytes of data transferred over the network that this application would generate, as well as the number transferred with POSH and its scheduling mechanism.

POSH overheads. Table 2 reports the latency of POSH's parsing and scheduling steps before execution for a single pipeline (single line of the script) from each application. The overheads are on the order of 10s of milliseconds and barely

Scenario	Latency	Data Movement
NFS Sync	225.8s ± 36.1s	6.38 GB
POSH	221.6s ± 22.1s	6.38 GB
POSH-OPT	33.27s	3.11 GB

Table 3: Expected latency of running POSH with a scheduler that can handle commands that need files from different mounts, for the command `comm A B`, for the university to cloud network.

affect total end-to-end latency. This includes time to parse the configuration file, parse all annotations (which is done once on shell startup), and parse and schedule each command in the pipeline. The ray-tracing and thumbnail generation workloads require resolving more filepaths, causing a larger overhead than the other applications.

9 Limitations and Future Work

Algorithm limitations. POSH's scheduling algorithm handles pipelines that access data on different mounts in a map-reduce style pattern [13], but cannot handle commands which access data on different mounts that cannot be split. Consider a command such as `comm`, that finds the common lines between two files on different mounts: POSH would schedule this command to run at the client, causing no performance benefits over `bash` over NFS. However, if POSH scheduled this command on one of the proxy servers, rather than the client, and transferred the necessary files beforehand, POSH could provide a benefit over NFS. To produce such a schedule, POSH could consider the input files for each command, the data transfer speeds between the proxy machines and the dependencies of the DAG to construct an optimization problem and use standard graph partitioning techniques to solve for the optimal execution location of all nodes. Table 3 shows the expected benefits of a such a scheduler ("POSH-OPT"), for a `comm` command that correlates two 3 GB files stored at two different proxies. It estimates execution time by summing the local execution time of `comm` with the time to transfer one of the files (measured by the time to `scp` the file between the two machines).

Security. POSH allows users to offload parts of shell commands to proxy servers, which could be running directly at the storage layer. POSH currently does not address the security implications of this system design. POSH might allow users to access files such as `/proc/sys` on the storage server which should be restricted. To mitigate this, POSH could ensure that offloaded programs run with limited file access permissions, so they do not access restricted files, and only access files that are specified by the input and output arguments parsed from the annotations. POSH could use sandboxing [20] mechanisms, for example, to restrict users from running offloaded programs that access the network.

Resource management. Since POSH proxy servers could run directly at the storage server, a shared storage server could result in an overloaded CPU and longer latencies for users who expected their commands to take less time since they were offloaded, as well as slowdowns to regular remote filesystem requests. POSH does not currently have policies for load balancing and multitenancy, but could explore policies suggested by prior work [6]. However, initial experiments show that POSH could use a simple policy on the storage server such as monitoring how many cores are in use, and refusing to run programs at the storage server when it is overloaded.

Failure recovery. Currently, POSH does not recover from server-side failures; it does not have mechanisms to migrate or restart jobs if single commands within pipelines fail. Since POSH aims to provide *shell semantics*, which involves streaming data without providing fault tolerance for failed commands, POSH currently does not provide the fault tolerance mechanisms present in standard cluster computing frameworks [17, 31, 61]. However, this is an interesting area of future work: POSH knows exactly what files are being modified or created from the annotations, so POSH could modify programs to write to temporary locations, and only write to the final location when the entire operation is successful.

10 Conclusion

I/O-intensive shell pipelines that run over networked storage incur a significant cost from moving data over the network. We present POSH, a framework that accelerates unmodified shell pipelines with I/O heavy components that access networked storage such as NFS. POSH intercepts shell pipelines and moves individual commands closer to the data by offloading them to run on proxy servers closer to the data than the client. POSH uses metadata about shell commands, written once per command, called annotations, that specify information relevant to safely offloading these commands to proxy servers as well as scheduling them to minimize data movement. POSH uses annotations to schedule and automatically parallelize shell pipelines across the client and proxy servers, while maintaining local execution semantics. We showed that POSH can accelerate a wide range of unmodified shell applications running over NFS and allow them to achieve local execution times.

Abstract

Accelerating SQL queries on stream processing by utilizing heterogeneous coprocessors, such as GPUs, has shown to be an effective approach. Most works show that heterogeneous coprocessors bring significant performance improvement because of their high parallelism and computation capacity. However, the discrete memory architectures with relatively low PCI-e bandwidth and high latency have dragged down the benefits of heterogeneous coprocessors. Recently, hardware vendors propose CPU-GPU integrated architectures that integrate CPU and GPU on the same chip. This integration provides new opportunities for fine-grained cooperation between CPU and GPU for optimizing SQL queries on stream processing. In this paper, we propose a data stream system, called FineStream, for efficient window-based stream processing on integrated architectures. Particularly, FineStream performs fine-grained workload scheduling between CPU and GPU to take advantage of both architectures, and it also provides efficient mechanism for handling dynamic stream queries. Our experimental results show that 1) on integrated architectures, FineStream achieves an average 52% throughput improvement and 36% lower latency over the state-of-the-art stream processing engine; 2) compared to the stream processing engine on the discrete architecture, FineStream on the integrated architecture achieves 10.4x price-throughput ratio, 1.8x energy efficiency, and can enjoy lower latency benefits.

1 Introduction

Optimizing the performance of stream processing systems has been a hot research topic due to the rigid requirement on the event processing latency and throughput. Stream processing on GPUs has been shown to be an effective method to improve its performance [23, 33, 34, 41, 54, 62, 67]. GPUs consist of a large amount of lightweight computing cores, which are naturally suitable for data-parallel stream processing. GPUs are often used as coprocessors that are connected to CPUs through PCI-e [42]. Under such discrete architectures, stream data need to be copied from the main memory to GPU memory via PCI-e before GPU processing, but the low bandwidth of PCI-e limits the performance of stream processing on GPUs. Hence, stream processing on GPUs needs to be carefully designed to hide the PCI-e overhead. For example, prior works have explored pipelining the computation and communication to hide the PCI-e transmission cost [34, 54].

Despite of various studies in previous stream processing engines on general-purpose applications [5, 23, 25, 33, 54, 62], relatively few studies focus on SQL-based relational stream processing. Supporting relational stream processing involves additional complexities, such as how to support window-based query semantics and how to utilize the parallelism with a small window or slide size efficiently. Existing engines, such as Spark Streaming [57], struggle to support small window and slide sizes, while the state-of-the-art window-based query engine, Saber [34], adopts a *bulk-synchronous parallel model* [66] for hiding PCI-e transmission overhead.

In recent years, hardware vendors have released integrated architectures, which completely remove PCI-e overhead. We have seen CPU-GPU integrated architectures such as NVIDIA Denver [13], AMD Kaveri [15], and Intel Skylake [27]. They fuse CPUs and GPUs on the same chip, and let both CPUs and GPUs share the same memory, thus avoiding the PCI-e data transmission. Such integration poses new opportunities for window-based streaming SQL queries from both hardware and software perspectives.

First, different from the separate memory hierarchy of discrete CPU-GPU architectures, the integrated architectures provide unified physical memory. The input stream data can be processed in the same memory for both CPUs and GPUs, which eliminates the data transmission between two memory hierarchies, thus eliminating the data copy via PCI-e.

Second, the integrated architecture makes it possible for processing dynamic relational workloads via fine-grained cooperations between CPUs and GPUs. A streaming query can consist of multiple operators with varying performance features on different processors. Furthermore, stream processing often involves dynamic input workload, which affects operator performance behaviors as well. We can place operators on different devices with proper workloads in a fine-grained manner, without worrying about transmission overhead between CPUs and GPUs.

Based on the above analysis, we argue that stream processing on integrated architectures can have much more desirable properties than that on discrete CPU-GPU architectures. To fully exploit the benefits of integrated architectures for stream processing, we propose a fine-grained stream processing framework, called FineStream. Specifically, we propose the following key techniques. First, a performance model is proposed considering both operator topologies and different architecture characteristics of integrated architectures. Second, a light-weight scheduler is developed to efficiently assign the operators of a query plan to different processors. Third, online profiling with computing resource and topology adjustment are involved for dynamic workloads.

We evaluate FineStream on two platforms, AMD A10-7850K, and Ryzen 5 2400G. Experiments show that FineStream achieves 52% throughput improvement and 36% lower latency over the state-of-the-art CPU-GPU stream processing engine on the integrated architecture. Compared to the best single processor throughput, it achieves 88% performance improvement.

We also compare stream processing on integrated architectures with that on discrete CPU-GPU architectures. Our evaluation shows that FineStream on integrated architectures achieves 10.4x price-throughput ratio, and 1.8x energy efficiency. Under certain circumstances, it is able to achieve lower processing latency, compared to the state-of-the-art execution on discrete architectures. This further validates the large potential of exploring the integrated architectures for data stream processing.

Overall, we make the following contributions:

- We propose the first fine-grained window-based relational stream processing framework that takes the advantages of the special features of integrated architectures.
- We develop lightweight query plan adaptations for handling dynamic workloads with the performance model that considers both the operator and architecture characteristics.
- We evaluate FineStream on a set of stream queries to demonstrate the performance benefits over current approaches.

2 Background

2.1 Integrated Architecture

We show an architectural overview of the CPU-GPU integrated architecture in Figure 1. The integrated architecture consists of a CPU, a GPU, a shared memory management unit, and system DRAM. CPUs and GPUs have their own caches. Some models of integrated architectures, such as Intel Haswell i7-4770R processor [3], integrate a shared last level cache for both CPUs and GPUs. The shared memory management unit is responsible for scheduling accesses to system DRAM by different devices. Compared to the discrete CPU-GPU architecture, both CPUs and GPUs are integrated on the same chip. The most attractive feature of such integration is the shared main memory which is available to both devices. With the shared main memory, CPUs and GPUs can have more opportunities for fine-grained cooperation. The most commonly used programming model for integrated architectures is OpenCL [49], which regards the CPU and the GPU as *devices*. Each device consists of several *compute units* (CUs), which are the CPU and GPU cores in Figure 1.

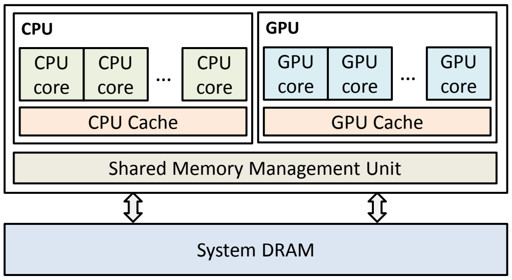

Figure 1: A general overview of the integrated architecture.

We show a comparison between the integrated and discrete architectures (discrete GPUs) in Table 1. These architectures are used in our evaluation (Section 7). Although the integrated architectures have lower computation capacity than the discrete architectures currently, the integrated architecture is a potential trend for a future generation of processors. Hardware vendors, including AMD [15], Intel [27] and NVIDIA [13], all release their integrated architectures. Moreover, future integrated architectures can be much more powerful, even can be a competitive building block for exascale HPC systems [47,55], and the insights and methods in this paper still can be applied. Besides, the integrated architectures are attractive due to their efficient power consumption [15,60] and low price [31].

Table 1: Integrated architectures vs. discrete architectures.

	Integrated Architectures		Discrete Architectures	
Architecture	A10-7850K	Ryzen5 2400G	GTX 1080Ti	V100
# cores	512+4	704+4	3584	5120
TFLOPS	0.9	1.7	11.3	14.1
bandwidth (GB/s)	25.6	38.4	484.4	900
price ($)	209	169	1100	8999
TDP (W)	95	65	250	300

The number of cores for each integrated architecture includes four CPU cores. For discrete architectures, we only show the GPU device.

2.2 Stream Processing with SQL

Although various heterogeneous stream processing systems have appeared [23, 33, 34, 41, 54, 62, 67], we find that most of these systems are used to process unstructured data, and only one work, Saber [34], is developed for structured stream processing on GPUs. Saber supports structured query language (SQL) on stream data [6]. The benefits of supporting SQL come from two aspects. First, with SQL, users can use familiar SQL commands to access the required records, which makes the system easy to use. Second, supporting SQL eliminates the tedious programming operations about how to reach a required record, which greatly expands the flexibility of its usage. Based on the analysis, this work explores stream processing with SQL on integrated architectures.

We consider supporting the basic SQL functions with stream processing, as shown in Figure 2. According to [6], SQL on stream processing consists of the following four major concepts: 1) **Data stream** S, which is a sequence of tuples, $< t_1,t_2,...>$, where t_i is a tuple. A tuple is a finite ordered list of elements, and each tuple has a timestamp. 2) **Window** w, which refers to a finite sequence of tuples, which is the data unit to be processed in a query. The window in stream has two features: *window size* and *window slide*. *Window size* represents the size of the data unit to be processed, and *window slide* denotes the sliding distance between two adjacent windows. 3) **Operators**, which are the minimum processing units for the data in a window. In this work, we support common relational operators including *projection*, *selection*, *aggregation*, *group-by*, and *join*. 4) **Queries**, which are a form of data processing, each of which consists of at least one operator and is based on windows. Additionally, note that in real stream processing systems such as Saber [34], data are processed in *batch* granularity, instead of window granularity. A batch can be a group of windows when the window size is small, or a part of a window when the window size is extremely large.

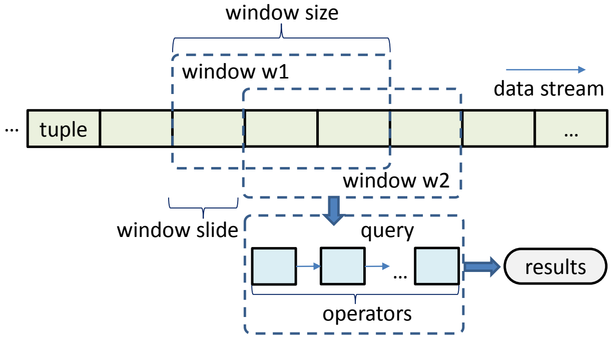

Figure 2: Stream processing with SQL.

3 Revisiting Stream Processing

We discuss the new opportunities (Section 3.1) and challenges (Section 3.2) for stream processing on integrated architectures in this section, which motivate this work.

3.1 Varying Operator-Device Preference

Opportunities: Due to the elimination of transmission cost between CPU and GPU devices on integrated architectures, we can assign operators to CPU and GPU devices in a fine-grained manner according to their device-preference.

We analyze the operators in a query, and find that different operators show various device preferences on integrated architectures. Some operators achieve higher performance on the CPU device, and others have higher performance on the GPU device. We use a simple query of *group-by* and *aggregation* on the integrated architecture for illustration, as shown in Figure 3. The GPU queue is used to sequentially execute the queries on the GPU, while the CPU queue is used to execute the related queries on the CPU. The window size is 256 tuples and the window slide is 64. Each batch contains 64,000 tuples, and each tuple is 32 bytes. The input data are synthetically generated, which is described in Section 7.1. When the query runs on the CPU, *group-by* takes about 18.2 ms and *aggregation* takes about 5.2 ms. However, when the query runs on the GPU, *group-by* takes about 6.7 ms and *aggregation* takes about 5.8 ms.

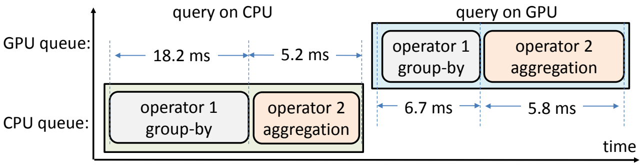

Figure 3: An example of operator-device preference.

We further evaluate the performance of operators on a single device in Table 2. Table 2 shows that using a single type of device *cannot* achieve the optimal performance for all operators. The *aggregation* includes the operators of *sum*, *count*, and *average*, and they have similar performance. We use *sum* as a representative for *aggregation*. From Table 2, we can see that *projection*, *selection*, and *group-by* achieve better performance on the GPU than on the CPU, while *aggregation* and *join* achieve better performance on the CPU than on the GPU. Additionally, *projection* shows similar performance on CPU and GPU devices. Specifically, for *join*, the CPU performance is about 6x the GPU performance. Such different device preferences inspire us to perform fine-grained stream processing on integrated architectures.

Integrated architectures eliminate data transmission cost between CPU and GPU devices. This provides opportunities for stream processing with operator-level fine-grained placement. The operators that can fully utilize the GPU capacity exhibit higher performance on GPUs than on CPUs, so these operators shall be executed on GPUs. In contrast, the operators with low parallelism shall be executed on CPUs. Please note that such fine-grained cooperations is inefficient on dis-

Table 2: Performance (tuples/s) of operators on the CPU and the GPU of the integrated architecture.

Operator	CPU only (10^6)	GPU only (10^6)	Device choice
projection	14.2	**14.3**	GPU
selection	13.1	**14.1**	GPU
aggregation	**14.7**	13.5	CPU
group-by	8.1	**12.4**	GPU
join	**0.7**	0.1	CPU

crete CPU-GPU architectures due to transmission overhead. For example, Saber [34], one of the state-of-the-art stream processing engines utilizing the discrete CPU-GPU architectures, is designed aiming to hide PCI-e overhead. It adopts a bulk-synchronous parallel model, where all operators of a query are scheduled to one processor to process a micro-batch of data [53].

3.2 Fine-Grained Stream Processing

Challenges: A fine-grained stream processing that considers both architecture characteristics and operator preference shall have better performance, but this involves several challenges, from both application and architecture perspectives.

Based on the analysis, we argue that stream processing on integrated architectures can have much desirable properties than that on discrete CPU-GPU architectures. Particularly, this work introduces a concept of fine-grained stream processing: co-running the operators to utilize the shared memory on integrated architectures, and dispatching the operators on devices with both architecture characteristics and operator features considered.

However, enabling fine-grained stream processing on integrated architectures is complicated by the features of SQL stream processing and integrated architectures. We summarize three major challenges as follows.

Challenge 1: Application topology combined with architectural characteristics. Application topology in stream processing refers to the organization and execution order of the operators in a SQL query. First, the relation among operators could be more complicated in practice. The operators may be represented as a directed acyclic graph (DAG), instead of a chain, which contains more parallel acceleration opportunities. Second, with architectural characteristics considered, such as the CPU and GPU architectural differences, the topology with computing resource distribution becomes very complex. In such situations, how to perform fine-grained operator placement for application topology on different devices of integrated architectures becomes a challenge. Third, to assist effective scheduling decisions, a performance model is needed to predict the benefits from various perspectives.

Challenge 2: SQL query plan optimization with shared main memory. First, a SQL query in stream processing can consist of many operators, and the execution plan of these operators may cause different bandwidth pressures and device preferences. Second, in many cases, independent operators may not consume all the memory bandwidth, but co-running them together could exceed the bandwidth limit. We need to analyze the memory bandwidth requirement of co-running. Third, CPUs and GPUs have different preferred memory access patterns. Current methods [5,23,25,33,34,54,62] do not consider these complex situations of shared main memory in integrated architectures.

Challenge 3: Adjustment for dynamic workload. During stream processing, stream data are changing dynamically in distributions and arrival speeds, which is challenging to adapt. First, workload change detection and computing resource adjustment need to be done in a lightweight manner, and they are critical to performance. Second, the query plan may also need to be updated adaptively, because the operator placement strategy based on the initial state may not be suitable when the workload changes. Third, during adaptation, online stream processing needs to be served efficiently. Resource adjustment and query plan adaptation on the fly may incur runtime overhead, because we need to adjust not only the operators in the DAG but also the hardware computing resources to each operator. Additionally, the adjustment among different streams also needs to be considered.

4 FineStream Overview

We propose a framework, called FineStream, for fine-grained stream processing on integrated architectures. The overview of FineStream is shown in Figure 4. FineStream consists of three major components, including performance model, online profiling, and dispatcher. The online profiling module is used to analyze input batches and queries for useful information, which is then fed into the performance model. The performance model module uses the collected data to build models for queries with both CPUs and GPUs to assist operator dispatching. The dispatcher module assigns stream data to operators with proper processors according to the performance model on the fly.

Next, we discuss the ideas in FineStream, including its workflow, query plan generation, processing granularity, operator mapping, and solutions to the challenges mentioned in Section 3.2.

Workflow. The workflow of FineStream is as follows. When the engine starts, it first processes several batches using only the CPUs or the GPUs to gather useful data. Second, based on these data, it builds a performance model for operators of a query on different devices. Third, after the performance model is built, the dispatcher starts to work, and the fine-grained stream processing begins. Each operator shall be assigned to the cores of the CPU or the GPU for parallel execution. Additionally, the workload could be dynamic.

For dynamic workload, query plan adjustment and resource reallocation need to be conducted.

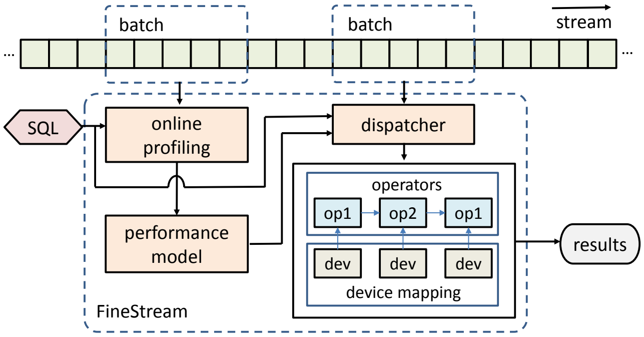

Figure 4: FineStream overview.

Topology. The query plan can be represented as a DAG. In this paper, we concentrate on relational queries. We show an example in Figure 5, where OP_i represents an operator. *OP7* and *OP11* can represent *joins*. We follow the terminology in compiler domain [52], and call the operators from the beginning or the operator after *join* to the operator that merges with another operator as a *branch*. Hence, the query plan is also a branch DAG. For example, the operators of *OP1*, *OP2*, and *OP3* form a branch in Figure 5. The main reason we use the branch concept is for parallelism: operators within a branch can be evaluated in a pipeline, and different branches can be executed in parallel, which shall be detailed in Section 5. The execution time in processing one batch is equal to the traversal time from the beginning to the end of the DAG. Because branches can be processed in parallel, the *branch* with the longest execution time dominates the execution time. We call the operator path that determines the total execution time as $path_{critical}$, so the branch with the longest execution time belongs to $path_{critical}$. For example, we assume that *branch2* has the longest execution time among the branches, its time is $t_{branch2}$, and the execution time for OP_i is t_{OP_i}. *OP7* and *OP11* can also be regarded as branches. Only when the outcomes of *OP3* and *OP6* are available, then *OP7* can proceed. So do to the operators of *OP7* and *OP10* to *OP11*. Assuming OP7 and OP11 are blocking join operators, the total execution time for this query is the sum of $t_{branch2}$, t_{OP7}, and t_{OP11}.

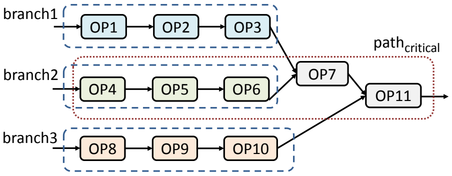

Figure 5: An example of query operators in DAG representation, where OP_i represents an operator.

Operator Mapping. The fine-grained scheduling lies in how to map the operators to the limited resources on integrated architectures. In FineStream, we allow an operator to use one or several cores of the CPU or the GPU device. When the platform cannot provide enough resources for all the operators, some operators may share the same compute units. For example, in Figure 5, *OP1* and *OP2* can share the same CPU cores. If so, the input batches sequentially goes through *OP1* and *OP2* and no pipeline exists between two batches for *OP1* and *OP2*.

Solutions to Challenges. FineStream addresses all the challenges mentioned in Section 3.2. For the first challenge, the performance model module estimates the overall performance with the help of the online profiling module by sampling on a small number of batches, and the dispatcher dynamically puts the operators on the preferred devices. For the second challenge, we have considered the bandwidth factor when building the performance model, which can be used to guide the parallelism for operators with limited bandwidth considered. For the third challenge, the online profiling checks both the stream and the operators to measure the data ingestion rate, and FineStream responses to these situations with different strategies based on the analysis for dynamic workloads. Next, we show the details of our system design.

5 Model for Parallelism Utilization

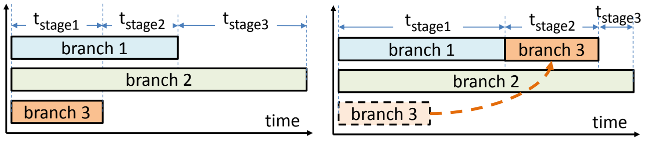
Guideline: A performance model is necessary for operator placement in FineStream, especially for the complicated operator relations in the DAG structure. The overhead of building fine-grained performance model for a query is limited because the placement strategy from the model can be reused for the continuous stream data.

We model the performance of executing a query in this section. The operators of the input query are organized as a DAG. In the performance model, we consider two kinds of parallelism. First, for intra-batch parallelism, we consider *branch co-running*, which means co-running operators in processing one batch. Second, for inter-batch parallelism, we consider *batch pipeline*, which means processing different batches in pipelines.

5.1 Branch Co-Running

Independent branches can be executed in parallel. With limited computation resources and bandwidth, we build a model for branch co-running behaviors in this part. We use *Bmax* to denote the maximum bandwidth the platform can provide. If the sum of bandwidth utilization from different parallel branches, *Bsum*, exceeds *Bmax*, we assume that the throughput degrades proportionally to the *Bmax*/*Bsum* of the throughput with enough bandwidth [60]. To measure the bandwidth utilization, generally, for *n* co-running tasks, we have *n* co-running stages, because tasks complete one by one. When multiple tasks finish at the same time, the number of stages decreases accordingly.

We use the example in Figure 5 for illustration. Assume that the time for different *branches* is shown in Figure 6 (a). If we co-run the three branches simultaneously, then the execution can be partitioned into three stages with different overlapping situations. We use t_{stage1}, t_{stage2}, and t_{stage3} to represent the related stage time when the system has enough bandwidth. Then, if the required bandwidth for $stage_i$ exceeds $Bmax$, the related real execution time t_{stage_i}’ also extends accordingly. We define t_{stage_i}’ in Equation 1. When the platform can provide the required bandwidth, r_i is equal to one. Otherwise, r_i is the ratio of the required bandwidth divided by $Bmax$.



(a) Branch parallelism.

(b) Branch scheduling optimization.

Figure 6: An example of branch parallelism and optimization.

$$t_{stage\_i}{}' = r_i \cdot t_{stage\_i} \tag{1}$$

To estimate the time for processing a batch in the critical path, generally for the branch DAG, we perform topology sort to organize the branches into different layers, and then we co-run branches on layer granularity. In each layer, we perform the above branch co-running. Then, the total execution time is the sum of time of all layers, as shown in Equation 2.

$$t_{total} = \sum_{j=0}^{n_{layer}} \sum_{i=0}^{n_{stage}} t_{stage\_i,layer\_j}{}' \tag{2}$$

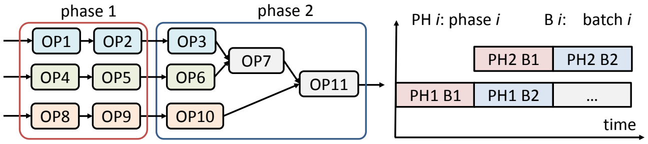
The throughput is the number of tuples divided by the execution time. Assume the number of tuples in a batch is m, then, the throughput is shown in Equation 3.

$$throughput_{branchCoRun} = \frac{m}{t_{total}} \tag{3}$$

Optimization. We can perform branch scheduling for optimization, which has two major benefits. First, by moving *branches* from the stage with fully occupied bandwidth utilization to the stage with surplus bandwidth, the bandwidth can be better utilized. For example, in Figure 6 (b), assume that in $stage_1$, the required bandwidth exceeds $Bmax$, but the sum of the required bandwidth of $branch2$ and $branch3$ is lower than $Bmax$, then we can move the execution of *branch3* after the execution of *branch1* for better bandwidth utilization. Second, the system may not have enough computation resources for all branches so that we can reschedule branches for better computation resource utilization. In *stage1* of Figure 6 (a), when the platform cannot provide enough computing resources for all the three branches, we can perform the scheduling in Figure 6 (b). Additionally, We can perform batch pipeline between operators in each branch, which shall be discussed next.

5.2 Batch Pipeline

We can also partition the DAG into phases, and perform co-running in pipeline between phases for processing different batches. For simplicity, in this part, we assume that the number of phases in the DAG is two. Please note that when the platform has enough resources, the pipeline for operators can be deeper. We show a simple example in Figure 7 (a). The operators in *phase1* and the operators in *phase2* need to be mapped into different compute units, so that these two phases can co-run in the pipeline. Figure 7 (b) shows the execution flow in pipeline. When FineStream completes the processing for *batch1* in *phase1* and starts to process *batch1* in *phase2*, FineStream can start to process *batch2* in *phase1* simultaneously. *Phase1* and *phase2* can co-run because they rely on different compute units.



(a) Phase partitioning.

(b) Batch pipeline.

Figure 7: An example of partitioning phases for batch pipeline.

We need to estimate the bandwidth of two overlapping phases, so that we can further estimate the batch pipeline throughput. The time for a phase, t_{phase_i}, is the sum of the execution time of the operators in the phase for processing a batch. We use t_{phase1} to denote the time for *phase1* while t_{phase2} for *phase2*. When two batches are being processed in different phases in the engine, FineStream tries to maximize the overlapping of t_{phase1} and t_{phase2} of the two batches. However, the overlapping can be affected by memory bandwidth utilization. The online profiling in Section 6.3 collects the size of memory accesses $s_{i,dev}$ (including read and write) and the execution time $t_{i,dev}$ for each operator. The bandwidth of the two overlapping phases is described as Equation 4.

$$bandwidth_{overlap} = MIN(Bmax, \frac{\sum_{i=0}^{m} s_{i,dev}}{t_{phase1}} + \frac{\sum_{i=m+1}^{n} s_{i,dev}}{t_{phase2}}) \tag{4}$$

When $bandwidth_{overlap}$ does not reach $Bmax$, the execution time for processing n batches, $t_{nBatches}$, is shown in Equation 5.

$$t_{nBatches} = n \cdot MAX(t_{phase1}, t_{phase2}) + MIN(t_{phase1}, t_{phase2}) \tag{5}$$

When $bandwidth_{overlap}$ reaches $Bmax$, the execution time of co-running two phases in the pipeline on different batches is longer than any of their independent execution time. We assume that the independent execution time of the longer phase is t_l and the independent time for the shorter phase is t_s. Then, the overlapping ratio for the two phases r_{olp} is t_s divided by t_l. Assuming the total size of the memory accesses for the longer phase is s_l, and the total size for the shorter phase is s_s, then the execution time of the overlapping interval, t_{olp}, is shown in Equation 6.

$$t_{olp} = \frac{s_s + r_{olp} \cdot s_l}{bandwidth_{overlap}} \tag{6}$$

To estimate the time of the rest part in the longer phase, we assume that the bandwidth of the independent execution of the longer phase is $bandwidth_l$. Then, the execution time t_{rest} is shown in Equation 7.

$$t_{rest} = \frac{(1 - r_{olp}) \cdot s_l}{bandwidth_l} \tag{7}$$

Then, when bandwidth $Bmax$ is reached, the execution time $t_{nBatches}$ to process n batches is shown in Equation 8.

$$t_{nBatches} = n \cdot (t_{olp} + t_{rest}) \tag{8}$$

We assume that a batch contains m tuples, and then, the throughput can be expressed by Equation 9. When bandwidth is sufficient, $t_{nBatches}$ is described as Equation 5; otherwise, Equation 8.

$$throughput_{batchPipeline} = \frac{m \cdot n}{t_{nBatches}} \tag{9}$$

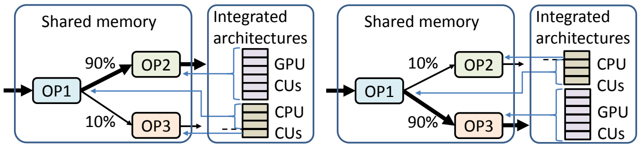
Optimization. Branch co-running can also be conducted in batch pipeline. For example, in Figure 7, the branches in *phase1* can be corun when the system can provide sufficient computing resources and bandwidth. The only thing we need to do is to integrate the branch co-running technique in the potential phases.

5.3 Handling Dynamic Workload

In branch co-running, the hardware resource binded to each branch is based on the characteristics of both the operator and the workload. During workload migration, the workload pressure for each branch may be different from the original state. Hence, the static computing resource allocation may not be suitable for dynamic workload.

A possible solution is to redistribute computing resources to operators in each branch according to the performance model. However, this solution has the following two drawbacks. First, only adjusting the hardware resources on different branches may not be able to maintain the performance, because query plan topology may not fit the current streaming application. In such cases, the query plan needs to be reoptimized for system performance. Second, resource redistribution incurs overhead. Therefore, efficient *resource reallocation* and *query plan adjustment* are necessary for FineStream handling dynamic workload.

Light-Weight Resource Reallocation. In FineStream, we use a light-weight dynamic resource reallocation strategy. When the workload ingestion rate of a branch decreases, we can calculate the reduced ratio, and assume that such proportion of computing resources in that branch can be transferred to the other branches. We use an example in Figure 8 for illustration. In Figure 8 (a), 90% workload after operator *OP1* flow to *OP2*. When the workload state changes to the state in Figure 8 (b), part of the computing resource associated with *OP2* shall be assigned to *OP3* accordingly.



(a) 90% workload goes to OP2.

(b) 90% workload goes to OP3.

Figure 8: An example of adjustment for dynamic workload.

In detail, for the ingestion-rate-falling branch (data arrival rate of this branch is decreasing) [30], we assume that the initial ingestion rate is r_{init}, while the current ingestion rate is r_{cur}. Then, the computing resource that shall be reallocated to the other branches is shown in Equation 10. This adaptive strategy is very light-weight, because we can monitor the ingestion rate during batch loading and redistribute the proportion of reduced computing resources to the branch that has a higher ingestion rate. In the case of Figure 8 (b), we can keep limited hardware resource in OP2 and redistribute the rest to OP3 after processing the current batch.

$$resource_{redistribute\_i} = \frac{r_{init} - r_{curr}}{r_{init}} \cdot resource_{OPi} \tag{10}$$

Query Plan Adjustment. With reference to [30], FineStream generates not only the query plan that soon will be used in the stream processing, but also several possible alternatives. During stream processing, FineStream monitors the size of intermediate results. If the performance degrades and the size of intermediate results varies greatly, FineStream shall switch to another alternative query plan topology. In the implementation, FineStream generates three additional plans by default, and picks them based on the performance model.

6 Implementation Details

6.1 How FineStream Works

We present the system workflow in Figure 9. In Figure 9, *thread1* is used to cache input data, while *thread2* is used to process the cached data. The detailed workflow is as follows. First, when FineStream starts a new query, the dispatcher executes the query on the CPU for *batch1* and then on the GPU for *batch2*. Second, during these single-device executions, FineStream conducts online profiling, during which the operator-related data that are used to build the performance model are obtained, including the CPU and GPU performance, and bandwidth utilization. Third, with these data, FineStream builds the performance model considering branch co-running and batch pipeline. Fourth, after building the model, FineStream generates several query plans with detailed resource distribution. With the generated query plan, the dispatcher performs fine-grained scheduling for processing the following batches. When dynamic workload is detected, FineStream performs related adjustment mentioned in Section 5.3. For the operators in FineStream, we reuse the operator code from OmniDB [64]. Please note that the goal of this work is to provide a fine-grained stream processing method on integrated architectures. The same methodology can also be applied for using other OpenCL processing engine such as Voodoo [45].

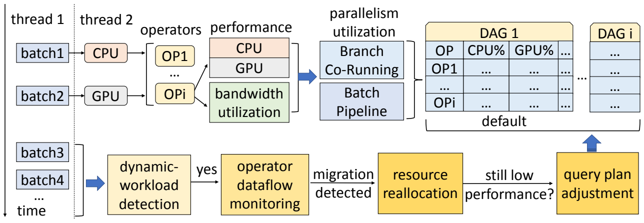


Figure 9: FineStream workflow.

Additionally, when users change the window size of a query on the fly, FineStream updates the window size parameter after the related batch processing is completed, and then continues to run with performance detection. If the performance decreases below a given value (70% of the original performance by default), FineStream re-determines the query plan with computing resource based on the parameters and the performance model.

6.2 Dispatcher

The dispatcher of FineStream is a module for assigning stream data to the related operators with hardware resources. The dispatcher has two functions. First, it splits the stream data into batches with a fixed size. Second, it sends the batches to the corresponding operators with proper hardware resources for execution. The goal of the dispatcher is to schedule operator tasks to the appropriate devices to fully utilize the capacity of the integrated architecture.

Algorithm 1 is the pseudocode of the dispatcher. When a stream is firstly presented in the engine, FineStream conducts branch co-running and batch pipeline according to the performance model mentioned in Section 5 (Lines 2 to 5). FineStream also detects dynamic workload (Lines 6 to 15). If dynamic workload is detected, FineStream conducts the related resource reallocation. If such reallocation does not help, it further conducts query plan adjustment.

Algorithm 1: Scheduling Algorithm in FineStream

```
1  Function dispatch($batch, resource, model$):
2      if $taskFirstRun$ then
3          $branchCoRun(resource, model)$
4          $batchPipeline(resource, model)$
5          $taskFirstRun = false$
       // Handling dynamic workload and query plan optimization
6      if $detectDynamicWorkload()$ then
7          $resourceReallocate()$
8          if $resourceChanged == true$ then
9              if $performanceDegrade()$ then
10                 $adjustQueryPlan()$
11                 $queryChanged = true$
12         $resourceChanged = true$
13         if $queryChanged == true$ then
14             $resourceChanged = false$
15             $queryChanged = false$
```

6.3 Online Profiling

The purpose of online profiling is to collect useful performance data to support building the performance model.

In online profiling, we have two concerns. The first is what data to generate in this module. This is decided by the performance model. These data include the data size, execution time, bandwidth utilization, and throughput for each operator on devices. The second is, to generate the data, what information we shall collect from stream processing.

FineStream performs online profiling for operators from memory bandwidth and computation perspectives.

Memory Bandwidth Perspective. Based on the above analysis, we use *bandwidth*, defined as the transmitted data size divided by the execution time, to depict the characteristics from data perspective of an operator. The transmitted data for an operator consists of input and output. The input relates to the batch while the output relates to both the operator and the batch. We define the bandwidth of the operator i on device dev in Equation 11. The parameters s_{input_i} and s_{output_i} denote the estimated input and the output sizes of the operator i, and $t_{i,dev}$ represents the execution time of the operator i on device dev.

$$bandwidth_{i,dev} = \frac{s_{input\_i} + s_{output\_i}}{t_{i,dev}} \qquad (11)$$

Computation Perspective. To depict the characteristics from the computation perspective, we use $throughput_{i,dev}$, which is defined as the total number of processed tuples n_{tuples} divided by the time $t_{i,dev}$ for operator i on device dev. All these values can be obtained from online profiling.

Table 3: The queries used in evaluation.

Query	Detail
Q1	select timestamp, category, sum(cpu) as totalCPU from TaskEvents [range 256 slide 1] group by category
Q2	select timestamp, jobID, avg(cpu) as avgCPU from TaskEvents [range 256 slide 1] where eventType == 1 group by jobId
Q3	select timestamp, eventType, userId, max(disk) as maxDisk from TaskEvents [range 256 slide 1] group by eventType, userId
Q4	select timestamp, avg (value) as globalAvgLoad from SmartGridStr [range 512 slide 1]
Q5	select timestamp, plug, household, house, avg(value) as localAvgLoad from SmartGridStr [range 512 slide 1] group by plug, household, house
Q6	(select L.timestamp, L.plug, L.household, L.house from LocalLoadStr [range 1 slide 1] as L, GlobalLoadStr [range 1 slide 1] as G where L.house == G.house and L.localAvgLoad >G.globalAvgLoad) as R – select timestamp, house, count(*) from R group by house
Q7	(select timestamp, vehicle, speed, highway, lane, direction, (position/5280) as segment from PosSpeedStr [range unbounded]) as SegSpeedStr – select distinct L.timestamp, L.vehicle, L.speed, L.highway, L.lane, L.direction, L.segment from SegSpeedStr [range 30 slide 1] as A, SegSpeedStr [partition by vehicle rows 1] as L where A.vehicle == L.vehicle
Q8	select timestamp, vehicle, count(direction) from PosSpeedStr [range 256 slide 1] group by vehicle
Q9	select timestamp, max(speed), highway, lane, direction from PosSpeedStr [range 256 slide 1] group by highway,lane,direction

7 Evaluation

7.1 Methodology

The baseline method used in our comparison is Saber [34], while our method is denoted as "FineStream". Saber is the state-of-the-art window-based stream processing engine for discrete architectures. It adopts a bulk-synchronous parallel model [66]. The whole query execution on a batch is distributed to a device, the GPU or the CPU, without further distributing operators of a query to different devices. The original CPU operators in Saber are written in Java, and we further rewrite the CPU operators in Saber in OpenCL for higher efficiency. Our comparisons to Saber examine whether our fine-grained method delivers better performance. To validate the co-running benefits of the two devices, we also measure the performance using only the CPU and the performance using only the GPU, denoted as "CPU-only" and "GPU-only". Further, to understand the advantage of using the integrated architecture to accelerate stream processing, we compare FineStream on integrated architectures with Saber on discrete CPU-GPU architectures.

Platforms. We perform experiments on four platforms, two integrated platforms and two discrete platforms. The first integrated platform uses the integrated architecture AMD A10-7850K [15], and it has 32 GB memory. The second integrated platform uses the integrated architecture Ryzen 5 2400G, which is the latest integrated architecture, and this platform has 32 GB memory. The first discrete platform is equipped with an Intel i7-8700K CPU and an NVIDIA GeForce GTX 1080Ti GPU, and along with 32 GB memory. The second discrete platform is equipped with two Intel E5-2640 v4 CPUs and an NVIDIA V100-32GB GPU, and has 264 GB memory.

Datasets. We use four datasets in the evaluation. The first dataset is Google compute cluster monitoring [2], which emulates a cluster management scenario. The second dataset is anomaly detection in smart grids [68], which is about detection in energy consumption from different devices of a smart electricity grid. The third dataset is linear road benchmark [7], which models a network of toll roads. These traces come from real-world applications, and are widely used in previous studies such as [19, 34, 39]. The fourth dataset is a synthetically generated dataset [34] for evaluating independent operators, where each tuple consists of a 64-bit timestamp and six 32-bit attributes drawn from a uniform distribution. To overfeed the system and test its performance capacity, we load the data from memory. This method avoids network being bottleneck. In practice, the system obtains stream data via network.

Benchmarks. We use nine queries to evaluate the overall performance of the fine-grained stream processing engine on the integrated architectures. Similar benchmarks have been used in [34]. The details of the nine queries are shown in Table 3. *Q1*, *Q2*, and *Q3* are conducted on the Google compute cluster monitoring dataset. *Q4*, *Q5*, and *Q6* are for the dataset of anomaly detection in smart grids. *Q7*, *Q8*, and *Q9* are for the dataset from the linear road benchmark.

Dynamic Workload Generation. We use the datasets and benchmarks to generate dynamic workload. For the first dataset of cluster monitoring, the seventh attribute of *category* gradually changes from type 1 to type 2 within 10,000 batches. We use the query *Q1* for illustration, and we denote it as *T1*. Similar evaluations are also conducted on the second dataset of smart grid with the query *Q5*, which is denoted as *T2*, and the third dataset of linear road benchmark with the query *Q8*, which is denoted as *T3*.

7.2 Performance Comparison

Throughput. We explore the throughput of FineStream for the nine queries. Figure 10 shows the processing throughput of the best single device, Saber, and FineStream for these queries on both the A10-7850K and Ryzen 5 2400G platforms. Please note that the y-axis of the figure is in log scale. We have the following observations. First, on the A10-7850K platform, FineStream achieves 88% throughput improvement over the best single device performance on average; compared to Saber, FineStream achieves 52% throughput improvement. Because of the efficient CPU and GPU co-running, FineStream nearly doubles the performance compared to the method of using only a single device. Because FineStream adopts the continuous operator model where each operator could be scheduled on its preferred device, FineStream utilizes the integrated architecture better than Saber that uses the bulk-synchronous parallel model. Such result clearly shows the advantage of fine-grained stream processing on the integrated architecture. Second, on the Ryzen 5 2400G platform, all hardware configurations have been upgraded in comparison with A10-7850K, especially the CPUs; the CPU-only throughput on Ryzen 5 2400G is much higher than that on A10-7850K. Moreover, Saber achieves a 56% throughput improvement compared to the throughput of the best single device, and FineStream is still 14% higher than Saber on this platform. Similar phenomena have also been observed in [58–60].

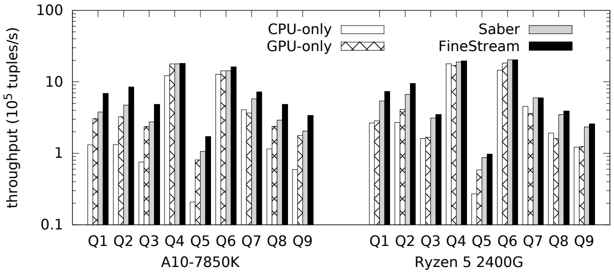

Figure 10: Throughput of different queries.

Latency. Figure 11 reports the latency of different queries on the integrated architectures. In this work, latency is defined as the end-to-end time from the time a query starts to the time it ends. FineStream has the lowest latency among these methods. First, on the A10-7850K platform, FineStream's latency is 10% lower than that of the best single device, and 36% lower than the latency of Saber. Second, on Ryzen 5 2400G platform, it is 2% lower than that of the best single device, and 9% lower than that of Saber. The reason is that FineStream considers device preference for operators and assigns the operators to their suitable devices. In this way, each batch can be processed in a more efficient manner, leading to lower latency.

Profiling. We show the relationship between throughput and latency of both FineStream and Saber in Figure 12. Figure 12 shows that queries with high throughput usually have low latency, and vice versa.

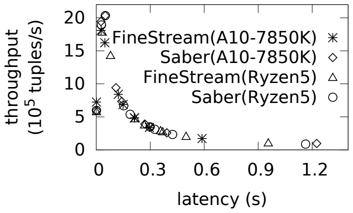

Figure 12: Throughput vs. latency.

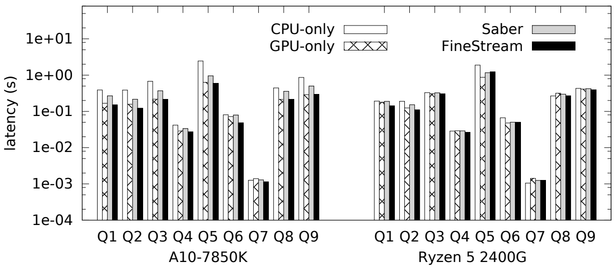

Figure 11: Latency of different queries.

We further study the CPU and GPU utilization of Saber and FineStream, and use the A10-7850K platform for illustration, as shown in Figure 13. In most cases, FineStream utilizes the GPU device better on the integrated architecture. As for *Q*4, the CPU processes most of the workload. On average, FineStream improves 23% GPU utilization compared to Saber, and have roughly the same CPU utilization as Saber. Since FineStream achieves better throughput and latency than Saber, such utilization results indicate that FineStream generates effective strategies in determining device preferences for individual operators.

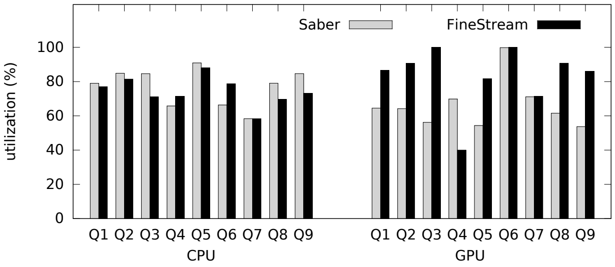

Figure 13: Utilization of the integrated architecture.

7.3 Comparison with Discrete Architectures

In this part, we compare FineStream on the integrated architectures and Saber on the discrete architectures from three perspectives: performance, price, and energy-efficiency.

Performance Comparison. The current GPU on the integrated architecture is less powerful than the discrete GPU, as mentioned in Section 2.1. The discrete GPUs exhibit 1.8x to 5.7x higher throughput than the integrated

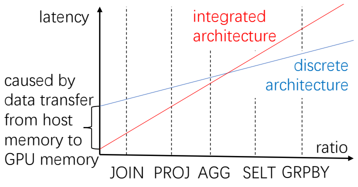

Figure 14: Latency comparison of different operators.

architectures, due to the more computational power of discrete GPUs. However, the integrated architecture demonstrates lower processing latency compared to the discrete architecture when the data transmission cost between the host memory and GPU memory in the workload is significant. For example, the latencies for *projection*, *selection*, *aggregation*, *group-by*, and *join* are 0.6, 1.5, 1.0, 10.6, and 1924.5 ms on Ryzen 5 2400G platform, while 1.1, 1.2, 1.2, 1.6, and 7600.1 ms on GTX 1080Ti platform; these operators are distributed in Figure 14, where *join* (JOIN), *projection* (PROJ), and *aggregation* (AGG) achieve lower latency on the integrated architecture, while *selection* (SELT), and *group-by* (GRPBY) prefer the discrete architecture. The x-axis represents the ratio of $m_{compute}/(s_{write}+s_{read})$ where $m_{compute}$ denotes the kernel computation workload size, and t_{write} and s_{read} denote the data transmission sizes from the host memory to the GPU memory and from the GPU memory to the host memory via PCI-e. For further explanation, to execute a kernel on discrete GPUs, the execution time t_{total} includes 1) the time t_{write} of data transmission from the host memory to the GPU memory via PCI-e, 2) the time $t_{compute}$ for data processing kernel execution, and 3) the time t_{read} of data transmission from the GPU memory to the host memory. As for executing a kernel on the integrated architecture, although its $t_{compute}$ is longer than that on discrete GPUs, its t_{write} and t_{read} can be avoided. For the queries in Table 3, the data movement overhead on discrete architectures ranges from 31 to 62%.

Price-Throughput Ratio Comparison. FineStream on integrated architectures shows a high price-throughput ratio, compared to Saber on the discrete architectures. The price of the 1080Ti discrete architecture is about 7x higher than that of the A10-7850K integrated architecture, and the price of the V100 discrete architecture is about 64x higher than that of the Ryzen 5 2400G integrated architecture. Figure 15 shows the comparison of their price-throughput ratio. On average, FineStream on the integrated architectures outperforms Saber on the discrete architectures by 10.4x.

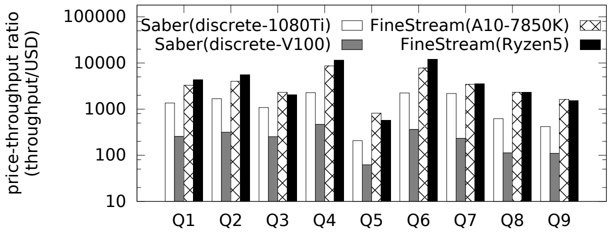

Figure 15: Comparison of price-throughput ratio.

Energy Efficiency Comparison. We also analyze the energy efficiency of FineStream and Saber. The Thermal Design Power (TDP) is 95W on A10-7850K, and 65W on Ryzen 5 2400G. For the 1080Ti platform, the TDP of the Intel i7-8700K CPU and NVIDIA GTX 1080Ti GPU are 95W and 250W, respectively. For the V100 platform, the TDP of the Intel E5-2640 v4 CPU and NVIDIA V100 GPU are 90W and 300W, respectively. Similar to [61], we use performance per Watt to define energy efficiency. On average, FineStream on the integrated architectures is 1.8x energy-efficient than Saber on the discrete architectures.

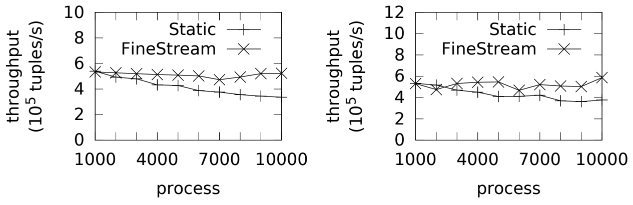
7.4 Handling Dynamic Workload

In this section, we discuss how to handle dynamic workloads. To demonstrate the capability of FineStream to handle dynamic workload, we evaluate FineStream on the dynamic workloads mentioned in Section 7.1. On average, FineStream achieves a performance of 323,727 tuples per second, which outperforms the static method (we denote "static" for FineStream without adapting to dynamic workload) by 28.6%, as shown in Table 4.

Table 4: Throughput of the queries on dynamic workloads.

Dynamic	A10-7850K (10^5 tuples/s)		Ryzen 5 2400G (10^5 tuples/s)	
Workload	Static	FineStream	Static	FineStream
T1	4.2	5.1	4.4	5.1
T2	0.8	1.2	1.1	1.5
T3	1.9	2.8	2.7	3.7

We use *T1* as an example, and show the detailed throughput along with the number of batches in Figure 16. In the timeline process, the static method decreases due to the improper hardware resource distribution. As for FineStream, the hardware computing resources can be dynamically adjusted according to the data distribution, so the performance does not decline with the changes.



(a) A10-7850K.

(b) Ryzen 5 2400G.

Figure 16: Throughput of *T1* on dynamic workloads.

7.5 Detailed Analysis

Performance Model Accuracy. In stream processing, after each batch is processed, we use the measured batch processing speed to correct our model. We use the example of *Q1* for illustration, as shown in Figure 17. We use the percent deviation to measure the accuracy of our performance model. The percent deviation is defined as the absolute value of the real throughput minus the estimated throughput, divided by the real throughput. The smaller the percent deviation is, the more accurate the predicted result is. The deviation decreases as the number of processed batches increases. After 20 batches are processed, we can reduce the deviation to less than 10%. Please note that in stream processing scenarios, input tuples are continuously coming, so the time for correcting performance prediction can be ignored in stream processing. For dynamic workload, the accuracy also depends on the intensity of workload changes.

Runtime Overhead Analysis. FineStream incurs runtime overhead in the batch processing phase from two aspects. First, it detects whether the input stream belongs to dynamic workload, which causes time overhead. Second, the scheduling also takes time. In our evaluation, we observe that the time overhead accounts for less than 2% of the processing time, which can be ignored in stream processing.

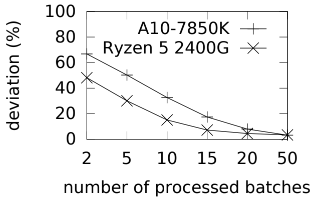


Figure 17: Deviation of *Q1*.

8 Related Work

Parallel stream processing [4, 10, 12, 21, 28, 29, 34, 43, 46, 63], query processing [9, 14, 16, 20, 22, 56], and heterogeneous systems [11, 17, 24, 26, 32, 35–38, 45, 48, 50] are hot research topics in recent years. Different from these works, FineStream targets sliding window-based stream processing, which focuses on window handling with SQL and dynamic adjustment. GPUs have massive threads and high bandwidth, and have emerged to be one of the most promising heterogeneous accelerators to speedup stream processing. Verner et al. [54] presented a stream processing algorithm considering various latency and throughput requirements on GPUs. Alghabi et al. [5] developed a framework for stateful stream data processing on multiple GPUs. De Matteis et al. [25] developed Gasser system for offloading operators on GPUs. Pinnecke et al. [44] studied how to efficiently process large windows on GPUs. Chen et al. [23] extended the popular stream processing system, Storm [1], to GPU platforms. Augonnet et al. [8] explored data-aware task scheduling for multi-devices, which can be integrated into this work. FineStream differs from those previous works in two aspects: firstly on integrated architectures, and secondly for SQL streaming processing.

The closest work to FineStream is Saber [34], which aims to utilize discrete CPU-GPU architectures. Saber [34] adopts a *bulk-synchronous parallel* model [53, 66], where the whole query (with multiple operators) on each batch of input data is dispatched on one device. Such a mechanism naturally minimizes the communication overhead among operators inside the same query. It is hence suitable in discrete CPU-GPU architectures, where PCI-e overhead is significant and shall be avoided as much as possible. However, it may result in suboptimality in integrated architectures for mainly two reasons. First, it overlooks the performance difference between different devices for each operator. Second, the communication overhead between the CPU and the GPU in integrated architectures is negligible. Targeting at integrated architectures, FineStream adopts continuous operator model [53, 66], where each operator of a query can be independently placed at a device. We further build a performance model to guide operator-device placement optimization. It is noteworthy that our fine-grained operator placement is different from classical placement strategies for general stream processing [18, 19, 40, 51, 65] for their different design goals. In particular, most prior works aim at reducing communication overhead among operators, which is not an issue in FineStream. Instead, FineStream needs to take device preference into consideration during placement optimization, which has not been considered before.

9 Conclusion

Stream processing has shown significant performance benefits on GPUs. However, the data transmission via PCI-e hinders its further performance improvement. This paper revisits window-based stream processing on the promising CPU-GPU integrated architectures, and with CPUs and GPUs integrated on the same chip, the data transmission overhead is eliminated. Furthermore, such integration opens up new opportunities for fine-grained cooperation between different devices, and we develop a framework called FineStream for fine-grained stream processing on the integrated architecture. This study shows that integrated CPU-GPU architectures can be more desirable alternative architectures for low-latency and high-throughput data strream processing, in comparison with discrete architectures. Experiments show that FineStream can improve the performance by 52% over the state-of-the-art method on the integrated architecture. Compared to the stream processing engine on the discrete architecture, FineStream on the integrated architecture achieves 10.4x price-throughput ratio, 1.8x energy efficiency, and can enjoy lower latency benefits.

OpenExpress: Fully Hardware Automated Open Research Framework for Future Fast NVMe Devices

Myoungsoo Jung
Computer Architecture and Memory Systems Laboratory
Korea Advanced Institute of Science and Technology (KAIST)
http://camelab.org

Abstract

NVMe is widely used by diverse types of storage and non-volatile memories subsystems as a de-facto fast I/O communication interface. Industries secure their own intellectual property (IP) for high-speed NVMe controllers and explore challenges of software stack with future fast NVMe storage cards. Unfortunately, such NVMe controller IPs are often inaccessible to academia. The research community, however, requires an open-source hardware framework to build new storage stack and controllers for the fast NVMe devices.

In this work, we present OpenExpress, a fully hardware automated framework that has no software intervention to process concurrent NVMe requests while supporting scalable data submission, rich outstanding I/O command queues, and submission/completion queue management. OpenExpress is available to download and offers a maximum bandwidth of around 7GB/s without a silicon fabrication.

1 Introduction

NVM Express (NVMe) is successful in bringing diverse solid state drive (SSD) and non-volatile memory (NVM) technologies closer to CPUs. NVMe supports many current I/O submissions and completions for higher throughput compared to traditional block storage interfaces. The storage-level firmware and host-side software can synchronize their communication over a flexible queueing method [26]. NVMe also provides a data transfer mechanism that allows the underlying NVMe devices to leverage abundant system memory resources of the host via physical region page (PRP) lists.

As NVMe devices have been widely used in a broad spectrum of computing domains [10, 17, 21], storage vendors secure their own *intellectual property* (IP) cores to build high-speed NVMe controllers. The NVMe specification stipulates these NVMe controller IP cores to be implemented in either firmware or hardware [26]. Considering the design flexibility of the underlying SSD architecture, many storage vendors and communities typically implement the controller IP cores as firmware [20,31,39]. Even though firmware-based controllers are sufficient to manage flash, their firmware execution can be a critical performance bottleneck when used in conjunction with faster NVM media, such as phase change memory (PRAM) and magnetoresistive memory (MRAM) [8, 23]. Since the latency of the emerging fast NVMs is shorter than that of flash by an order of magnitude, CPU cycles to execute the firmware cannot be hidden behind or overlapped with I/O burst times of the underlying NVM backend.

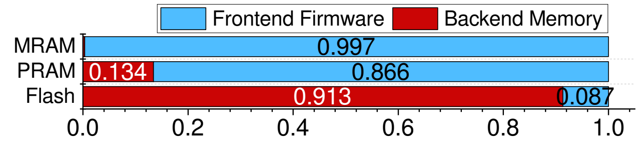

Figure 1: Decomposition comparison for execution cycles with different non-volatile memories.

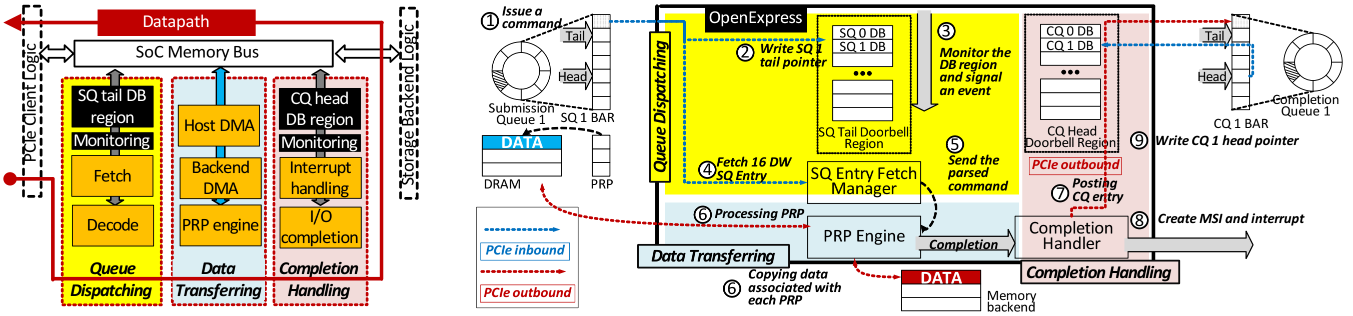
To illustrate this overhead, we perform an emulation study to decompose the latency of an NVMe SSD into two parts: i) NVMe firmware execution time (*Frontend*) and ii) NVM backend access latency (*Backend*). In this study, we intermix read and write requests (1:1) and issue them to our PCIe hardware platform; this platform executes the NVMe firmware on a 1 GHz processor and emulates three different types of NVM backends, each employing 16 flash chips [14], and 16 PRAM [23] chips, and 16 MRAM chips [8], respectively. As shown in Figure 1, the access latency of flash-based backend contributes 91% of the total NVMe service time, which makes it possible to hide the front-end firmware latency by interleaving with flash I/O bursts. In contrast, the firmware execution cannot be overlapped with the I/O burst times of PRAMs and MRAMs as its execution time accounts for 86% and 99% of the total I/O latency. To address this challenge, industries have begun to employ hardware automated NVMe controller IP cores [9,24]. For example, recent state-of-the-art prototypes [9] automate NVMe control logic in an SSD to achieve 1 million I/O per second (IOPS).

Unfortunately, such NVMe hardware IP cores are prohibited to access and redesign from academia. There exist a few third-party vendors that do hardware IP business [7, 15, 16]. However, their IP cores require expensive “per-month” unitary prices, ranging from \$30K $\sim$ \$45K; the price of single-use source code is around \$100K. There are even restrictions on modifying the hardware IP and architecture, which is inadmissible in research communities. Because of such unapproachability and high costs of NVMe IP cores, many recent studies that redesign the existing storage stack, such as bypass kernel designs or NVM file systems implemented atop a fast NVMe device, are mostly performed by a simulation [11, 12, 19, 34] or an emulation [22, 37, 40]. In addition, most academic studies related to SSDs such as firmware algorithm developments [4, 6, 25, 29] and cross-layer optimizations [5, 18, 38], are all performed by the simulation/emulation.



a) OpenExpress overview.

b) Functional descriptions for OpenExpress.

Figure 2: Overview and hardware details of the proposed OpenExpress.

While there are benefits for the simulation/emulation-based studies (e.g., fast prototyping and validation), many researchers still require real NVMe devices that they can modify to develop full-system prototypes and perform end-to-end performance evaluation with no strings attached. In this work, we propose *OpenExpress*, a framework that fully automates NVMe control logic in hardware to make it possible to build customizable NVMe devices. To the best of our knowledge, OpenExpress is only the open research framework that realizes NVMe hardware accelerator IPs [1], which does not require any software intervention to process concurrent read and write NVMe requests. Considering diverse demands of the academic research, OpenExpress leverages multiple DRAM channels and modules as storage backend and supports scalable data submission, rich outstanding NVMe commands and submission/completion queue management.

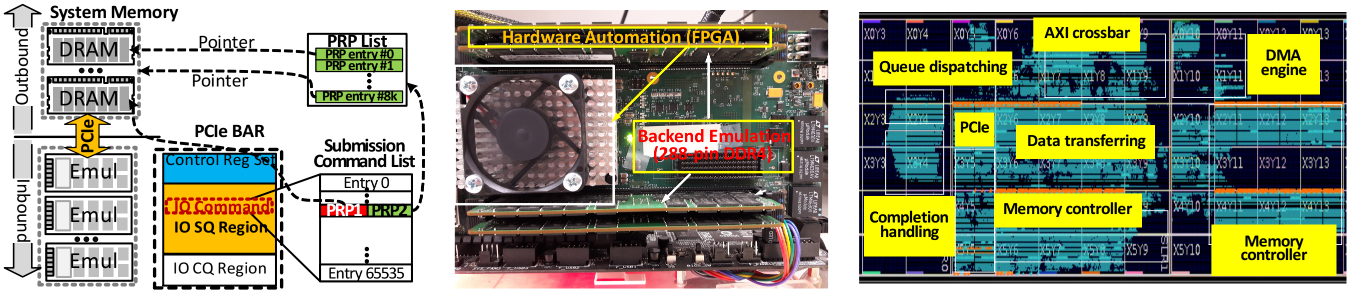
We prototype OpenExpress with a commercially available Xilinx FPGA board [3] and optimize all its logic components to operate at a high frequency. Even though it is a well-known fact that FPGAs are slower than CPUs, we demonstrate that OpenExpress can expose the true performance of backend memory modules to users over PCIe. At its peak, OpenExpress provides an access bandwidth of 7GB/s. Our evaluation also shows that OpenExpress can, on average, exhibit 76.3% better performance than an Optane SSD [13], which is one of the fast NVMe devices in the market.

2 Module Design of OpenExpress

Overview. Figure 2a illustrates a high-level view of OpenExpress, which is composed of three groups of hardware modules: i) *queue dispatching*, ii) *data transferring*, and iii) *completion handling*. At the beginning of OpenExpress's datapath, queue dispatching hardware modules fetch and decode all incoming I/O requests by monitoring multiple NVMe *submission queues* (SQs). Data transferring hardware modules then check the host system memory over *physical region page* (PRP) lists, and perform DMA for both host and backend memories. Once the data is successfully served by the backend, OpenExpress's completion handling modules manage interrupts and NVMe *completion queues* (CQs) over a set of registers (*doorbells*) mapped to a system-on-chip (SoC) internal memory bus. The details of the three different hardware module groups are explained in Figure 2b.

Queue dispatching modules. [① ∼ ⑤] of Figure 2b describe the queue dispatching functions that OpenExpress implements over hardware, including a set of procedures for automatic NVMe doorbell monitoring, command fetches, and command decodes. Specifically, when the host issues an NVMe command by pushing an SQ entry into the per-core queue [①], it should also write (i.e., ring) the corresponding entry of the doorbell (DB). Thus, OpenExpress creates a DB entry per queue by grouping two sets of DBs, each keeping track of a *tail* pointer per SQ and a *head* pointer per CQ. We map these sets of DBs, called *DB region*, to the internal SoC memory bus address space, and in parallel, we expose it to a PCIe's *base address register* (BAR) [②]. Since our fetch and decode modules can detect any DB updates (made by the host) through the memory-mapped DB region, OpenExpress is able to synchronize the host NVMe queue states with its internal NVMe queue states. Note that ringing a DB at the host side is the same as writing a PCIe packet (i.e., PCIe inbound) in NVMe. Therefore, OpenExpress can simply catch each ringing event by monitoring the memory bus address space mapped to the DB region for changes. Whenever OpenExpress observes an update of a DB that exists in the SQ-tail DB region and CQ-head DB region, it generates an event signal [③]. This event signal includes information relevant to the target SQ, and is passed to the underlying SQ entry *fetch manager*. Since multiple event signals can arise simultaneously, our fetch manager arbitrates between different NVMe queues in a round robin manner as specified by NVMe 1.4 [26]. The fetch manager then checks the delivered information and copies the 16-double-word (DW) NVMe command, associated with the target SQ entry, from the host-side system memory. After fetching the command, OpenExpress can see all relevant request information, such as the operation code (opcode), logical block address (LBA), block size, and PRPs [④]. Our fetch manager finally parses

[1] The intellectual property (IP) cores and/or register transfer level (RTL) code our OpenExpress is available to download for non-commercial and academic uses from http://openexpress.camelab.org.



a) Data transferring (PRP).

b) Reference board for our prototype.

c) Floorplan of OpenExpress.

Figure 3: Implementation View of OpenExpress.

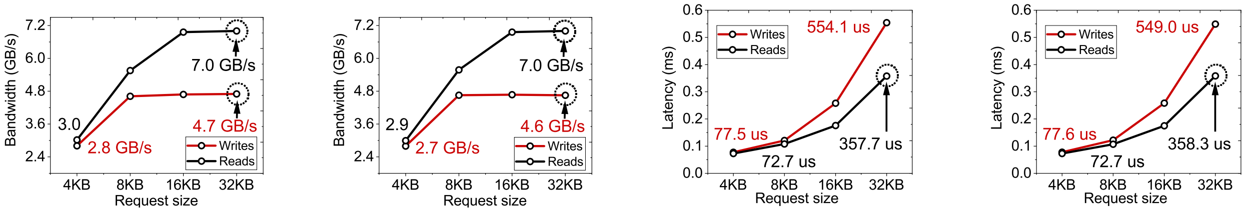
the request information and forwards it to the underlying PRP engine. To enhance responsiveness of the storage frontend (i.e., queue dispatching), the fetch manager pipelines its processing of other remaining requests with other operations of data transferring and completion handling modules [⑤].

Data transferring modules. To handle page-aligned data, our PRP engine accesses the location of the host-side system memory via a PRP, which in turn generates an out-bound PCIe packet. The PRP engine then initiates data transfer by setting the source address (i.e., host-side system memory) and the destination address (i.e., OpenExpress's memory) of our backend DMA engine [⑥]. The PRP engine copies the data from the host DRAM to our DMA engine for each 512B chunk to make device memory compatible with sector-based block I/O services. On the other hand, the DMA engine employs multiple DMA IP cores (as many as FPGA's backend memory channels) to fully parallelize data transfers. Specifically, the DMA engine splits the data of a single request into multiple small-sized data chunks and spreads them across the multiple DMA engine IP cores of the target backend. Doing so will help shorten the I/O latency of underlying NVM emulation memories. Note that the payload size of a PCIe packet is 4KB. Thus, if the request offset is not aligned to a 4KB boundary, the target data can exist in two different system memory pages of the host-side DRAM. To manage this case, as shown in Figure 3a, the PRP engine fetches the target data from two different host locations, referred by *PRP1* and *PRP2*, respectively. Specifically, if the request size is greater than a page, the PRP engine brings a page and the PRP list, indicated by PRP1 and PRP2, respectively, from the host DRAM and parses each entry of the list. The PRP engine then traverses all entries of the PRP list and transfers the data of each entry from the host system memory pages to the underlying memories. Once the data transfers are completed by the DMA engine, the PRP engine signals the completion handler, which in turn creates a completion request (CQ entry), and manages an *message-signaled interrupt* (MSI) packet corresponding to the submission request.

Completion handling modules. The functions of completion handling that we implement include I/O completion (CQ management) and interrupt processing. Based on the NVMe specification states, an NVMe queue is logically composed by a pair of an SQ and a CQ. Thus, to make the NVMe queues easy to manage, one may locate the SQ-tail DB region with the CQ-head DB region, side-by-side. However, as in-flow velocities of NVMe submissions and NVMe completions are asymmetric, a physical integration of the SQ-tail DB region and CQ-head DB region close together is not ideal from both performance and implementation angles. Thus, OpenExpress completely separates the SQ-tail DB region and CQ-head DB region. To pair OpenExpress's CQ and SQ status in an appropriate manner, we introduce a completion handler that automatically detects which CQ is engaged with the I/O request finished to process by the data transferring modules. Specifically, the detection is performed by checking the corresponding request information, which is forwarded from the SQ entry fetch manager of the queue dispatching modules. Once the completion handler finds out the appropriate CQ, the handler posts the target CQ entry by directly writing it to the corresponding host-side system memory (BAR) [⑦]. The completion handler then interrupts the host by pushing (writing) a PCIe packet to an MSI region that the host driver manages to inform the host of the I/O service completion [⑧]. The host driver later invokes its own interrupt service routine, which will notify the completion to the user who requested such I/O service. The host finally terminates the I/O service and synchronizes its CQ state with OpenExpress by updating the CQ-head DB region [⑨]. Note that queue synchronization means that the completion handler releases the target SQ and CQ entry pair from the corresponding NVMe queue. In this way, the internal CQ and SQ states of our OpenExpress can be consistent with the host-side SQ and CQ states of NVMe driver(s).

3 Hardware Prototyping

We implement OpenExpress on an Xilinx FPGA board [3] that employs an UltraScale [36] chip and PCIe Gen3 interface, which are shown in Figure 3b. We use four 288-pin DDR4 dual in-line memory modules (DIMMs) for storage-backend emulation. In our implementation, the FPGA logic modules are classified into two: frontend and backend automa-



(a) Sequential bandwidth.

(b) Random bandwidth.

(c) Sequential latency.

(d) Random latency.

Figure 4: Bandwidth and latency performance for multi-block I/Os.

tions. The frontend automation contains most logic modules for queue dispatching and completion handling. It also exposes PCIe BAR registers and maps them into the internal advanced extensible interface (AXI) memory crossbar [1,35]. The queue dispatching IP cores fetch and decode NVMe commands issued by the host while completion handling logic manages all aspects of I/O request completion, including interrupt handling. The completion handling logic also maintains all the contexts to automatically pair different SQs and CQs by collaborating with queue dispatching cores. On the other hand, the backend automation consists of data transferring IP cores, DDR4 memory controllers, and a DMA engine. The data transferring IP cores traverse all PRP entries and migrate the corresponding data between the host's system memory and FPGA memory modules through the DDR4 memory controllers and DMA engine.

Frequency tuning. To satisfy diverse demands of NVMe-related academic research, employing reconfigurable hardware such as FPGA is essential. However, its slow clock speed is one of challenges for our prototyping to overcome. We therefore minimize the number of connections among all logic modules to make OpenExpress operate with the highest frequency of our FPGA platform. Specifically, in our implementation, the logic modules are directly engaged one-to-one, and their input and output ports are connected in a undirectional manner. The target logic can directly retrieve any necessary information that is not forwarded from a source module by accessing the memory address space of the AXI crossbar. Note that all these hardware IP cores process different parts of I/O request(s) in a pipelined manner to improve I/O bandwidth.

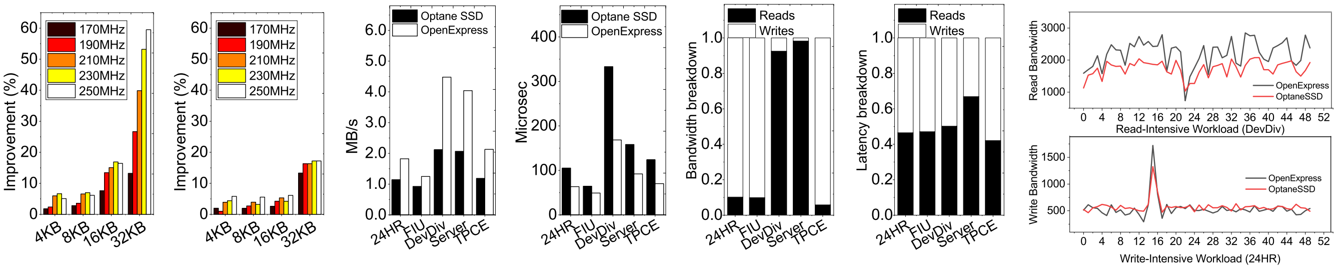
Our frequency tuning process involves gradual trial-and-error attempts to reduce the amount of route delay in a critical path. Since the delay is not straightly related to logic design, it cannot be reduced by revamping only the design itself. Instead, we perform multiple iterations of the FPGA implementation process (i.e., physical design layout decision), including a translate, map, and place-and-route (PAR) for different high-clock frequencies, ranging from 50MHz to 250 MHz. Typically, applying a higher clock frequency introduces different timing constraint violations. Unfortunately, fixing the timing violation of one core has an impact on other cores' timing characteristics. Thus, we separate the memory controller IPs from OpenExpress logic modules to the extent permitted by each each module's timing constraint, and then, we group the logic together by considering a boundary of super logic region (SLR) that contains multiple fabric modules and IP cores. The result of our design is a physical layout that is able to successfully operate at the highest frequency of the target FPGA platform as shown in Figure 3c. While all the logic modules of OpenExpress are located around PCIe and AXI crossbar, the modules associated with data transferring and DMA engine, including the memory controller IP cores, occupy only two SLRs. Lastly, the memory backend is emulated as NVMe's low-level storage complex over four channel FPGA memory IP cores. Note that, while the current prototype uses DRAM memory channels and components for the storage backend, OpenExpress IP cores can be integrated with other persistent memories.

4 Evaluation

The host system that we tested employs 8-core, 3.3GHz Intel Skylake-X processor (i9-9820X) with 32GB DDR4. Our OpenExpress prototype is attached to the host over PCIe Gen3 [30]. In this evaluation, we mainly focus on demonstrating that OpenExpress can be adopted in a real system as an open-source hardware research platform.We characterize the performance behaviors of OpenExpress (Section 4.1) and then show the performance enhancement by tuning the FPGA clock frequency (Section 4.2). We also compare the performance of OpenExpress with that of an Optane SSD [13] under diverse real workloads [32]. Note that we do not claim that OpenExpress can be faster than other fast NVMe devices. Instead, the evaluation results show that, despite the slow clock-frequency, an FPGA-based design and implementation for NVMe IP cores can offer good performance to make it a viable candidate for use in storage systems research. We use FIO [2] and execute diverse types of real workloads [32] for the user-level. We observe that the computation of a single I/O thread is insufficient to extract the maximum performance of OpenExpress. Thus, we execute FIO with a ten I/O threads, each having its own NVMe queue and I/O workload execution.

4.1 OpenExpress Characterization

Bandwidth. Figures 4a and 4b show the bandwidth trends of sequential and random I/O requests whose size varies ranging from 4 KB to 32KB, respectively. We observe that all device tests exhibit the best performance at the queue depth 8, and thus, we present only the results at such queue depth. There



(a) Read imprv. (b) Write imprv. (c) Bandwidth. (d) Latency. (e) BW. brkdown. (f) Lat. brkdown. (g) Random bandwidth.

Figure 5: Performance improvement analysis and in-depth performance comparison analysis with real workloads

is no much bandwidth difference between reads and writes at the page-size (4KB) I/O service; 3.0 GB/s and 2.8 GB/s for sequential reads and writes, respectively. As the I/O request size increases, the read and write performance improve. Note that OpenExpress reaches the maximum bandwidth with 16KB-sized I/O services; the write and read maximum bandwidth for both random and sequential are 4.6∼4.7GB/s and 7.0 GB/s, respectively. Interestingly, as the request size increases, the read bandwidth gets better than the write bandwidth. This is because of PCIe packet management issues, impacted by what we tuned for a high FPGA clock frequency, which will be analyzed in details in Section 4.2. Generally speaking, the data and command movement of reads are not congested as much as that of writes; all doorbell register updates, and command/write data payloads come together through PCIe inbound links.

Latency. Figures 4c and 4d present the latency of sequential and random I/O requests, respectively. Like the bandwidth behaviors of OpenExpress, the trend of latency curve with varying request sizes for sequential and random is similar to each other; for both reads and writes, their latency increases as the request size grows; the average latency of page-sized reads and writes is 72.7 us and 77.5 us, respectively. This is because OpenExpress exhibits the same execution latency for data transferring at a same queue depth condition. In addition, the latency of backend memory accesses with a bulk of pages does not depend on their access patterns. Even though write latency characteristics are similar to those of reads for 4∼8 KB sized requests, as increasing the I/O sizes, the latency disparity becomes more distinguishable. Specifically, the read and write latency of 32KB-sized requests is 358 us and 551.5 us, on average, respectively; for both sequential and random patterns, the writes are 54% slower than reads, on average.

Note that the latency of page-sized requests is observed with high queue depths to achieve the best bandwidth. While bandwidth is the matter on block storage, OpenExpress can reduce the latency by 62% with single queue depth operations (by sacrificing the bandwidth). Specifically, the latency of 4KB-sized requests (72.7us ∼ 77.5us) are evaluated with 8 queue depths to achieve the max bandwidth that OpenExpress can offer. Optane SSD's latency for 4KB-sized requests is 120 ∼ 150us with those queue depths. The user-level latency of 4KB-sized requests for OpenExpress is 27us ∼ 30us with a single queue-depth, which is similar to the latency that Optane SSD provides.

4.2 Frequency Tuning and Real Workload

FPGA clock frequency optimization. Figure 5a and 5b show the percentage of bandwidth improvement (as representative) by tuning the FPGA clock frequency, ranging from 150 MHz to 250 MHz. We normalize all the results to the bandwidth that we can achieve by executing OpenExpress at 150 MHz. As shown in Figure 5b, the write bandwidth improvement is 8.6%, on average. Our frequency tuning exhibits higher bandwidth improvements in cases of larger size requests. This is related to the amount of data (per request) that OpenExpress should move between the host and underlying memory backend. The small requests (4 KB∼16 KB) have a few system addresses that OpenExpress needs to be involved in parsing the PPR entries and perform DMA, which implies that there are more operations related to NVMe protocol management of SQ, CQ, doorbell, etc. To handle the large requests (32 KB), data transferring modules successfully remove the software intervention related to all PRP traversing, address parsing and DMA control. They are also well operated with other hardware automation modules in a pipeline manner, which can improve the overall performance by 17.1%. We observe that the performance improvement of reads are more significant (Figure 5a). The read bandwidth improvement for 4 KB, 8 KB, 16 KB and 32 KB-sized requests is 5%, 6.1%, 16.4% and 59.4%, on average, respectively. All NVMe-related traffic for the reads are not congested as much as that of the writes thanks to the dual-simplex design of PCIe. Specifically, as the operations of queue dispatching modules are mostly engaged with PCIe inbound links, data transferring modules can write up data to the host system memory in serving the read requests via PCIe outbound links, in parallel. Because of this, our hardware automation becomes more promising to serve the large block-sized read requests than the writes.

Real workload. We compare the bandwidth and latency of OpenExpress with those of Optane SSD by executing diverse workloads, and the results are shown in Figures 5c and 5d, respectively. For better understanding, we decompose the bandwidth and latency for each workload, which are shown in Figures 5e and 5f, respectively. The bandwidth and latency of OpenExpress are better than that of Optane SSD by 76.3% and 68.6%, on average, respectively. Since our frequency turning gives better performance on reads, the performance on read-intensive workloads (DevDiv and Server) is better than write-intensive workloads (24HR, FIU and TPCE). In particular, OpenExpress achieves more than 4 GB/s on DevDiv workload execution, which is 111.5% higher than the performance that Optane SSD provides (2.1 GB/s).

To see each of device bandwidth behaviors, Figure 5g shows the time series analysis of read-only and write-only bandwidth for DevDiv and 24HR workloads in a certain amount of I/O processing periods. As reads are dominant on DevDiv, the read-only bandwidth of OpenExpress is 27.1% better than Optane SSD. In contrast, the write-only bandwidth of OpenExpress for 24HR shows a similar or a little bit worse characteristic, compared to Optane SSD. We conjecture that Optane SSD buffers write requests into its internal DRAM, and thus, FPGA-based automation makes the performance difference between OpenExpress and Optane SSD (all logic is built on an ASIC). For both read and write bandwidth, the trends of dynamic performance curve for OpenExpress and Optane SSD are similar to each other.

5 Discussion, Related Work and Future Work

Related work. There are only a handful of frameworks that enable NVM-related storage systems research. OpenSSD [27, 28] provides flash software, which can be modified by users based on their research demands. We believe that OpenSSD offers yet an excellent opportunity to examine the diversity in flash management, but it only supports low speed SATA and non-standard interfaces. Unfortunately, their low performance (<350MB/s [33]) is not suitable for conducting research related with high-speed NVM technologies. In addition, OpenSSD does not allow users to modify hardware design and architecture. Note that OpenSSD is also not a cost-free open-source platform; Jasmine and Cosmos require around $2K and $3.5K per-device license fees, respectively.

Dragon fire card (DFC) implements a customized FPGA design, but it is only used for back-end flash controllers. All other functionalities are managed by software and a heavy operating system, which executes on multiple CPU cores. DFC is not in a public domain yet and unfortunately available for only a small, closed research community. Note that, in addition to the lack of open licensing and limitations with respect to support for fast, NVM devices, all the above frameworks require software to manage the host communication and NVMe protocol in contrast to OpenExpress.

Limits. Our hardware automated logic can remove software involvement for NVMe management, thus, providing performance inline with the expected user case – a fast PCIe storage card for NVM research. However, the automated hardware modules may require more technical efforts than what software-based NVMe utilities need to pay for a change, in cases where one needs to either apply the hardware logic to different types of FPGA technologies, or employ additional hardware/software logic. While OpenExpress implements most critical modules on both read and write paths, it requires users to modify the hardware logic to add new NVMe features and other commands for good measure. Even with these limits, we believe that OpenExpress is worthwhile to explore, as third-part NVMe IP cores are hard nut to crack to access for research purposes because of their expensive per-month unitary prices and restrictions to modify.

Future work and use cases. As an on-going research, we are updating the existing Linux storage stack and memory subsystem modules to exploit the true performance, exposed by different types of emerging NVMs. We are also fully updating OpenExpress to have a real NVM storage backend rather than DRAM emulation for a device-level study. This project requires a set of extra RTL designs and modifications to remove all firmware executions from the internal I/O path of an existing SSD. It also needs new types of NVM controllers the corresponding and physical layers to correctly handle the NVM backend complex with a low power. Lastly, we leverage a part of OpenExpress to i) build disaggregated pooled memory over a cache coherent interconnect for accelerators and ii) process data near storage class memory, which requires different computational IP cores for such new interface and in-storage processing acceleration.

6 Acknowledge

The author thanks Raja Appuswamy and Heiner Litz for shepherding this paper. The author also thanks anonymous reviewers for their constructive feedback as well as MemRay for their sample donations and technical support. This work is supported by MemRay grant (G01190170) and performed as a part of its open NVMe interface research project.

7 Conclusion

We propose an open-source hardware research platform, called OpenExpress. OpenExpress is an NVMe host accelerator IP for the integration with an easy-to-access FPGA design. We prototype OpenExpress on a commercially available Xilinx FPGA board and optimize all the logic modules to operate a high frequency. Using a thorough evaluation, we demonstrate that OpenExpress, with a maximum bandwidth of 7 GB/s, is an open research platform that can further storage system research related to fast NVM devices.

Abstract

The high packet rates handled by network appliances and similar software-based packet processing applications place a challenging load on caches such as flow caches. In these environments, both hit rate and cache hit latency are critical to throughput. Much recent work, however, has focused exclusively on one of these two desiderata, missing opportunities to further improve overall system throughput. This paper introduces *Bounded Linear Probing* (*BLP*), a new cache design optimized for network appliances. BLP works well across different workloads and cache sizes by balancing between hit rate and lookup latency. To accompany BLP, we also present a new, lightweight cache eviction policy called Probabilistic Bubble LRU that achieves near-optimal cache hit rate (assuming the algorithm is offline) without using any extra space. We make three main contributions: a theoretical analysis of BLP, a comparison between existing and proposed cache designs using microbenchmarks, and an end-to-end evaluation of BLP in the popular Open vSwitch (OvS) system. Our end-to-end experiments show that BLP is effective in practice: replacing the microflow cache in OvS with BLP improves throughput by up to 15%.

1 Introduction

Network virtualization is a core infrastructure component for cloud computing. In virtualized networks, virtual switches route packets between virtual machines (VMs) and between VMs and the outside world. Like the VMs themselves, the virtual switch resides in the hypervisor. The high speed of modern NICs—40Gb/s, 100Gb/s, and even 200Gb/s [2]—makes virtual switches a critical network performance bottleneck.

Many software-based network systems, such as appliances, middleboxes, packet analytic frameworks, and virtual switches, rely on fast flow caches to achieve good average-case performance [10, 38]. These environments impose challenging—and, indeed, somewhat contradictory—requirements upon the caches they use. First, of course, they benefit from high hit rates. But, either to avoid wasting memory or to fit in faster levels of the CPU cache, they also strive to be compact. In addition, because of the high rates at which packet-centric systems operate, the flow cache lookups must have extremely low latency.

These competing requirements place such systems in an interesting middle ground compared to much of the prior work, which usually fall into one of the two extremes. Higher-level caching systems such as web caches and memcached often adopt comparatively expensive cache designs and replacement algorithms to maximize hit rate [9, 26]. On the other hand, CPU caches have such tight timing requirements that they use very simple set associative designs that sacrifice hit rate for extremely low access time measured in clock cycles.

In this paper, we present the design, theoretical analysis, and empirical evaluation of a new cache design called *Bounded Linear Probing*, or BLP, that provides higher cache hit rates than simple set-associative designs, while remaining fast and hardware-friendly. BLP achieves low latency by ensuring *purely local access* to the cache data structure: Look-ups require a single read that spans at most two consecutive CPU cache lines. At the same time, BLP allows *non-local propagation* of full buckets. A basic set-associative cache provides only one location for a given set of objects. BLP allows those objects to creep into later bins, and over repeated inserts and evictions, this property allows high-occupancy bins to shift some of their load to nearby, less-occupied bins. To better serve skewed workloads, we accompany it with a cache eviction algorithm called *Probabilistic Bubble LRU*, or PBLRU, that fulfills the same design goals as BLP: It requires no extra space, adds little latency overhead and achieves near-optimal cache hit rate.

BLP is a simple and effective design for performance-critical software caches; despite its simplicity, we believe it to be a novel design point in the space of "cache table" designs, and provide a theoretical analysis of why it provides an improved hit rate over basic set-associative designs that access the same number of elements. The result is a design that performs nearly as well as the fastest set-associative designs, with hit rates that are closer to that of more advanced, yet expensive, designs such as cuckoo or hopscotch-based caches. We validate these results empirically using both microbenchmarks and by incorporating BLP into Open vSwitch [30], the most popular virtual switch, which is widely used in production. Replacing the microflow cache in OvS with BLP improves throughput by up to 15%: Its lookup latency is about 10 clock cycles longer than that of the basic set-associative design, but BLP's increased cache hit rate more than compensates for the higher latency. In contrast, many of the more expensive

[*] work started while at Carnegie Mellon University

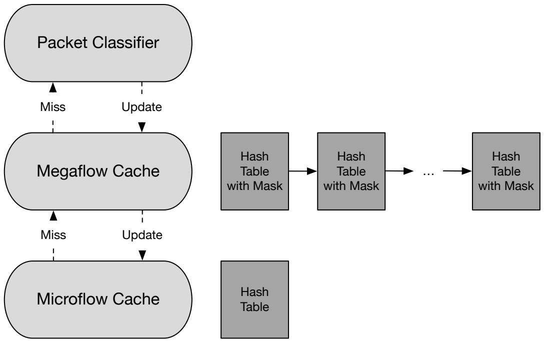

Figure 1: Flow Caching Hierarchy in Open vSwitch

cache designs that can achieve high cache hit rates do not justify their huge latency penalties. Our new cache eviction algorithm PBLRU further improves the throughput by up to 10% even if the workload is only modestly skewed.

2 Flow Caching in Open vSwitch

Open vSwitch achieves high performance through extensive flow caching. Open vSwitch's caching hierarchy consists of three layers: a microflow cache, a megaflow cache, and a caching-aware packet classifier, as illustrated in Figure 1.

The first cache that a packet encounters in OvS is the *microflow cache*, which caches forwarding decisions for each transport connection (or *microflow*). The microflow cache is a hash table that maps microflows to OpenFlow flows if there is an exact match using all the packet header fields. If the packet misses in the microflow cache, then OvS does a lookup in its *megaflow cache*. This cache supports wildcard matching but does not use flow priorities. The megaflow cache is a set of n hash tables, each with a unique wildcard mask. For each hash table, the lookup key is the packet header after applying the mask associated with the table. These hash tables are reactively created and populated by the packet classifier. Because looking up a packet in the megaflow cache searches all n hash tables, it is more expensive than a microflow cache lookup. Therefore, the cache hit rate of the microflow cache (the first cache) is critical to the performance of OvS.

The key observation that inspired our work is that although a microflow cache miss is expensive, it is not *immensely* more expensive than a microflow hit. In typical deployments, where the average number of hash table searches per megaflow lookup is small (as noted in Section 7.2 of Pfaff et al. [30]), the microflow miss penalty is only hundreds to thousands of cycles on modern server CPUs. Hence, making the correct tradeoff between cache hit rate and lookup latency is crucial to the system throughput. In contrast, much of the previous work on software cache designs focuses primarily on improving cache hit rate [9, 14, 18, 13]. In the situations studied by previous work, optimizing for hit rate makes sense: the cache misses in these systems were much more expensive than a hit because they often involved querying very slow backend services such as a database. The cache hit rate, therefore, determines not only the throughput, but also end-to-end request latency [14, 27].

The rest of this paper uses the OvS microflow cache as a case study to analyze and evaluate various design options and demonstrate the effectiveness of our new caching algorithm, Bounded Linear Probing (BLP). We show how BLP can balance cache hit rate (and thus miss penalty) and lookup latency to improve the throughput of Open vSwitch compared to alternate designs.

3 Background and Related Work

3.1 Network Packet and Flow Caching

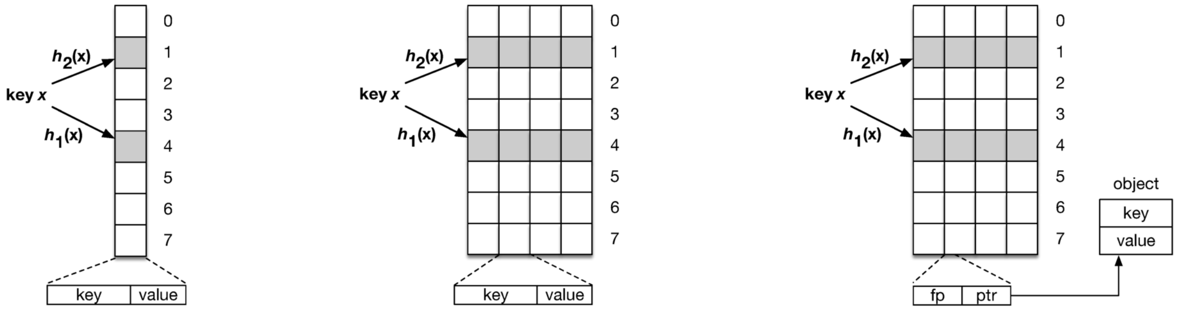
Caching is a common and effective technique for speeding up network packet processing; existing solutions include hardware-based [12, 38, 29] and software-based [10] approaches. Many early hardware routers used flow caching to achieve fast average-case performance. In the modern era, most hardware routers and switches have moved to more costly, but guaranteed-performance designs, such as TCAMs, to be able to provide their maximum forwarding rate under arbitrary (and possibly malicious) traffic. Software switches, however, broadly retain a cache-based design [3, 36].

3.2 Hash Table Options For Caching

Caching is typically managed using a hash table as its basic data structure, but unlike the "full" problem of a general hash table, caches gain an extra degree of freedom: By definition, they do not need to store all possible keys and may choose to evict an existing item.

One of the contributions of this paper is to explore the tradeoff between the cache's hit rate and the lookup/insertion cost imposed by its hash table structure. To illustrate this tradeoff, we begin in Section 4 by describing points that operate at two extremes of the spectrum: First, a basic set-associative cache, in which an item can be stored only in one of m different slots shared by all other items that hash to the same bucket (row) of the hash table. This design is fast but achieves a relatively low hit rate. Next, we introduce two more advanced cache designs that incorporate ideas from cuckoo and hopscotch hashing, which can achieve much higher table occupancy (and thus hit rates), but at the cost of more expensive inserts and lookups. In the rest of this section, we present prior work on fast caches, including a brief introduction to cuckoo and hopscotch hashing.

Cuckoo and hopscotch hashing Cuckoo [28] and hopscotch [21] hashing both aim to achieve high table occupancy (upwards of 90%) in an "open-addressed" hash table design, i.e., one that does not need to use linked lists to store data items. The pointer chasing of a linked-list design adds substantial lookup latency, and the pointers themselves can add substantial memory overhead, especially when the entries in the table are small, which is the case for flow caches.



(a) Basic cuckoo hash table

(b) 4-way set-assoc. cuckoo hash table

(c) Partial-key cuckoo hashing

Figure 2: Cuckoo Hashing

Both designs share a theoretical basis that allowing items to occupy a small number of slots that are "not too close" to each other allows buckets that would otherwise be too full to spill their contents recursively into other, hopefully less-full buckets. (Recall that when throwing n balls into n bins, the maximally loaded bin will have in the range of $(2 + o(1)) \times \frac{\log n}{\log \log n}$ elements. With 1 million entries in a table, this would result in more than 10 elements falling into the most-loaded bin. Traditional linear probing approaches handle this by keeping the table occupancy under 50%, which conflicts with the desire for high table occupancy.)

Cuckoo hashing Cuckoo hashing [28] maps each key x to two candidate buckets using two hash functions (two is a common choice, but using a larger number of hash functions is also possible). Each key is stored in one of these candidate buckets. Figure 2a shows a basic cuckoo hash table with eight buckets, where key x maps to bucket 4 by $h_1(x)$ and bucket 2 by $h_2(x)$. To lookup a key in a cuckoo hash table, we need to check both candidate buckets to see if the key resides in either bucket. Inserting a new key might relocate an existing key to its alternate bucket. In its basic form, cuckoo hashing provides an expected table load factor of 50%. By using 4-way or higher set-associative buckets, as shown in Figure 2b, the table space utilization increases to over 90% [17].

Partial-key cuckoo hashing [24, 18], illustrated in Figure 2c, extends the basic cuckoo hashing by storing in the table itself only a short hash of the key along with a pointer to the value. This short hash, or *fingerprint*, serves two purposes. First, during lookups, it eliminates the necessity of retrieving full keys unless the fingerprints match. Although false positives could happen, the probability is considerably low. For example, with 1-byte fingerprints, the chance of fingerprint-collision is less than 0.4% ($1/2^8$). Second, fingerprints are enough to derive the alternative bucket for a key, thereby allowing insertion to complete without retrieving the full keys. Replacing full keys with fingerprints substantially improves the memory efficiency and the performance of cuckoo hash tables.

Recent work proposes using a partial-key cuckoo hashing–based key/value cache to improve the performance of OvS (Cuckoo Distributor [37]). For each microflow, it stores a 16-bit fingerprint of the full packet header (key) along with a 16-bit megaflow index (value) in the table. This approach achieves high cache hit rate, but, as we will show in Section 7, the need to access two unrelated cache lines is detrimental to its lookup latency, resulting in lower overall performance.

Full key versus fingerprint The decision to store full keys versus smaller fingerprints goes beyond cuckoo hashing. Open vSwitch itself has two implementations of the microflow cache. The first implementation, called the exact-match cache or EMC [1], matches all the packet header fields to avoid false positives. Because each entry in EMC takes more than 550 bytes, it can only cache a small number of microflows. As of OvS v2.10.1, the default EMC configuration has a capacity of 8192 entries. This limitation causes severe performance drops when the number of active flows is large, as most packets will miss the microflow cache and trigger megaflow lookups [37].

To overcome this shortcoming, OvS introduced a second implementation, called the signature-match cache or SMC [4]. The signature-match cache is a 4-way set-associative cache that maps 16-bit fingerprints, instead of full packet headers, to megaflows. The megaflow entry can then be used for verification of the full flow header. This simple cache design has fast lookup latency; however, as our analysis demonstrates in Section 4, it suffers from low cache hit rate. This is the flow cache upon which the rest of our paper focuses.

Hopscotch Hashing Hopscotch hashing [21] is an open addressed hashing scheme that uses multi-phased probing and displacement to resolve hash collisions. In hopscotch hashing, a key hashed to a bucket will always be stored in that bucket, or in one of the next $H-1$ buckets, where H is a constant. In other words, a bucket and its next $H-1$ neighbors form a *virtual bucket* with H slots. To accelerate key lookup and insertion, each bucket maintains an H-bit bitmap, indicating which of the H slots in its virtual bucket contain keys that are hashed to the bucket. These bitmaps are updated during key displacement.

Because all the candidate buckets of a key are contiguous in memory, hopscotch hashing has good cache locality. Our cache design, BLP, resembles hopscotch hashing in the sense that it allows a key to be placed in one of the H buckets starting from the one it is hashed to.

3.3 Hardware Cache Designs

Although the focus of this work is on software caches, there are many parallels to related work on hardware caches.

Cache hit rate versus lookup latency Balancing the cache hit rate and lookup latency has been studied in the context of DRAM hardware caches. Alloy Cache [31], for example, improved performance over prior work by reducing the hit latency, even though doing so slightly reduced the hit rate.

Set-associative caches Hardware caches are often organized into *rows* (i.e., buckets) and *ways* (i.e., slots). An m-way set-associative cache uses a subset of the address bits to index into a row; the cache block (cache line) can be stored in one of the row's m ways. To balance the load across rows, researchers have proposed using a hash of the block address as the index [23] as is commonly done in software-based hash tables and caches.

Skewed-associative caches and cuckoo-like cache designs Skewed-associative caches [35] extend this idea and allow each way to be indexed with a different hash function. In an m-way skewed-associative cache, a cache block B could be stored in row $h_i(B)$ for way i, for $0 \le i < m$.

Inspired by cuckoo hashing, zcache [34] is an extension of skewed-associative caching. Instead of replacing one of the m existing blocks on a cache miss, it performs a breadth-first search to find additional eviction candidates. After picking a victim entry, it relocates blocks on the cuckoo path to accommodate the new block. These designs are not well-suited for high speed, low latency software caches for packet processing, as they require several cache line reads per lookup.

3.4 Cache Design and Eviction Policy

A large amount of prior work on caching [7, 20, 32, 9, 8, 14, 13] focuses on cache eviction policies. Improved policies, ranging from LRU and LFU to modern alternatives such as LHD [9], increase cache hit rate under skewed workload distributions by biasing eviction towards likely less-useful candidates.

The majority of prior cache eviction algorithms require additional tracking metadata to implement their eviction policies. In contrast, our new algorithm, PBLRU, adds no space overhead. The most related work to our algorithm is an earlier paper by Zhang and Xue [39] that explores the same *bubbling* idea. We discuss the differences between PBLRU and their algorithm, DC-Bubble, in Section 5.3.

4 Design and Analysis

We begin by presenting two baseline cache designs, a set-associative option and a "cuckoo-like" option, and analyze their expected hit rates. We then introduce bounded linear probing and its analysis using the same framework.

To understand the expected hit rate, we assume that the working set is fixed, and that each lookup key is drawn *uniformly* at random from that working set. We only analyze uniform distributions in this section, for the following two reasons: a) prior works studied caching performance on uniformly-distributed workloads [25] and b) the expected hit rate under the uniform distribution is easier to analyze, yet it provides a *lower bound* on the hit rate under any other distribution (see Appendix C for a formal argument). We use α to denote the ratio of the working set size to the number of entries in the cache table, which we call the *oversubscription factor*. When $\alpha < 1$, the cache has more capacity than there are items in the working set. We determine hit rate in terms of α, and then provide numerical interpretations for some values observed in the OvS workloads, such as $\alpha = 0.95$. In Section 7, we show empirical hit rate curves for real implementations across a range of α values.

All of the designs we evaluate use some amount of set-associativity. The caches are partitioned into n buckets, each containing m entries. To determine if an item is in a bucket, the implementation examines whether it is stored in *any* of the entries in the bucket. The table contains a total of $n \times m$ entries, and the working set has size $\alpha \times n \times m$. To store a key-value pair (k, v), one hashes the key and determines in a table-specific way a set of (one or more) buckets that could hold the key, and stores both *fingerprint*(k) and v in an appropriate entry. In OvS, v is a pointer to a megaflow cache entry. Each design uses a different algorithm to decide which entry of the table will store a given pair.

4.1 Analytical Framework for Hit Rate

To analyze the expected hit rate of a cache design, it suffices to estimate the expected number of keys the cache could hold after a sufficiently long warm-up period. This is because, in our formulation, each cache access is uniformly random, so the cache hit rate is equal to the total number of cached keys divided by the size of the working set. Moreover, the number of keys stored in all the cache designs we evaluate never decreases with an increasing number of cache accesses, and it has a maximum value of $n \times m$. Therefore, it will eventually stop increasing. Denote the *final* number of occupied entries in bucket i by c_i. The probability of a cache hit is equal to

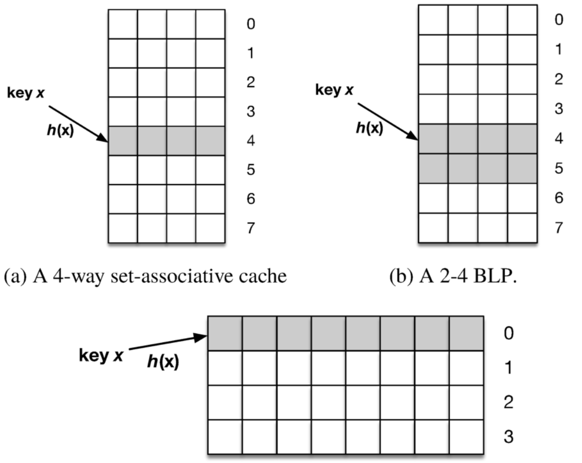
$$\frac{c_0 + \cdots + c_{n-1}}{\alpha n m}. \tag{1}$$

By symmetry, all c_i have the same expected value. Hence, by linearity of expectation, the expected cache hit rate is $\mathbb{E}[c_i]/(\alpha m)$. For each cache design, we describe how its hit rate is estimated from a high level, and leave all the details to appendices.

4.2 Set-associative Cache

We start with a simple design—a set-associative cache. In an m-way set-associative cache, each item is mapped to a bucket by a hash function h, and each bucket has m slots. Figure 3a and Figure 3c show 4-way and 8-way set-associative designs for identical-capacity caches respectively.

The lookup algorithm is straightforward. Given a key k, it checks bucket $h(k)$ for an entry containing *fingerprint*(k). Because it is possible for two different keys to have the same fingerprint, if the fingerprint matches, the full key is fetched to further verify it was indeed the correct one. The chance of fingerprint collision is small, roughly $m/2^{|\text{fingerprint}|}$. Insertion looks for an empty entry in bucket $h(k)$. If one exists, the new key-value pair goes there; if not, we evict a random entry in the bucket to make room for the new item.[1]



(a) A 4-way set-associative cache

(b) A 2-4 BLP.

(c) An 8-way set-associative

Figure 3: Set-associative Cache and BLP

We model the expected hit rate when performing a lookup on a uniformly random key from the working set using the standard balls-into-bins problem. We view each key in the working set as a ball and each bucket as a bin. Assuming the hash function is perfectly random, mapping the keys to the buckets can be viewed as placing αnm balls randomly into n bins, where each bin can hold at most m balls. When $\alpha \leq 1$, the data structure as a whole has sufficient *total* space for all balls, i.e., if the balls are placed evenly across the bins, no bin will overflow. However, a small fraction of the bins will still have more than m balls mapped to them. For set-associative caches, that means some keys (balls) will map to such buckets (bins) that are full, triggering a cache miss and an eviction.

Using the aforementioned analytical framework, our analysis shows that $\mathbb{E}[c_i] \approx m - \sum_{t=0}^{m}(m-t) \cdot \frac{(\alpha m)^t}{e^{\alpha m} t!}$. (The full derivation of this result is listed in Appendix A.) Given $\alpha \approx 0.95$ (1,000,000 keys, 2^{20} cache entries), the cache hit rate of a 4-way set-associative cache is ~ 82% and the cache hit rate of an 8-way set-associative cache is ~ 88%. Both 4-way and 8-way set-associative caches have low lookup latency: assuming each item has a size of 32 bits (16-bit fingerprint + 16-bit value), each lookup only requires 1 cache line read. The downside, however, is their relatively low cache hit rates. As we will show in Section 7, low hit rates hurt throughput in many scenarios.

4.3 Cuckoo-lite

The second cache design, which we call *cuckoo-lite*, is very similar to cuckoo hashing. In an H-m cuckoo-lite cache, each bucket has m slots. Each key is mapped to H buckets by hash functions $h_1, h_2, \cdots, h_H$. A 2-4 cuckoo-lite cache shares the same structure as the 2-4 cuckoo hash table (Figure 2b).

Lookup in a cuckoo-lite cache is the same as lookup in a cuckoo hash table. Insertion, however, differs: To insert a key x to a 2-4 cuckoo-lite, we examine whether there is an empty slot in either of x's two candidate buckets. If there is, we insert x there; otherwise, we choose a random slot from the two buckets to replace with x. In other words, instead of searching for a cuckoo path to displace existing keys, cuckoo-lite simply *evicts* one of the existing keys to make room for the new key. This difference highlights the flexibility of a cache over a hash table. In the latter, every inserted key needs to be stored in the table. When there is no empty slot for the new key, the only options are to relocate an existing key via a sequence of key displacements, resize the table, or return an error. A cache, however, can evict arbitrary keys.

Although cuckoo-lite never relocates existing keys, it can achieve at least the same load factor as a cuckoo hash table after a sufficiently long warm-up period.

Following the analytical framework, the expected cache hit rate is at least $\frac{\text{load factor}}{\alpha}$. Prior work [17] estimated the achievable load of cuckoo hashing under various parameters using simulation. In particular, their experimental results showed that for 2-4 cuckoo hashing, 93% load is achievable 99% of the time.[2] Their results, when translated to a 2-4 cuckoo-lite cache, indicate that for $\alpha \leq 0.93$, the expected hit rate must be *at least* 0.99. Therefore, for $\alpha > 0.93$, the expected hit rate is at least $0.99 \times 0.93/\alpha$. Given $\alpha \approx 0.95$, 2-4 cuckoo-lite achieves close to 100% cache hit rate. The drawback, however, is the need to access two unrelated cache lines, which increases lookup latency.

4.4 Bounded Linear Probing (BLP)

We now present our cache design—Bounded Linear Probing, or BLP. The core idea behind BLP is simple: instead of restricting a key to only one bucket, or multiple unrelated buckets, BLP (like hopscotch hashing) can store it at one of the H buckets starting from the one to which it hashes. Unlike hopscotch hashing where each bucket maintains an H-bit bitmap for key displacement, BLP never relocates keys, and searches for all H buckets during the lookup, eliminating the need for per-bucket bitmaps. We call a BLP cache with m-way set-associative buckets, where the key can be in any of the $H-1$ subsequent buckets, an H-m BLP. Figure 3b demonstrates a 2-4 BLP. In this example, key x is mapped to

[1] We use random eviction in all cache designs, and discuss other eviction policies in Section 5.

[2] Their experiments are performed with 64K entries and a fixed amount of work per insertion.

Algorithm 1: `Lookup(`k`)` for 2-4 BLP

```
f = fingerprint(k);
i = h(k);
if bucket[i] has (f,ptr) then
    if ptr.key == k then
        return ptr.value;
j = (i+1) mod n;
if bucket[j] has (f,ptr) then
    if ptr.key == k then
        return ptr.value;
return not found;
```

Algorithm 2: `Insert(`k,v`)` for 2-4 BLP

```
f = fingerprint(k);
i = h(k);
if bucket[i] has an empty entry then
    add (f, ptr) to bucket[i];
    return Done;
j = (i+1) mod n;
if bucket[j] has an empty entry then
    add (f, ptr) to bucket[j];
    return Done;
select a random entry e from bucket[i] ∪ bucket[j];
replace e with (f,ptr);
return Done;
```

bucket 4 by hash function h. Therefore, x can be placed in either bucket 4 or bucket 5.

The lookup algorithm is straightforward. Given a key k, if any one of the H buckets contains *fingerprint*(k), the full key and value fetched via the pointer stored in the table. If the full key matches k, the algorithm returns the value, otherwise it returns "not found." See Algorithm 1 for the pseudocode of lookup for 2-4 BLP.

To insert a key-value pair (k,v) to a H-m BLP, the algorithm first checks if there is an empty slot in any one of the H buckets starting from $h(k)$. If so, the item is inserted to the empty slot; otherwise, the algorithm chooses an entry from the H buckets randomly (unless there is an entry with the same fingerprint, in which case the algorithm always chooses the matching entry), and replaces that entry with the new item. Algorithm 2 contains the simplified pseudocode for insertion for 2-4 BLP. Like cuckoo-lite, BLP does not relocate existing keys and reaches its maximum hit rate only after a warm-up period. Appendix D analyzes the relationship between the cache hit rate and the warm-up time in more details.

4.5 Why BLP might be better?

Intuitively, a 2-4 BLP cache should have higher cache hit rate than a 4-way or 8-way set associative cache, but lower hit rate than 2-4 cuckoo-lite. With 32-bit keys, a lookup in 2-4 BLP will read one or two *consecutive* cache lines; therefore, it has higher latency than 4-way and 8-way set-associative cache, but lower than 2-4 cuckoo-lite.

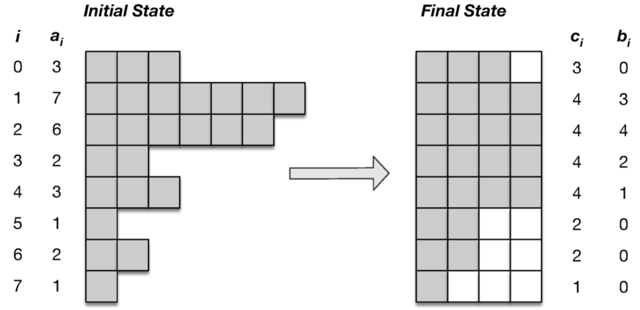


Figure 4: Analysis of BLP

Expected cache hit rate We use the following approach to analyze the expected hit rate of 2-4 BLP. We have two arrays a and b, where a_i is the number of keys from the working set that map to cache bucket i and b_i is the number of keys that spill from bucket i to bucket $i+1$ in the final state (after a sufficiently long warm-up period), for $i = 0, \dots, n-1$. See Figure 4 for an example.

In the final state, a total of $b_{i-1} + a_i$ keys are served by bucket i. When $b_{i-1} + a_i \le m$, bucket i has enough entries to store all these keys, and no keys will spill to bucket $i+1$, i.e., $b_i = 0$. If $m < b_{i-1} + a_i \le 2m$, bucket i can store m keys, and the extra $b_{i-1} + a_i - m$ will spill to the next bucket.[3] If $b_{i-1} + a_i > 2m$, then bucket i will store m keys, and m of the extra keys will spill to bucket $i+1$. Summarizing the above relations, we have the following equations for b_i and c_i:

$$b_i = \begin{cases} 0 & \text{if } b_{i-1} + a_i \le m, \\ m & \text{if } b_{i-1} + a_i \ge 2m, \\ b_{i-1} + a_i - m & \text{otherwise,} \end{cases} \tag{2}$$

$$\text{and } c_i = \min\{b_{i-1} + a_i, m\}, \tag{3}$$

where we assumed $b_0 = b_n$.

Analyzing b_i By Equation (3), the key to compute $\mathbb{E}[c_i]$ is to estimate the distribution of b_i, which is described by its probability densities $(p_0, \dots, p_m)$. We observed that b_i has almost identical distribution regardless of i, i.e., the same density vector $(p_0, \dots, p_m)$ describes all n distributions of $b_0, \dots, b_{n-1}$. Note that the above observation only concerns the marginal distribution of each b_i, and it does not assert how $b_0, \dots, b_{n-1}$ are jointly distributed. In fact, b_i and b_j for close i, j can be (very) correlated. We then observe that b_{i-1} is almost independent of a_i, the number of keys mapped to bucket i, and the distribution of a_i has a closed form. Therefore, we are able to derive a system of linear equations on the probability densities based on Equation (2). (The full derivation and solutions are listed in Appendix B.) For $\alpha = 0.95$ and $m = 4$, we calculated $\mathbb{E}[c_i] = 3.59$, and by Equation (1), the expected hit-rate is ~ 94%.

[3] Note that we only allow keys to spill to the next bucket. By definition, b_{i-1} is an integer between 0 and m, which implies that $b_{i-1} + a_i - m \le a_i$. Hence, there are sufficient keys that are mapped to bucket i to spill to the next bucket.

Design	Lookup Speed (cache line reads)	Hit Rate
4-way set-assoc	1	~ 82%
8-way set-assoc	1	~ 88%
2-4 cuckoo-lite	2 *unrelated*	~ 99%
2-4 BLP	1.5 *consecutive*	~ 94%

Table 1: Qualitative comparison of cache designs with α=0.95

Summary Table 1 summarizes 4-way set-associative, 8-way set-associative, 2-4 cuckoo-lite and 2-4 BLP caches in terms of lookup speed and estimated cache hit rate with $\alpha = 0.95$. 2-4 BLP increases the cache hit rate by 12% and 6% compared with 4-way and 8-way set associative caches, respectively, at a cost of 0.5 cache line reads on average.

5 Better Cache Replacement with Probabilistic Bubble LRU

The choice of cache eviction policy is largely orthogonal to the cache design. The cache design proposed in this paper, however, raises interesting and challenging requirements for the cache replacement policy. Like the cache design itself, we need the replacement policy to be fast and memory efficient; we also want a policy that can achieve near-optimal cache hit rate, especially in skewed workloads.

5.1 Traditional LRU approximations are too expensive

Perhaps the most commonly-deployed cache eviction policy is the least recently used (LRU) replacement. Traditional LRU suffers from several drawbacks, including high space overhead [9]. Even its approximations, such as CLOCK [15], requires maintaining 1-bit per key of state [18]. Although many applications can tolerate this amount of space overhead, introducing *any* extra cache management state is likely both to break the cache's careful memory alignment and to increase latency because of state updates.

5.2 Probabilistic Bubble LRU (PBLRU)

To address the aforementioned concerns, we propose a simple cache eviction algorithm that adds *no* extra space and produces near-optimal cache hit rate by combining both recency and frequency information. The core idea behind our algorithm is to assign different priorities to each slot in a bucket: the first slot has the highest priority, the second one has the second highest priority, so forth. After a cache hit, we *promote* the lookup key's priority by exchanging it with the key in the next highest priority slot (unless it is already stored in the first slot of the bucket). When we need to select a victim, we evict the key in the lowest priority slot (i.e., the last slot in a bucket). We call the process of promoting an entry *bubbling* and our algorithm *bubble LRU*. Bubbling effectively achieves the combination of LRU and LFU (least frequently used) without storing any extra information.

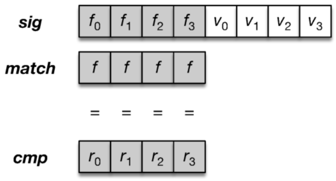

Figure 5: SIMD-optimized 4-way associative cache

Applying Bubble LRU to BLP Applying bubble LRU to set-associative caches is straightforward because each key is mapped to only one bucket. In BLP, however, each key could be placed in two or more consecutive buckets. To avoid introducing more complicated and expensive bucket selection logic, we simply pick a random bucket to apply bubbling.

Probabilistic Bubbling Although the basic bubble LRU does not use any extra space, it still requires a memory write on every lookup, which puts more pressure on the memory subsystem. To alleviate this issue, we adopt an optimization called *probabilistic bubbling*. With probabilistic bubbling, a cache hit does not always promote an entry's position in the bucket. Instead, we promote every n-th hit on average to reduce the number of memory writes. Intuitively, probabilistic bubbling should not hurt the cache hit rate because hot keys will still get promoted more often than cold keys. Our experiments in Section 7 demonstrate that PBLRU substantially improves the cache hit rate with modest overhead of lookup latency.

5.3 PBLRU and DC-Bubble

A non-probabilistic design of the bubble LRU with higher metadata tracking overhead called DC-Bubble was invented in 2009 by Zhang et al. [39]. Instead of always evicting the last entry in a bucket, DC-Bubble implements a more expensive replacement policy that requires updating an extra per-bucket bit on most accesses, which they use to track whether the last access to the same bucket is a hit or a miss. If the last access is a hit, then the last entry is replaced; otherwise, they evict the first entry, promote *all* the rest entries in the bucket, and put the new entry in the last slot.

PBLRU has two advantages over DC-Bubble. First, the authors of DC-Bubble designed their algorithm in the context of hardware cache where operations like setting a flag are cheap, but such operations incur non-negligible overhead in software caches. Second, it is non-trivial to convert their design to a probabilistic version. In our evaluation, we show that PBLRU has substantially lower latency and moderately higher cache hit rate than DC-Bubble.

6 Implementation

We have implemented all of the cache designs in C++. Like stock OvS's SMC (Section 3), we use 16-bit fingerprints and 16-bit values. Within each bucket, we store the fingerprints packed together followed by packed values. We applied several optimizations to improve the cache lookup performance:

SIMD-optimized Lookup To accelerate lookups, we use SIMD instructions to compare multiple fingerprints at the same time (similar to techniques used by Google's Swiss Tables [6]). Figure 5 shows how the lookup works in a 4-way set-associative cache. The stock OvS design does not use SIMD-accelerated reads for its microflow cache, so to ensure a fair basis for comparison, we implemented this optimization and use it as the baseline for comparison.

To search for fingerprint f in a bucket, we first duplicate it four times and store it in a 64-bit integer `match`. Then, we load the first 64 bits of the bucket into another 64-bit integer `sig`. We compare the packed 16-bit integers in `sig` and `match` for equality, storing the results in `cmp`. `cmp` consists of 4 16-bit integers r_0,r_1,r_2 and r_3, where r_i is 0xFFFF if $f_i = f$ and 0 otherwise. We can then count the number of trailing zeros in `cmp` to figure out which slot f matches in the bucket.

Lookup in an 8-way set-associative cache works similarly to the 4-way set-associative cache, but uses 128-bit integers instead of 64-bit integers. For 2-4 cuckoo-lite, because the eight candidate fingerprints are not consecutive, we have to first copy the fingerprints from two buckets into one 128-bit integer, then perform packed integer comparison.

SIMD-accelerated lookup in 2-4 BLP works as follows: The eight candidate fingerprints are not contiguous in memory (unlike cuckoo-lite), but are separated by the 64 packed value bits. Therefore, instead of *copying* fingerprints, we load *both* buckets into a wider 256-bit integer and mask off all the value bits. Eliminating the extra load instruction reduces the lookup latency by ~ 10% and makes BLP more SIMD-friendly than cuckoo-lite.

Buffer Bucket In 2-4 BLP, if the lookup key hashes to the last bucket of the table, both the first and the last bucket are searched. This corner case requires both a second cache line read and, more importantly, an extra branch. To avoid incurring branch prediction misses, we added a *buffer bucket* following the original cache table. This buffer bucket has minimal impact on the cache miss rate but improves lookup speed: When the lookup key hashes to the last bucket, and that bucket is full, the new key spills to the buffer bucket instead of wrapping around the table. At lookup time, we search both the last bucket and this buffer bucket, which avoids the branch misprediction and allows for processor prefetching[4]. One thing which worth mentioning is that this optimization is specific to BLP and does not work well with other cache designs — it breaks the alignment of the number of buckets (typically a power of 2). Moreover, the extra space given by this buffer bucket is negligible compared to the size of the cache. We therefore only apply the optimization to BLP.

Batched Lookup with Prefetching We use batched lookup with prefetching to overlap bucket computation with memory reads, which minimizes the impact of DRAM access latency. This technique is common in many existing packet processing applications and frameworks [40, 22, 11].

7 Evaluation

We present our evaluation top-down: We begin with a description of the experimental setup followed by a set of end-to-end benchmarks that compare the different cache table designs (described above) in the context of Open vSwitch. These results demonstrate the benefits and generality of BLP in a realistic packet processing application. Next, we use a set of microbenchmarks to understand more deeply the fundamental tradeoffs that each of the cache design brings to the table.

7.1 Experiment Setup

Our experiments are conducted on c220g2 instances from CloudLab [33]. Each of the instances is equipped with the following hardware:

Hardware	Description
CPU	2× Intel Xeon E5-2660v3 CPUs (2.60GHz)
DRAM	160 GiB DDR4 Memory
L3 Cache	2× 24 MiB
NIC	Intel X520 dual-port 10GbE

We also controlled for the following factors, which otherwise had noticeable effects on our results:

Random Number Generator Throughout the experiments, we use PCG-32 [5], a fast and statistically robust algorithm for our random number generation.[5]

Cache Warming As discussed in Section 4, 2-4 cuckoo-lite and 2-4-BLP do not displace keys. Instead, they depend purely on cache warming to reach the maximum hit rate. Therefore, in each experiment, we first warm the testing cache until it reaches a stable state, i.e., the cache hit rate stops increasing.

All experimental results reported below are the average of five runs. The variance was low, so we omit error bars from our graphs. Because the differences between many of the designs are small—in the range of 10% or so—while the absolute performance differences between a high cache hit rate (low alpha) and a low cache hit rate (high alpha) are relatively large, we deliberately choose not to start axes at 0; the graphs are "zoomed-in" to the regions of interest.

7.2 End-to-end Benchmarks

As a concrete end-to-end benchmark using an important application, we modified the microflow cache in Open vSwitch (v2.10.1) to use the various cache designs described above.

Open vSwitch was running on the a c220g2 instance with two 10Gb Ethernet ports, port 0 and port 1. To accurately

[4] Note that this optimization means that no keys will ever spill *into* the first bucket.

[5] The quality of the random number generator directly affects the cache hit rates. Unintended workload locality (i.e., back-to-back keys that hash to nearby buckets) produces higher than expected hit rates; poor random number generators exacerbate this effect. Earlier in the research process for this work, a bad, hand-crafted random number generator caused this issue.

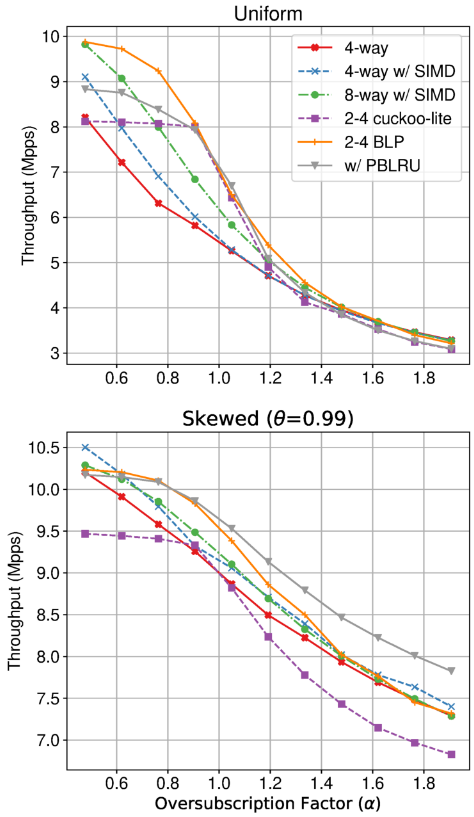

Figure 6: End-to-end Benchmark: Throughput

measure the throughput of Open vSwitch, we instruct the traffic generator to send synthetic network packets to port 0 of OvS and configure flows in OvS to have only one action: send packets out via port 1. This setup allows us to measure how fast OvS can process incoming packets by simply measuring the RX throughput on the traffic generator. We configured Open vSwitch to use one thread per port to handle network packets. On the traffic generator, we used MoonGen [16] to generate minimum-sized (64B) UDP packets. We configured it to use 4 TX threads, because a single thread could not saturate the 10Gb link.

Because public datasets are not readily available[6], we created a synthetic rule set and traffic patterns that creates roughly 20 hash tables in the megaflow cache, similar to the one used by Wang et al. [37]. By default, OvS's SMC has a total of 2^{20} entries (4 MiB), and we use the same cache size in our end-to-end benchmarks. We conducted our experiments with oversubscription factors between 0.5 and 2 because we believe they are the most plausible values in actual deployments – too low of oversubscription factor leads to underutilized caches while too high of oversubscription factor diminishes the effect of caching.

In our experimental result figures, "4-way" means a 4-way set associative cache (OvS's default SMC implementation without our SIMD optimizations), "4-way w/ SIMD" is the same cache design but with SIMD-optimized lookup. "8-way w/ SIMD," "2-4 cuckoo-lite," and "2-4 BLP" are 8-way set associative, 2-4 cuckoo-lite and 2-4 BLP caches respectively, each with their own SIMD-optimized lookups. "w/ PBLRU" is 2-4 BLP with PBLRU instead of random eviction. We use these notations throughout microbenchmarks and end-to-end benchmarks.

The overall throughput results are shown in Figure 6. Under a uniform workload, the higher hit rate achieved by BLP causes it to outperform alternative designs through a wide range of α values. Under a Zipf distribution of skewness 0.99 (denoted by θ) [19], BLP similarly outperforms in the middle range, losing to the lower-latency 4-way and 8-way SIMD lookups only at very low and very high oversubscription factors. PBLRU does not help in the uniform distribution, but improves the overall throughput in the skewed distribution. We explore the reasons for these results below.

Uniform Workload Figure 7a shows the microflow cache hit rate and microflow cache lookup latency that corresponding to the throughput numbers in Figure 6 (top). Despite 2-4 cuckoo-lite having a higher cache hit rate, and both 4-way and 8-way SIMD having lower lookup latency, 2-4 BLP is the clear winner. It achieves the highest throughput within the entire range of oversubscription factors, outperforming alternative designs by as much as 15%. 2-4 cuckoo-lite's marginal cache hit rate improvement is not enough to compensate for its higher lookup latency. Because PBLRU is unable to improve the cache hit rate in the uniform distribution, it slightly hurts the throughput.

Skewed Workload Figure 7b shows the latency and hit rate results for the Zipf distribution throughput in Figure 6 (bottom). As with the uniform distribution, the simpler 4-way and 8-way lookup designs have lower latency, and 2-4 cuckoo-lite has a mildly higher hit rate. But here too, 2-4 BLP achieves the highest throughput except when the oversubscription factor is very small (close to 0.5) or very large (close to 2). Even in such scenarios, its throughput is very close to the highest. PBLRU further improves cache hit rate, especially when the oversubscription factor is high and increases throughput by up to 7.5%. This is rather expected because when the oversubscription factor is low, using random eviction is enough to get hit rates that are close to 100%.

Summary When used to implement the microflow cache in OvS, 2-4 BLP has the best overall performance. It always achieves the highest, or close to the highest throughput across workloads. Compared to other designs, it improves the throughput by up to 15% with uniform workloads and up to 4% with skewed workloads. PBLRU further improves the throughput with skewed workloads by up to 7.5%.

[6] We contacted the lead author of Open vSwitch, who acknowledged this issue.

(b) Skewed Distribution

Figure 7: End-to-end Benchmark: Analysis

7.3 Microbenchmarks

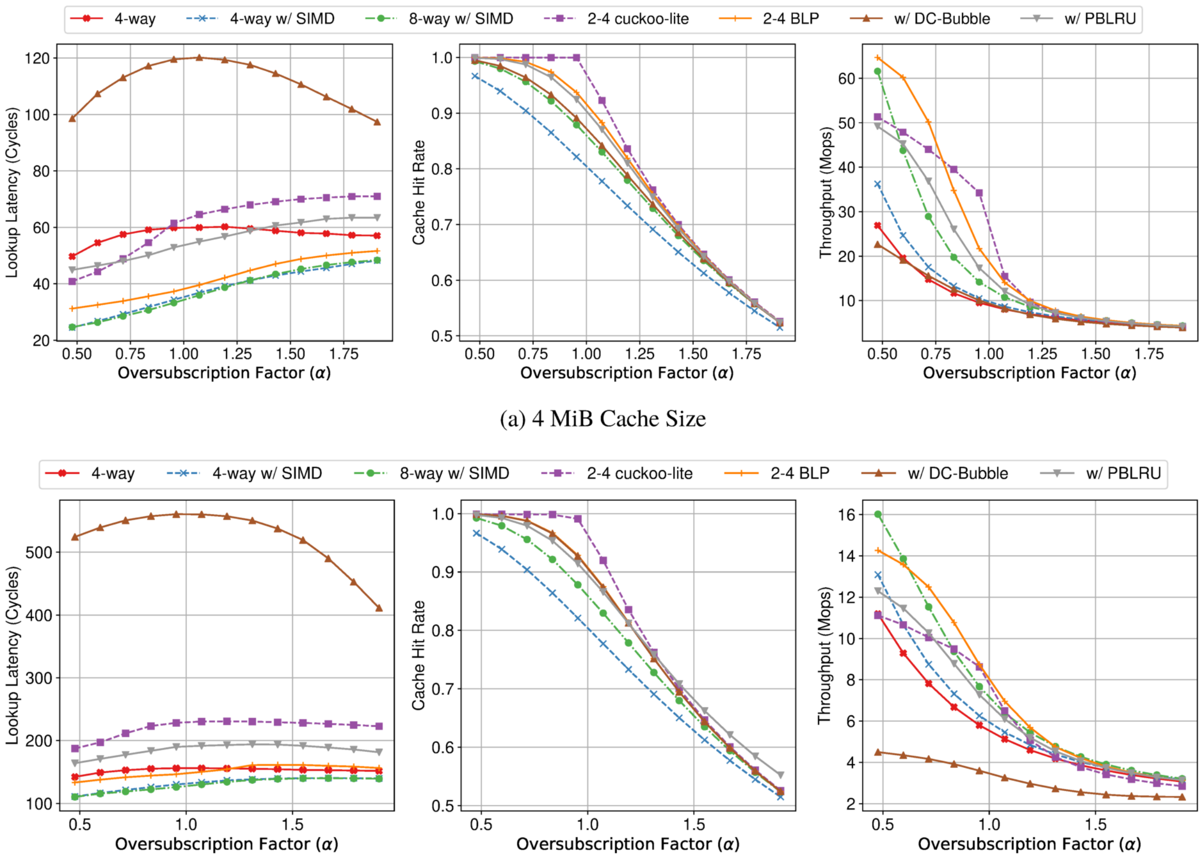
To understand how each cache design performs under different settings, we conducted a series of microbenchmarks outside of Open vSwitch. Each microbenchmark measures lookup latency, cache hit rate, and throughput with a *emulated* cache miss penalty of 1000 cycles. In these experiments, we emulate the cache miss penalty as a fixed cost instead of directing packets into the OvS megaflow lookup process, whose megaflow hash tables are searched can add substantial measurement noise. Because of this decision and because the microbenchmarks lack the instruction and data cache pressure of the full OvS system, the microbenchmark results differ slightly from the end-to-end numbers, but remain useful for exploring why and when the different cache designs excel. For microbenchmarks, we also implemented DC-Bubble [39] and compared it against PBLRU.

We evaluate two cache sizes to understand the performance when the table does and does not fit in the CPU's L3 cache. The workloads are pre-generated to minimize the impact of random number generation; each cache is fed exactly the same set of keys in the same order (for a given trial).

Uniform Workload, Small Cache Size We start by testing the cache designs for a small cache size (4 MiB) under uniform workloads. Figure 8a shows the results.

A few things stand out. As in the end-to-end benchmarks and analytical results, 2-4 cuckoo-lite has the highest cache hit rate for all oversubscription factors and 2-4 BLP has higher cache hit rate than 8-way. Second, 4-way w/ SIMD and 8-way have the lowest lookup latency, between 20 to 50 cycles per lookup. 2-4 BLP's latency is slightly higher and 2-4 cuckoo-lite is the slowest. Third, for oversubscription factors between 0.75 and 1.25, 2-4 cuckoo-lite achieves the highest throughput whereas 2-4 BLP achieves the highest for all other oversubscription factors. This result is because when the cache size is small, it is more likely to reside in the CPU's L3 cache (regardless of caching scheme). Therefore, although 2-4 cuckoo-lite issues one more memory read comparing with other approaches, its increased cache hit rate is enough to overcome the small lookup latency overhead. PBLRU is slower than 2-4 BLP, but much faster than DC-Bubble.

Takeaway When lookup latency overhead is small, higher cache hit rate produces higher throughput.



(a) 4 MiB Cache Size

(b) 64 MiB Cache Size

Figure 8: Micro-benchmark: Uniform Distribution

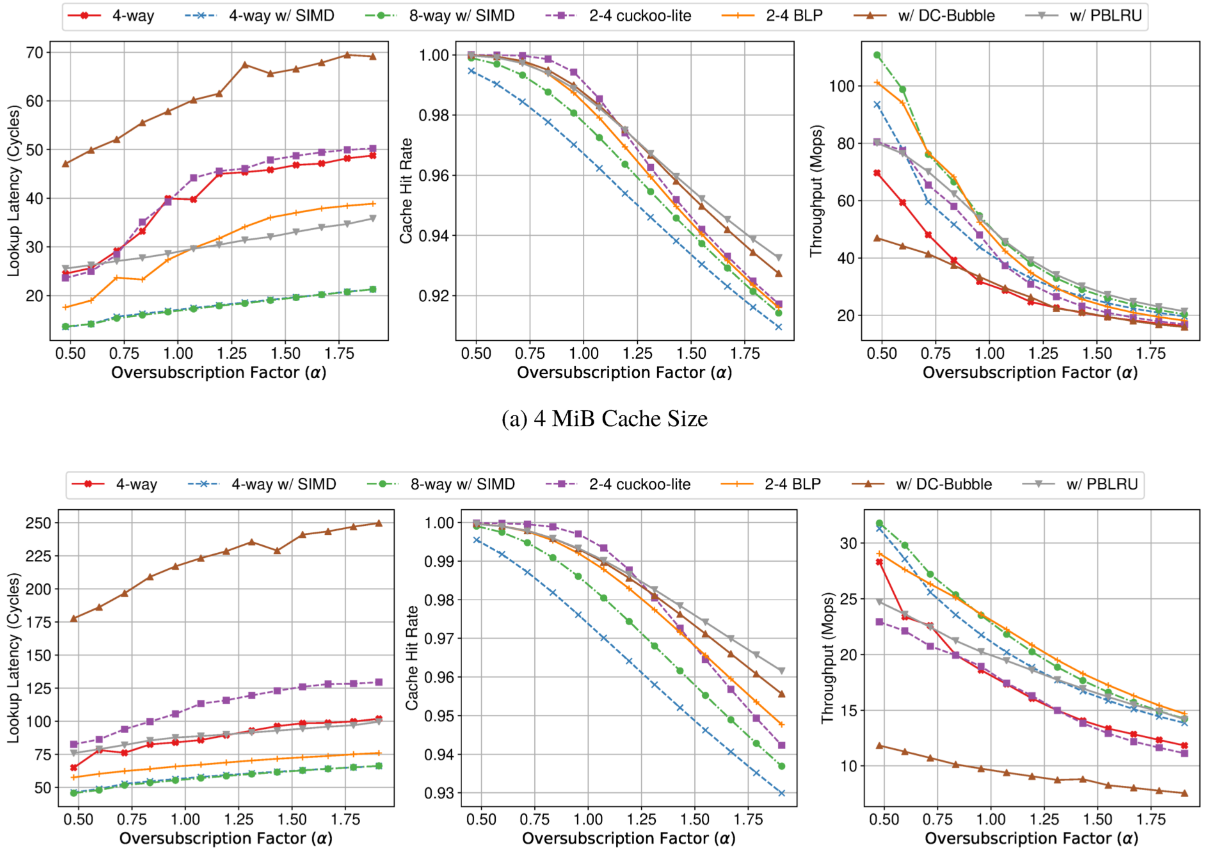
Uniform Workload, Large Cache Size In the second set of microbenchmarks, we increase the cache size to 64 MiB, which is larger than the CPU's L3 cache size. Comparing the results shown in Figure 8b with Figure 8a, the most notable difference is that lookup latencies are higher for all cache designs, especially 2-4 cuckoo-lite. Despite 2-4 cuckoo-lite's advantage in terms of cache hit rate, its overall throughput is lower than 2-4 BLP. Also, when oversubscription factor is small, 8-way outperforms 2-4 BLP because 8-way has a lower lookup latency than 2-4 BLP.

Takeaway When lookup latency overhead is large, lookup latency matters more than cache hit rate.

Skewed Workload The third and fourth set of experiments evaluate the cache designs with the same skewed workload (Zipf-distribution with θ=0.99) as in end-to-end benchmarks. Figures 9a and 9b depict the results for small and large cache sizes, respectively. Compared with uniform workloads, the relative order of 4-way w/ SIMD, 8-way, 2-4 cuckoo-lite and 2-4 BLP remains the same for both cache hit rate and lookup latency. However, across all the cache designs, cache hit rates are significantly increased and lookup latencies are significantly lower, which means that skewed workloads *favor* 4-way and 8-way set associative caches. As shown in these two figures, 8-way achieves the highest throughput. 2-4 BLP has much higher throughput than 2-4 cuckoo-lite (only 1-2% behind 8-way). With skewed workloads, PBLRU achieves higher cache hit rate, lower latency, and therefore higher overall throughput than DC-Bubble. Unlike in the end-to-end benchmarks, PBLRU has a lower throughput than 2-4 BLP in these microbenchmarks. This inversion is because the lookup latencies of both designs are substantially lower in the microbenchmarks, which amplifies the significance of the overhead introduced by PBLRU.

Takeaway With skewed workloads, 8-way and 2-4 BLP provide the highest throughput. PBLRU achieves higher cache hit rate than 2-4 BLP with modest overhead.

Summary As demonstrated by the micro-benchmarks above, 2-4 BLP balances cache hit rate and lookup latency across different cache sizes and workload skews. Compared with 4-way and 8-way set-associative caches, it has slightly higher lookup latency (1.5 v.s. 1 cache line reads / lookup), but much higher cache hit rate, especially with uniform workloads. Compared with 2-4 cuckoo-lite cache, 2-4 BLP replaces 2 *distant* cache line reads with one or two *consecutive* cache line reads, and therefore achieves much lower lookup latency at the cost of slightly lower cache hit rate.



(a) 4 MiB Cache Size

(b) 64 MiB Cache Size

Figure 9: Micro-benchmark: Skewed Distribution (θ=0.99)

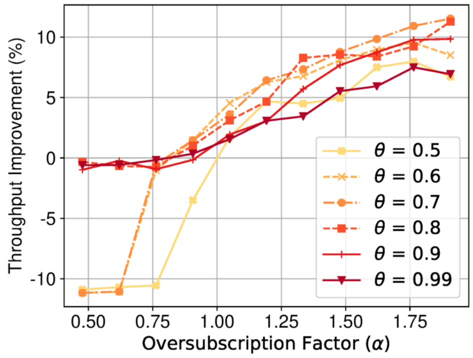


Figure 10: Throughput Improvement of PBLRU over 2-4 BLP

7.4 When should we use PBLRU?

Experiments above have shown that PBLRU outperforms random eviction in certain scenarios. To better understand when should we use PBLRU instead of random eviction, we compared the end-to-end throughput of 2-4 BLP with PBLRU against 2-4 BLP with random eviction using workloads with various skewnesses (θ). Higher θ means the workload is more skewed. Figure 10 illustrates the result.

Two things stand out. First, the performance improvement of PBLRU increases with the oversubscription factor. This is expected because when the oversubscription factor is low, the cache hit rate with random eviction is already high enough so that PBLRU's marginal cache hit rate improvement is not enough to overcome the additional lookup latency. Second, save for a few operating regimes (both skewness and oversubscription factor are low), PBLRU always provides equivalent or better throughput than the baseline.

8 Conclusion

Bounded Linear Probing (BLP) is a new cache design that introduces a new point in the "cache table" design space that balances between cache hit rate and lookup latency. BLP combines the speed of traditional set-associative caches with the high load factor (cache hit rate) and compact size of modern open-addressed hash tables. PBLRU is a new lightweight cache eviction algorithm that is fast and adds no space overhead. Our analysis and microbenchmarks show when each design offers advantages—for which workloads, data sizes, and miss penalties. Finally, we show that replacing the microflow cache in Open vSwitch can improve system throughput by up to 15% and PBLRU further improves the throughput by up to 10% when the workload is skewed.

A Expected Cache Hit Rate of Set-associative Caches

In a m-way set-associative cache with n buckets, for each bucket, the probability that there are exactly t keys mapped to it is

$$\binom{\alpha nm}{t} \cdot n^{-t} \cdot (1-1/n)^{\alpha nm - t}$$
$$= \frac{\alpha nm(\alpha nm-1)\cdots(\alpha nm-t+1)}{t! \cdot n^t} \cdot (1-1/n)^{\alpha nm - t}$$

which when $t \ll \alpha nm$, is approximately

$$\frac{(\alpha nm)^t}{t! \cdot n^t} \cdot (1-1/n)^{\alpha nm} = \frac{(\alpha m)^t}{t!} \cdot (1-1/n)^{\alpha nm}$$

which by the fact that $1 - \epsilon \approx e^{-\epsilon}$ for small ϵ, is approximately

$$\frac{(\alpha m)^t}{t!} \cdot e^{-\alpha nm/n} = \frac{(\alpha m)^t}{e^{\alpha m} t!}$$

If $t \le m$, then all t keys will be cached; otherwise, only m will be cached. Therefore, the expected number of keys that are cached in a bucket is approximately

$$\sum_{t=0}^{m} t \cdot \frac{(\alpha m)^t}{e^{\alpha m} t!} + \sum_{t=m+1}^{\infty} m \cdot \frac{(\alpha m)^t}{e^{\alpha m} t!},$$

which by the fact that $\sum_{t \ge 0} \frac{(\alpha m)^t}{e^{\alpha m} t!} = 1$, is equal to

$$= m - \sum_{t=0}^{m} (m-t) \cdot \frac{(\alpha m)^t}{e^{\alpha m} t!},$$

Hence, the expected cache hit rate is $(m - \sum_{t=0}^{m}(m-t) \cdot \frac{(\alpha m)^t}{e^{\alpha m} t!})/(\alpha m)$.

B Expected Cache Hit Rate of 2-4 BLP

Recall that a_i is the number of keys from the working set that map to cache bucket i and b_i is the number of keys spill from bucket i to $i+1$ after a sufficiently long warm-up period. For $j \ge 0$, we have:

$$\Pr[a_i = j] = \binom{\alpha nm}{j} \cdot n^{-j} \cdot (1-1/n)^{\alpha nm - j}.$$

By the law of total expectation and Equation (2) in Section 4.5, for $0 < l < m$, we have

$$p_l \approx \begin{cases} \sum_{j'=0}^{m} \left(\sum_{j=0}^{m-j'} \Pr[a_i = j]\right) \cdot p_{j'} & \text{if } l = 0, \\ \sum_{j=l}^{l+m} \Pr[a_i = j] \cdot p_{l+m-j} & \text{if } 0 < l < m, \end{cases}$$

and by the definition of probability distribution,

$$p_0 + \cdots + p_m = 1.$$

Solving the above system of linear equations for $(p_0, \ldots, p_m)$ with $m = 4$, $\alpha = 0.95$ gives us $p_0 = 0.37889778$, $p_1 = 0.15160669$, $p_2 = 0.14369602$, $p_3 = 0.12041777$ and $p_4 = 0.20538175$. By Equation (3), we get $E[c_i] = 3.59$.

C Expected Hit Rate of BLP under Non-Uniform Distributions

In the following, we prove that the expected hit rate obtained in Section 4.5 for the uniform distribution is always a lower bound for any other distribution. Fix any distribution over the working set S, let p_x be the probability of key x. Without loss of generality, we may assume $p_x > 0$ for all $x \in S$, since otherwise, we could simply remove all x with zero probability from the working set. Recall that c_i denotes the *final* number of occupied entries in bucket i. Observe that $c_0, \ldots, c_{n-1}$ are determined only by the hash function, i.e., how many keys are mapped to each bucket. They do not depend on the probability distribution of the keys (as long as all keys have non-zero probability), the distribution only affects how fast the final numbers are achieved.

After a sufficiently long warm-up period, all buckets achieved their final numbers of occupied entries. Now, consider all possible memory configurations *after* the warm-up. Further key lookups define a *Markov chain* over them, where the transition probability from memory configuration A to configuration B is the probability that A becomes B after one lookup. Observe that this Markov chain is *aperiodic* (i.e., there does not exist a $t > 1$ and a state A such that A can only go back to itself after steps of multiples of t). It is well-known that for any aperiodic Markov chain and any initial state, as the number of steps (key lookups) increases, the distribution of the state will approach *some* final stationary distribution (note that the stationary distribution may not be unique, hence the final stationary distribution may depend on the initial state). The *final* hit rate is computed from this stationary distribution and the distribution of the keys. More specifically, let q_x be the expectation, over a random hash function and random lookups in the warm-up period (which determine the Markov chain and the distribution of initial state), of the probability that key x is cached according to the final stationary distribution. Thus, the expected hit rate is equal to $\sum_{x\in S} p_x q_x$.

Next, by linearity of expectation, $\sum_{x\in S} q_x$ is equal to the expected total number of occupied entries in the data structure, $\mathbb{E}[c_i] \cdot n$. The key observation is that if $p_x \geq p_y$ then $q_x \geq q_y$, i.e., if a key is more likely to occur, then it has a higher probability to appear in the final stationary distribution, *over a random hash function and warm-up period.*[7] Let $S_{\text{high}} := \{x : p_x \geq 1/|S|\}$ be the set of keys that occur with at least the average probability and $S_{\text{low}} := \{x : p_x < 1/|S|\}$ be the set of keys that occur with probability lower than the average, and let $q := \min_{x\in S_{\text{high}}} q_x$. Hence, $q \geq q_x$ for all $x \in S_{\text{low}}$. We have

$$\begin{aligned}\sum_{x\in S} p_x q_x &= \sum_{x\in S} \frac{q_x}{|S|} + \sum_{x\in S}(p_x - 1/|S|)q_x \\ &= \frac{1}{|S|}\sum_{x\in S} q_x + \sum_{x\in S_{\text{high}}}(p_x - 1/|S|)q_x + \sum_{x\in S_{\text{low}}}(p_x - 1/|S|)q_x\end{aligned}$$

which by the fact that $p_x \geq 1/|S|$ and $q_x \geq q$ for $x \in S_{\text{high}}$, and the fact that $p_x < 1/|S|$ and $q_x \leq q$ for $x \in S_{\text{low}}$, is at least

$$\begin{aligned}&\geq \frac{1}{|S|}\sum_{x\in S} q_x + \sum_{x\in S_{\text{high}}}(p_x - 1/|S|)q + \sum_{x\in S_{\text{low}}}(p_x - 1/|S|)q \\ &= \frac{\mathbb{E}[c_i]\cdot n}{|S|} + \sum_{x\in S} p_x \cdot q - \sum_{x\in S}\frac{1}{|S|}\cdot q \\ &= \frac{\mathbb{E}[c_i]\cdot n}{|S|} + q - q \\ &= \frac{\mathbb{E}[c_i]\cdot n}{|S|}.\end{aligned}$$

The last quantity $\frac{\mathbb{E}[c_i]\cdot n}{|S|}$ is precisely the expected hit rate under the uniform distribution, as we argued in Section 4. Therefore, the expected hit rate under any non-uniform distribution is always lower bounded by the hit rate under the uniform distribution.

D Analysis on Warm-up Time

In the following, we present an informal estimation on the relationship between the hit rate of BLP and its warm-up time. As we argued in Section 4.5, the hit rate is equal to the number of occupied entries in the BLP divided by the size of the working set. In each lookup in the warm-up period, the key may be either a) in the BLP already, or b) not in the BLP and the buckets are full, or c) not in the BLP and the bucket is not full. Only in case c), do we increase the number of occupied entries by one. Denote the *final* hit rate by $r_{\max}$. When the current hit rate is r, we are going to *approximate* the probability of case c) by $r_{\max} - r$. That is, we assume there is a fixed set of $(r_{\max} - r) \cdot (\alpha mn)$ keys in the working set such that they are the missing keys from the BLP in order to achieve the maximum hit rate of $r_{\max}$.

Therefore, let L be the length of the warm-up, we have

$$\frac{\mathrm{d}r}{\mathrm{d}L} = \frac{r_{\max} - r}{\alpha mn},$$

and when $L = 0, r = 0$. By solving this ordinary differential equation, we obtain

$$r = r_{\max}(1 - e^{-\frac{L}{\alpha mn}}).$$

That is, when the length of the warm-up is a large constant times the working set size, the estimated hit rate becomes very close to $r_{\max}$. For $\alpha = 0.95$, we have verified by experiments that a warm-up period of length 20 times the working set size is sufficient to obtain a hit rate that is less than 1% lower than $r_{\max}$.

[7] Note that this is not true if the hash function is fixed.

Reexamining Direct Cache Access to Optimize I/O Intensive Applications for Multi-hundred-gigabit Networks

Abstract

Memory access is the major bottleneck in realizing multi-hundred-gigabit networks with commodity hardware, hence it is essential to make good use of cache memory that is a faster, but smaller memory closer to the processor. Our goal is to study the impact of cache management on the performance of I/O intensive applications. Specifically, this paper looks at one of the bottlenecks in packet processing, i.e., direct cache access (DCA). We systematically studied the current implementation of DCA in Intel® processors, particularly Data Direct I/O technology (DDIO), which directly transfers data between I/O devices and the processor's cache. Our empirical study enables system designers/developers to optimize DDIO-enabled systems for I/O intensive applications. We demonstrate that optimizing DDIO could reduce the latency of I/O intensive network functions running at 100 Gbps by up to ~30%. Moreover, we show that DDIO causes a 30% *increase* in tail latencies when processing packets at 200 Gbps, hence it is crucial to selectively inject data into the cache or to explicitly bypass it.

1 Introduction

While the computer architecture community continues to focus on hardware specialization, the networking community tries to achieve greater flexibility with Software-defined Networking (SDN) together with Network Function Virtualization (NFV) by moving from specialized hardware toward commodity hardware. However, greater flexibility comes at the price of lower performance compared to specialized hardware. This approach has become more complex due to the end of Moore's law and Dennard scaling [14]. Furthermore, commercially available 100-Gbps networking interfaces have revealed many challenges for commodity hardware to support packet processing at multi-hundred-gigabit rates. More specifically, the interarrival time of small packets is shrinking to a few nanoseconds (i.e., less than Last Level Cache (LLC) latency). Consequently, any costly computation prevents commodity hardware from processing packets at these rates, thereby causing a tremendous amount of buffering and/or packet loss. As accessing main memory is impossible at these line rates, it is essential to take *greater* advantage of the processor's cache [81]. Processor vendors (e.g., Intel®) introduced new monitoring/controlling capabilities in the processor's cache, e.g., Cache Allocation Technology (CAT) [59]. In alignment with the desire for better cache management, this paper studies the current implementation of Direct Cache Access (DCA) in Intel processors, i.e., Data Direct I/O technology (DDIO), which facilitates the direct communication between the network interface card (NIC) and the processor's cache while avoiding transferring packets to main memory. Our goal is to complete the recent set of studies focusing on understanding the leading technologies for fast networking, i.e., Peripheral Component Interconnect express (PCIe) [58] and Remote Direct Memory Access (RDMA) [37]. We believe that understanding & optimizing DDIO is the missing piece of the puzzle to realize high-performance I/O intensive applications. In this regard, we empirically reverse-engineer DDIO's implementation details, evaluate its effectiveness at 100/200 Gbps, discuss its shortcomings, and propose a set of optimization guidelines to realize performance isolation & achieve better performance for multi-hundred-gigabit rates. Moreover, we exploit a little-discussed feature of Xeon® processors to demonstrate that *fine-tuning* DDIO could improve the performance of I/O intensive applications by up to ~30%. To the best of our knowledge, we are the first to: (i) systematically study and reveal details of DDIO and (ii) take advantage of this knowledge to process packets more efficiently at 200 Gbps.

Why DCA matters? Meeting strict Service Level Objectives (SLO) and offering bounded latency for Internet services is becoming one of the critical challenges of data centers while operating on commodity hardware [54]. Consequently, it is essential to identify the sources of performance variability in commodity hardware and *tame* them [51]. In computer

[*] Both authors contributed equally to the paper.
[†] This author has made all open-source contributions.

systems, one of these sources of variability is the cache hierarchy, which can introduce uncertainty in service times, especially in tail latencies. Additionally, the advent of modern network equipment [82] enables applications to push costly calculations closer to the network while keeping & performing only stateful functions at the processors [36, 38], thereby making modern network applications ever *more* I/O intensive. Hence, taming the performance variability imposed by the cache, especially for I/O, is now more crucial than before. Moreover, as CPU core count goes up, it is important to be able to deliver appropriate I/O bandwidth to them. Therefore, we *go one level deeper* [61] to investigate the impact of I/O cache management, done by DCA, on the performance of multi-hundred-gigabit networks.

Contributions. In this paper, we:

① Design a set of micro-benchmarks to reveal little-known details of DDIO's implementation[*] (§4),

② Extensively study the characteristics of DDIO in different scenarios and identify its shortcomings[*] (§5),

③ Show the importance of balancing load among cores and tuning DDIO capacity when scaling up (§6),

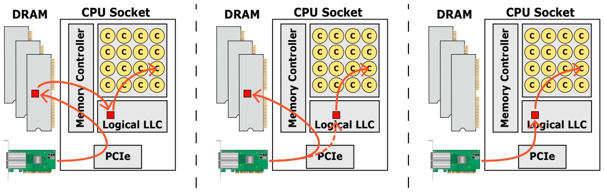
④ Measure the sensitivity of multiple applications (i.e., Memcached, NVMe benchmarks, NFV service chains) to DDIO (§7),

⑤ Demonstrate the necessity and benefits of bypassing cache while receiving packets at 200 Gbps (§8),

⑥ Discuss the lessons learned from our study that are essential for optimizing DDIO-enabled systems receiving traffic at multi-hundred-gigabit rates (§9).

2 Direct Cache Access (DCA)

A standard method to transfer data from an I/O device to a processor is Direct Memory Access (DMA). In this mechanism, a processor, typically instructed by software, provides a set of memory addresses, aka receive (RX) descriptors, to the I/O device. Later, the I/O device directly reads/writes data from/to main memory without involving the processor. For inbound traffic, the processor can be informed about newly DMA-ed data either by receiving an interrupt or polling the I/O device. Next, the processor fetches the I/O data from main memory to its cache in order to process the data. For outbound traffic, the processor informs the I/O device (via transmit (TX) descriptors) of data that is ready to be DMA-ed from main memory to the device. The main source or destination of traditional DMA transfers is main memory, see Fig. 1a. However, the data actually needs to be loaded into the processor's cache for processing. Therefore, this method is inefficient and costly in terms of (i) number of accesses to main memory [43] (i.e., $2n+5$ for n cache lines [43]), (ii) access latency to the I/O data, and (iii) memory bandwidth usage. Moreover, the negative impact of these inefficiencies becomes increasingly severe with higher link speeds. For instance, a server has 6.72 ns to process small packets at 100 Gbps, whereas every access to main memory takes ~100 ns, 15× more expensive. Therefore, placing the I/O data directly in the processor's cache rather than in main memory is desirable. The advent of faster I/O technologies motivated researchers to introduce Direct Cache Access (DCA) [25, 42, 43]. DCA exploits PCIe Transaction Layer Packet Processing Hint [30], making it possible to prefetch portions of I/O data to the processor's cache, see Fig. 1b. Potentially, this overcomes the drawbacks of traditional DMA, thereby achieving maximal I/O bandwidth and reducing processor stall time. Although this way of realizing DCA can effectively prefetch the desired portions of I/O data (e.g., descriptors and packet header), it is still inefficient in terms of memory bandwidth usage since the whole packet is DMA-ed into main memory. Additionally, this requires operating system (OS) intervention and support from the I/O device, system chipset, *and* processor [1]. To address these limitations and avoid ping-ponging data between main memory & the processor's cache, Intel rearchitected the prefetch hint-based DCA, introducing Data Direct I/O technology (DDIO) [28].



(a) Trad. DMA. (b) DCA. (c) DDIO.

Figure 1: Different approaches of DMA for transferring data from an I/O device (e.g., NIC). Red arrows show the path that a packet traverses *before* reaching the processing core.

3 Data Direct I/O Technology (DDIO)

Intel introduced DDIO technology with the Xeon E5 family. With DDIO, I/O devices perform DMA directly to/from Last Level Cache (LLC) rather than system memory, see Fig. 1c. DDIO is also known as write-allocate-write-update-capable DCA (wauDCA) [45], as it uses this policy to update cache lines in an n-way set associative LLC, where n cache lines form one set. For packet processing applications, NICs can send/receive both RX/TX descriptors and the packets themselves via the LLC, thereby improving applications' response time & throughput[†]. DDIO works as follows [41]:

Writing packets. When a NIC writes a cache line to LLC via PCIe, DDIO overwrites the cache line if it is already present in *any* LLC way (aka a PCIe write hit or *write update*). Otherwise, the cache line is allocated in the LLC and DDIO writes the data into the newly allocated cache line (aka a PCIe write miss or *write allocate*). In the latter case, DDIO is restricted to use only a limited portion of LLC when allocating

[*] The source code is available at: https://github.com/aliireza/ddio-bench

[†] We will use the terms I/O device and NIC interchangeably.

cache lines. It is possible to *artificially* increase this portion by warming up the cache with processor writes to the address of these buffers, then DDIO performs write-updates [16].

Reading packets. A NIC can read a cache line from LLC if the cache line is present in *any* LLC way (aka a PCIe read hit). Otherwise, the NIC reads a cache-line-sized chunk from system memory (aka a PCIe read miss).

To monitor DDIO and its interaction with I/O devices, Intel added uncore performance counters to its processors [29]. The Intel Performance Counter Monitor (PCM) tool (e.g., `pcm-pcie.x`[*]) [86] can count the number of PCIe write hits/misses (represented as an ItoM event) and PCIe read hits/misses (represented as a PCIeRdCur event). Next, we discuss the inherent problem of DDIO, which makes it hard to achieve low-latency for multi-hundred-gigabit NICs.

3.1 How can DDIO become a Bottleneck?

Researchers have shown some scenarios in which DDIO cannot provide the expected benefits [11, 41, 50, 83]. Two typical cases occur when new incoming packets repeatedly evict the previously DMA-ed packets (i.e., *not-yet-processed* and *already-processed packets*) in the LLC. Consequently, the processor has to load not-yet-processed packets from main memory rather than LLC and the NIC needs to DMA the already-processed packets from the main memory, thereby missing the benefits of DDIO. Tootoonchian et al. referred to this problem as *the leaky DMA problem* [83]. To mitigate this problem, they proposed reducing the number of "in-flight" buffers (i.e., descriptors) such that all incoming packets fit in the limited portion of LLC used for I/O. Thus, performance isolation can be done using *only* CAT (i.e., cache partitioning). Unfortunately, reducing the number of RX descriptors is only a temporary solution due to increasing link speeds. Multi-hundred-gigabit NICs introduce new challenges, specifically:

① **Packet loss.** At sub-hundred-gigabit link speeds reducing the number of RX descriptors may not result in a high packet loss rate, but at $\geq$100 Gbps packet loss increases due to the tight processing time budget before buffering/queuing happens. For instance, every extra ~7 ns spent stalling or processing/accessing a packet causes another packet to be buffered when receiving 64-B packets at 100 Gbps. When there are insufficient resources for immediate processing, increasing the number of RX descriptors permits packets to be buffered rather than dropped. Delays in processing might occur because of interrupt handling, prolonged processing, or a sudden increase in the packet arrival rate [17]; therefore, multi-hundred-gigabit networks cannot avoid packet loss without having a *sufficiently large* number of descriptors. Increasing the number of processing cores can reduce the packet loss rate, but applications that are compute- or memory-intensive require many cores to operate at the speed of the underlying hardware, e.g., Thomas et al. [81] mention that a server performing *one* DRAM access per packet needs 79 cores to process packets at 400 Gbps.

② **TX buffering.** One of the scenarios that makes DDIO inefficient is the eviction of already-processed packets. Reducing the number of RX descriptors may solve this problem for systems that require a small number of TX descriptors, but this is not the case for 100-Gbps NICs. Unfortunately, the *de facto* medium for DMA-ing packets (i.e., PCIe 3.0) induces some transmission limitations [58]. Consequently, packets often need to be buffered in the computer system for some time before being DMA-ed to the NIC. This buffering can be realized by either a software queue or increasing the number of TX descriptors [35]. Unfortunately, either of these alternatives increases the probability of eviction of already-processed packets. Therefore, completely solving the leaky DMA problem requires fine-tuning *both* the size of the software queue and the number of RX & TX descriptors.

③ **PAUSE frames.** To alleviate packet loss, one can use Ethernet flow control mechanisms (e.g., PAUSE frames) that cause packets to be buffered earlier in the network, i.e., PAUSE frames stop the previous network node from transmitting packets for a short period. However, these mechanisms are costly in terms of latency, making them less desirable than packet loss for time-critical applications. The minimum and maximum pause duration of a 100-Gbps interface are 5.12 ns and 335.5 µs [56]. Our measurements show that a core that is simply forwarding packets at 100 Gbps with 1024 RX & TX descriptors causes the NIC to send ~179 k PAUSE frames while receiving ~80 M packets.

Dynamic reduction. As reducing the number of RX buffers cannot *fully* solve the problem and it shifts the problem to another part of the network, most probably the previous node; therefore, an alternative is to *dynamically* reduce the pressure on the LLC when the number of I/O caused cache evictions starts to increase[†]. These cache evictions can be tracked by monitoring either PCIe events or the length of the software queue. After detecting a problem, the processor should fetch a smaller number of packets from the NIC (i.e., reducing the RX burst size). Thus, the processor passes fewer free buffers to the NIC, reducing the number of DMA transactions. Unfortunately, this approach does not perform well, hence we need a *proactive* solution, not a reactive one.

Is it sufficient to scale up? Due to the demise of the Dennard scaling [14], processors are now shipped with more cores rather than higher clock frequencies. Moreover, the per-core cache quota (i.e., LLC slices) has decreased in recent Xeon processors, i.e., the size of LLC slices reduced from 2.5 MiB to 1.375 MiB in the Xeon scalable family (i.e., Skylake) [55]. This reduction in per-core cache size directly affects the optimal number of descriptors as these are proportional to the limited space for DDIO. For instance, using 18 cores, each having 256 RX descriptors, requires ~6.5 MiB, which is equal

[*] The description of events can be found in [27] and pp. 63-66 of [41].

[†] Our implementation is available at: https://github.com/tbarbette/fastclick/tree/DMAdynamic

to ~26.6% of the LLC in this processor and greater than the available DDIO capacity (see §4.1).

Our approach. To overcome these challenges, it is necessary to study and analyze DDIO empirically in order to *make the best use of it*. A better understanding of DDIO and its implementation can help us optimize current computer systems and enables us to propose a better DCA design for future computer systems that could accommodate the ever-increasing NIC link speeds. For instance, Fig. 2 demonstrates that tuning DDIO's capacity makes it possible to achieve a suitable performance while using a large number of descriptors (our approach), as opposed to using a limited number of descriptors (ResQ's approach proposed by Tootoonchian et al. [83]).

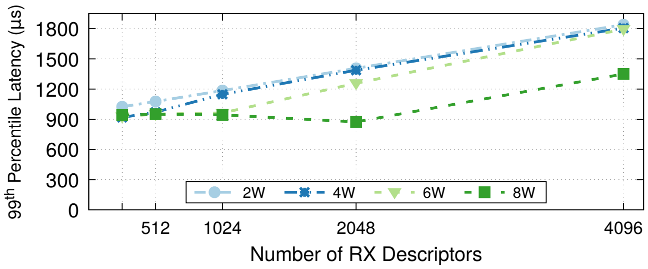


Figure 2: Using more DDIO ways ("W") enables 2 cores to forward 1500-B packets at 100 Gbps with a larger number of descriptors while achieving better or similar tail latency.

4 Understanding Details of DDIO

This section discusses four questions: ① What part of LLC is used for I/O? ② How does I/O interact with other applications? ③ Does DMA via remote sockets pollute LLC? and ④ Is it possible to disable/tune DDIO?

Testbed. We use a testbed with the configuration shown in Table 1 running Ubuntu 18.04.2 (Linux kernel-4.15.0-54). We use the Skylake server unless stated otherwise. FastClick [9] is used to generate & process packets. Additionally, we use a campus trace as a real workload (with mixed-size packets) and generate synthetic traces (with fixed-size packets). For our multicore experiment, we use RSS [24] to distribute packets among different queues (one queue per core), unless stated otherwise. Furthermore, we isolate the one CPU socket on which we run the experiment to increase the accuracy of the measurements. PAUSE frames are disabled to avoid taking into account pause duration in the end-to-end latency. In all experiments, the NIC driver sets the appropriate number of TX descriptors based on the number of TX queues, and to avoid extra looping at the transmitting side FastClick buffers up to 1024 packets. We use the Network Performance Framework (NPF) tool [57] to run the experiments.

4.1 Occupancy

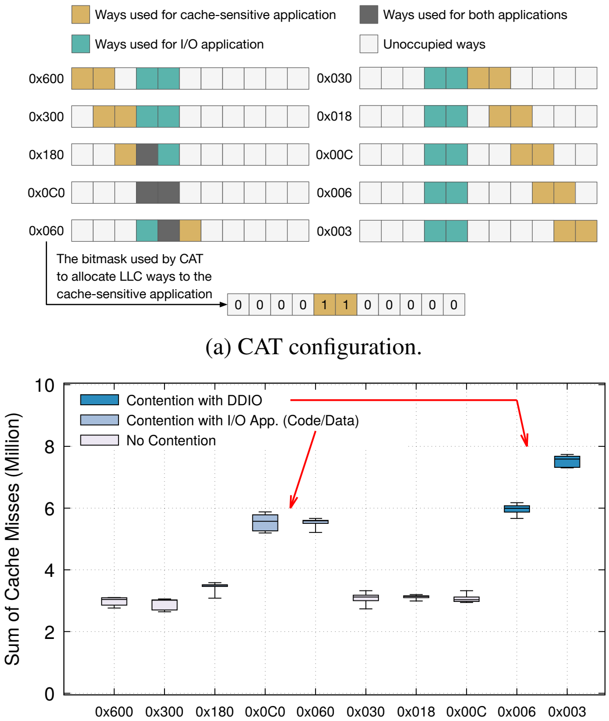
Initially, Intel announced that DDIO only uses 10% of LLC [28] and did not mention what *part* of the LLC is used (i.e., ways, sets, or slices [15]). Recent Intel technical reports mention that DDIO only uses a subset of LLC ways, by default two ways [41, 72]. However, it is still unclear whether this "subset" is fixed or whether it can be dynamically selected using a variant of Least Recently Used (LRU) policies [33, 34, 65, 87]. Knowledge of these details could avoid I/O contention and optimize performance isolation [83] by performing precise cache management/partitioning [13, 62] (e.g., way partitioning with CAT [59]). This issue becomes increasingly critical for newer generations of Xeon processors that have lower LLC set-associativity (e.g., 11 ways in some Skylake processors, as opposed to 20 ways in Haswell processors), thereby using a larger portion ($\frac{2}{11} \approx 18\%$) of the LLC for I/O. Lower set-associativity makes the cache less flexible when the LLC is divided into multiple partitions, each of which could be used to accommodate different applications' code & data. To clarify this, we assumed that the ways that are used for DDIO are *fixed* and then try to confirm this with an experiment in which we co-run an I/O and a cache-sensitive application. To increase the pressure on the LLC by DMA-ing more cache lines, we used an L2 forwarding DPDK-based application as the I/O intensive application. Specifically, it receives large packets (1024-B) at a high rate (~82 Gbps) using a large number of RX descriptors (4096 RX descriptors). For the cache-sensitive application, we chose `water_nsquared` from the Splash-3 benchmark suite [62, 66, 69] since it performs a large number of LLC accesses; hence, it interferes with the I/O application.

Each application is run on a different core and CAT is used to allocate different cache ways to each core. We allocate two *fixed* ways to the I/O application and two *variable* ways to the cache-sensitive application. To avoid memory bandwidth contention, we also used Memory Bandwidth Allocation (MBA) technology [21] to limit the memory bandwidth of each core to 40%. Fig. 3a shows the CAT configuration used in the experiment. We start by allocating the two leftmost ways (i.e., bitmask of 0x600) to the cache-sensitive application and then we keep shifting the allocated ways one

Table 1: Details of our testbed. In each case, the NIC is a Mellanox ConnectX-5 VPI.

Configuration / Machine	Intel Xeon Processor			Memory	Last Level Cache (LLC)	
	Model	Frequency	#Cores		Size	Associativity
Packet generator (Skylake)	Gold 6134	3.2 GHz	8	512 GiB	18×1.375 MiB	11
Server (Skylake)	Gold 6140	2.3 GHz	18	256 GiB	18×1.375 MiB	11
Server (Haswell)	E5-2667 v3	3.2 GHz	8	128 GiB	8×2.5 MiB	20

to the right until we cover all the LLC ways while measuring the LLC misses of the I/O application. Fig. 3b shows the results of this experiment. These results demonstrate that the cache-sensitive application interferes with the I/O application in *two* regions. The first (see 0x0C0 in Fig. 3b) occurs when the cache-sensitive application uses the same ways as the I/O application, due to the code/data interference of the two applications. However, the second (see 0x003 in Fig. 3b) cannot be explained with this same argument since the I/O application is limited to using other ways (i.e., 0x0C0). Furthermore, since the CPU socket is isolated, no other application can cause cache misses. CAT only mitigates the contention induced by code/data not DDIO. Therefore, we conclude that the second interference is most probably due to I/O, which means DDIO uses the two rightmost ways in LLC (i.e., bitmask of 0x003). The interference is proportional to the number of received packets per second × average packet size. We expected to see roughly the *same* amount of cache misses for bitmasks of 0x180 and 0x060, as they are completely symmetrical in terms of way occupancy. However, the undocumented LRU policy of the CPU may affect how the application uses the cache ways.



(a) CAT configuration.

(b) Sum of cache misses for the I/O application.

Figure 3: Interference of an I/O and a cache-sensitive application using the `parsec_native` configuration (to cause a high rate of cache misses) when the cache-sensitive application uses different LLC ways. The rise in the rightmost side shows the contention with DDIO ways.

4.2 I/O Contention

One of the established mechanisms to ensure performance isolation and mitigate cache contention is CAT, which limits different applications to a subset of LLC ways. However, §4.1 showed that DDIO uses two *fixed* LLC ways. Therefore, isolating applications using CAT may not *fully* ensure performance isolation, due to cache contention caused by I/O. Such contention may occur in two common scenarios:

① **I/O vs. Code/Data.** When an application is limited to using those ways which are also used by DDIO, then cache lines allocated in LLC for DDIO may evict the code/data of any application (i.e., either I/O or non-I/O application). This issue was discussed by Tootoonchian et al. [83]. Their proposed framework, ResQ, uses only 90% of LLC to avoid interfering with DDIO's reserved space, but does not mention which part of LLC is isolated. §4.1 showed the destructive (i.e., ~2.5×) impact on the cache misses of the I/O application due to a cache-hungry application overlapping with DDIO, see the rise in cache misses at the right side of Fig. 3b. However, it did not show the impact of contention on the cache-hungry application; therefore, we repeated the experiment and measured the cache misses of the cache-sensitive application while using a lighter configuration. Fig. 4 illustrates that the cache misses of the cache-sensitive application were similarly adversely affected. Therefore, overlapping any application with DDIO ways in LLC can reduce the performance of *both* applications. To tackle this, one can isolate the I/O portion of LLC (e.g., the two ways used for DDIO) by using CAT so that applications share the LLC *without* overlapping with I/O. Comparing Fig. 3b and 4, we see that an unexpected rise (almost 3×) in cache misses occurs in a different region (i.e., bitmask of 0x600 in Fig. 4 as opposed to bitmask of 0x003 in Fig. 3b) when I/O is evicting code/data. Hence, we speculate that CAT does not use a *bijective* function to map I/O & code/data to ways, thus $\boxed{f : \text{code/data} \rightarrow \text{Ways}}$ is not equivalent to $\boxed{g : \text{I/O} \rightarrow \text{Ways}}$. Specifically, I/O evicts code/data when the latter is located in the two leftmost ways whereas code/data evicts I/O when the latter is using the two rightmost ways. Such information is useful to know, as it will give us an understanding of the eviction policy and the default priority of code/data and I/O.

② **I/O vs. I/O.** When multiple I/O applications are isolated from each other with CAT, they could still *unintentionally* compete for the *fixed* ways allocated to DDIO. §8.1 elaborates the negative impact of this type of contention.

Security implication. Since DDIO uses two *fixed* ways in LLC, it is possible to extend microarchitectural attacks to extract useful information from I/O data (e.g., NetCAT [44] and Packet Chasing [76, 77]). Furthermore, I/O applications can be vulnerable to performance attacks.

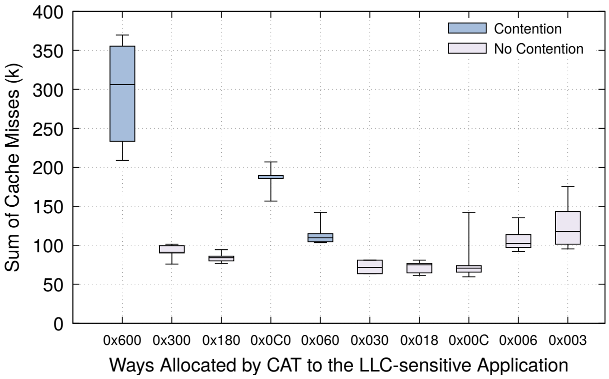


Figure 4: Interference of the cache-sensitive and the I/O applications. Y axis shows the sum of cache misses of the cache-sensitive application. The cache-sensitive application uses a lighter configuration (i.e., `ddio_sim`), which causes fewer cache misses than the I/O application.

4.3 DMA via Remote Socket

According to Intel [16, 32], the current implementation of DDIO only affects the local socket. Consequently, if a core accesses I/O data from an I/O device connected to a remote socket, the data has to traverse the inter-core interconnect, i.e., Intel QuickPath Interconnect (QPI) or Intel Ultra path Interconnect (UPI). It was uncertain whether data traversing the inter-core interconnect is loaded into the LLC of the remote socket or not. We clarified this by running the same experiment discussed in §4.2 while the NIC is connected to a remote socket. The result (removed for brevity) showed that cache misses of neither application were affected by the *I/O* cache lines, hence packets coming through the UPI links *do not end up in the local LLC*. Additionally, the cache misses of the I/O application dramatically increased to 20× greater than when receiving packets via the local socket without any contention. Thus, DDIO is ineffective for the remote socket *and* it pollutes the LLC on the socket connected to the NIC.

4.4 Tuning Occupancy and Disabling DDIO

Although [20, 72] mention that DDIO uses two ways by *default*, there is no mention of whether it is *possible* to increase or decrease the number of ways used by DDIO. A little-discussed Model Specific Register (MSR) called "IIO LLC WAYS" with the address of 0xC8B[*] is discussed in a few online resources [64, 79] and server manuals [73, 74]. For Skylake, the default value of this register is equal to 0x600 (i.e., two bits set). While these bits cannot be unset, it is possible to set additional bits and the maximum value for this register on our CPU is 0x7FF (i.e., 11 bits set: the same as the number of LLC ways). New values for this register follow the same format as CAT bitmasks. On a processor with the Skylake microarchitecture, these new values should contain consecutive ones, while the Haswell microarchitecture does not require this (i.e., allowing any value in [0x60000, 0xFFFFF]).

To see whether this MSR register has an effect on performance, we measured the PCIe read/write hit rates (i.e., ItoM and PCIeRdCur events) while using different values for IIO LLC WAYS. We calculate the hit rate based on the number of hits and misses during an experiment where an I/O application processes packets of 1024 B at 100 Gbps while using 4096 RX descriptors. Fig. 5 shows that increasing the value of this MSR register leads to a higher PCIe read/write hit rate. This suggests that increasing the value of this register could improve the ability of the system to handle packets at high rates. We believe that the value of this register is *positively* correlated with the fraction of LLC used by DDIO. Using the technique in §4.1, we could not detect the newly added I/O ways, thus we speculate that the newly added ways follow a different policy (e.g., LRU) than the first two ways used for I/O. Therefore, we assume that the number of bits set specifies the number of ways used by DDIO.

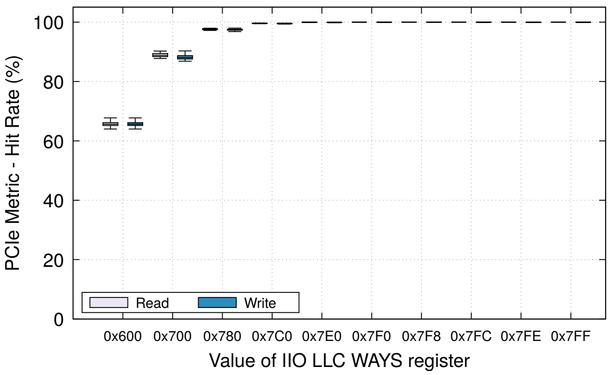

Figure 5: Tuning IIO LLC WAYS register increases PCIe read/write hit rates. The achieved throughput is 82-86 Gbps in this experiment.

Disabling DDIO. DDIO is bundled as a part of Intel Virtualization Technology (Intel VT), hence it is possible to enable/disable it in BIOS for some vendors [16, 23, 88]. According to [44, 72], DDIO can be disabled globally (i.e., by setting the `Disable_All_Allocating_Flows` bit in "iiomiscctrl" register) **or** per-root PCIe port (i.e., setting bit `NoSnoopOpWrEn` and unsetting bit `Use_Allocating_Flow_Wr` in "perfctrlsts_0" register). Some brief discussions of the benefits of disabling DDIO exist [11, 78], but we elaborate this more thoroughly in §7. We implemented an element for FastClick, called *DDIOTune*, which can enable/disable/tune DDIO[†].

[*] One can read/write this register via `msr-tools` (e.g., rdmsr and wrmsr).

[†] The element is available at: https://github.com/tbarbette/fastclick/wiki/DDIOTune

5 Characterization of DDIO

This section scrutinizes the performance of DDIO in different scenarios while exploiting the tuning capability of DDIO. The goal is to show where DDIO becomes a bottleneck and when tuning DDIO matters. Therefore, we examined the impact of both system parameters (i.e., #RX descriptors, #cores, and processing time) and workload characteristics (i.e., packet size and rate) on DDIO performance. All of these measurements were done 20 times for both Skylake and Haswell microarchitectures. We observed the same behavior in both cases, but only discuss the Skylake results for the sake of brevity. We initially focus on the performance of an L2 forwarding network function, as an example of an I/O intensive application. Later, we discuss the impact of applications requiring more processing time per packet.

5.1 Packet Size and RX Descriptors

§3.1 discussed the negative consequence of a large number of RX descriptors on DDIO performance. This section continues this discussion by looking at the PCIe read/write hit rate metrics for different numbers of RX descriptors and different packet sizes. Fig. 6 shows the results of our experiments for PCIe write hit rate. PCIe read hit rates (not included for brevity) demonstrate similar behavior. When packets are >512 B, the PCIe read/write hit rates monotonically decrease with an increasing number of RX descriptors. More specifically, sending 1500-B packets, even with a relatively small number of RX descriptors (i.e., 128), causes 10% misses for both PCIe read and PCIe write hit rates. Furthermore, increasing the number of RX descriptors to 4096 makes DDIO operate at ~40% hit rate, hence 60% of packets require cache allocation and they had to be DMA-ed back to the NIC from main memory rather than LLC. Note that the packet generator is generating packets as fast as possible. Therefore, small packets show the case when the arrival *rate* is maximal, while large packets demonstrate maximal *throughput*, see Fig. 7.

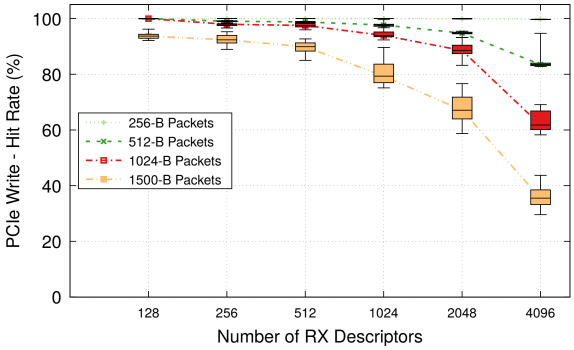

Figure 6: Increasing the number of descriptors and/or packet size *adversely* affects the performance of 2-way DDIO, while one core is forwarding packets at the maximum possible rate. We removed the results for 64-B and 128-B packets, as they show a behavior similar to 256-B packets.

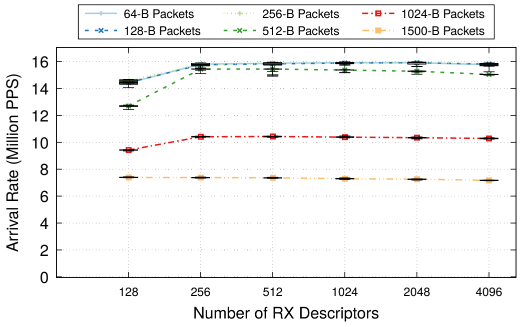
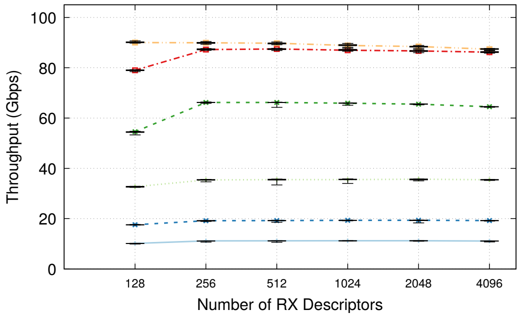


(a) Arrival rate.



(b) Throughput.

Figure 7: Increasing the packet size reduces the arrival rate, i.e., the number of received/processed packets per second, due to NIC and PCIe limitations. Note that our testbed cannot exceed 90 Gbps when *only* one core is forwarding packets.

Unexpected I/O evictions. In some cases (e.g., 1500-B packets with 128 RX descriptors in Fig. 6), the size of the injected data is smaller than the DDIO capacity (i.e., 187.5 KiB $\ll$ 4.5 MiB). Even taking into account the TX descriptors and the FastClick's software queue, the maximum cache footprint of this workload is ~2 MiB. However, DDIO still experiences ~10% misses. We believe that this behavior may occur when an application cannot use the whole DDIO capacity due to (i) the undocumented cache replacement policy and/or (ii) the cache's complex addressing [15], thus multiple buffers may be loaded into the same cache set.

5.2 Packet Rate and Processing Time

§5.1 demonstrated that DDIO performs extremely poorly when a core does minimal processing at 100 Gbps. Next, we focus on the worst-case scenario of the previous experiment (i.e., sending 1500-B packets with 4096 RX descriptors) while changing the packet rate. To achieve 100 Gbps, we use two cores. Fig. 8 shows the PCIe read and PCIe write hit rates. The PCIe read metric results reveal that DDIO performs relatively well until reaching 98 Gbps. However, the PCIe write results indicate that DDIO has to continually allocate cache lines in LLC for 25% of packets at most of these throughputs, due to insufficient space for all of the buffers. Moreover, throughputs above 75 Gbps exacerbate this problem.

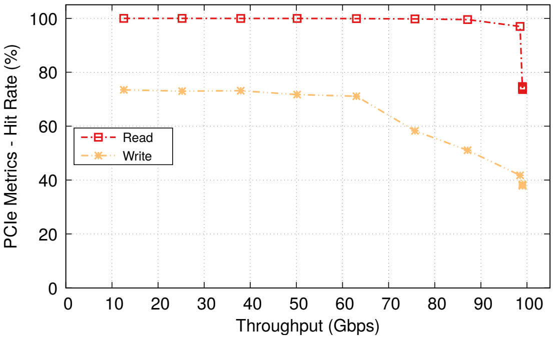


Figure 8: Increasing packet rates *negatively* impact the PCIe metrics, when 2 cores forward 1500-B packets with 4096 RX descriptors. The PCIe write metric is more degradation-prone.

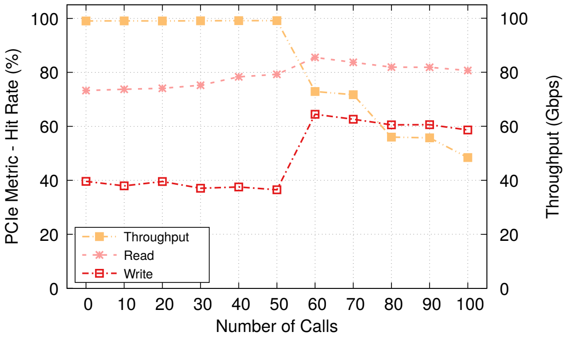

Figure 9: Making an application more compute-intensive results in better PCIe metrics, but *lower* throughput. In addition to forwarding packets, two cores call a dummy computation, while receiving 1500-B packets with a total of 4096 RX descriptors at 100 Gbps.

So far, we analyzed DDIO performance when cores performed minimal processing (i.e., swapping MAC addresses). Now, we analyze DDIO performance for more compute/memory-intensive I/O applications. Memory-intensive applications access memory frequently and execute few instructions per memory access. The time to accessing memory differs depending upon the availability of a cache line in a given part of the memory hierarchy. Therefore, we focus on the number of CPU cycles of the computation; noting that a memory access can be accounted for as given number of cycles. Note that increasing the processing time can change the memory access pattern, as packets continue to be injected by the NIC while some packets are enqueued in the LLC. To see the impact of different packet processing times on the performance of DDIO, we vary the amount of computation per packet by calling the `std::mt1993` random number generator multiple times. Ten such calls take ~70 cycles. Fig. 9 illustrates the effect of increasing per-packet processing time on the PCIe metrics & achieved throughput. These results demonstrate that increasing processing time slightly improves PCIe read hits rates up to ~60 calls, i.e., 400 cycles. This is expected, as increasing processing makes the application less I/O intensive as the application provides buffers to the NIC at a slower pace. However, increasing processing causes the available processing power (i.e., #cores) to become a bottleneck, substantially decreasing throughput. Similarly, PCIe write hit rates increases after exceeding 60 calls, due to a decrease in throughput & amount of cache injection. Therefore, DDIO performance *matters most* when an application is I/O bound, rather than CPU/memory bound.

5.3 Numbers of Cores and DDIO Capacity

When processing power limits an application's performance, the system should scale up/out. However, this scaling can affect DDIO's performance. To see the effect of scaling up, we measured the PCIe metrics while different numbers of cores were forwarding large packets. Fig. 10 shows that when an application is I/O intensive, increasing the number of cores improves the PCIe read/write hit rate, as it enhances the packet transmission rate because of more TX queues and faster consumption of packets enqueued in the LLC. To avoid synchronization problems, every queue is bound to one core. However, beyond a certain point (i.e., four cores in our testbed), increasing the number of cores causes *more* contention in the cache, as every core loads packets independently into the limited DDIO capacity. Furthermore, since newer processors are shipped with more cores, scaling up, even with a small number of RX descriptors, eventually causes the leaky DMA problem–the same problem as having a large number of descriptors (see §3.1).

Fig. 11 shows PCIe metrics for 1, 2, and 4 cores while changing the number of DDIO ways. Comparing the DDIO performance of different numbers of cores/DDIO ways, we conclude that increasing DDIO capacity leads to similar improvements for PCIe metrics. Therefore, increasing the DDIO capacity rather than the number of cores is beneficial when an application's bottleneck is *not* processing power or number of TX queues. Unless scaling up happens efficiently, some cores may receive more packets than others, causing

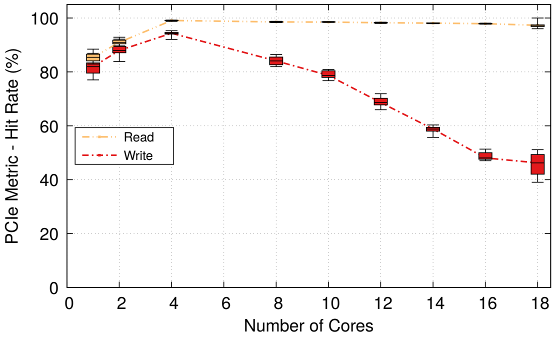

Figure 10: Increasing the number of cores does *not* always improve PCIe metrics for an I/O intensive application. Different numbers of cores are forwarding 1500-B packets at 100 Gbps with 256 RX descriptors per core.

performance degradation. We discuss the impact of load imbalance on DDIO performance in the next section.

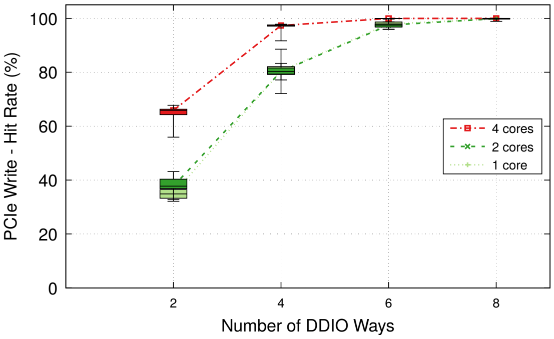

Figure 11: Increasing the number of DDIO ways can have a similar *positive* effect as increasing the number of processing cores, while forwarding 1500-B packets at 100 Gbps with a total of 4096 RX descriptors. PCIe read hit rate shows the same behavior as PCIe writes.

6 Application-level Performance Metrics

The previous section focused on the PCIe read/write hit rates and showed that increasing link speed & packet size and the number of descriptors & cores could degrade these metrics. PCIe read/write hit rates represent the percentage of I/O evictions (i.e., the performance of DDIO), but also *indirectly* affect application performance. The correlation between PCIe metrics and meaningful performance metrics (e.g., latency and throughput) depends on an application's characteristics. For instance, a low PCIe write hit rate can severely affect an application that requires the whole DMA-ed data. Conversely, the impact is much less for an application that needs only a subset of the DMA-ed packet. Fig. 2 showed one example of this correlation for the latter case, where the application only accessed the packet header. These results showed that *even* when an application does not require the whole DMA-ed data, increasing the number of descriptors (i.e., causing a reduction in PCIe hit rate metrics) could negatively affect the 99th percentile latency. Note that we observed the same effect at median latency. This section further elaborates this impact in two scenarios where a stateful network function is processing a realistic workload[*] via 18 cores with a run-to-completion model [38, 93]. The benefits of increasing cache performance are not limited to this model and could be even greater for a pipeline model where fewer cores handle the I/O.

Stateful service chain. To evaluate the effect of increasing DDIO capacity, we chose a stateful service chain composed of a router, a network address port translator (NAPT), and a round-robin load balancer (LB) as a suitable chain to exploit hardware offloading capabilities of modern NICs while still keeping state at the processor. In this case, we offload the routing table of the router to the NIC and only handle the *stateful tasks* (i.e., NAPT + LB) and the basic functionality of the router in software. We generated 2423 IP filter rules for the campus trace using the GenerateIPFlowDirector element in Metron [38] and use DPDK's Flow API technology [31] to offload them into a Mellanox NIC. To examine the impact of load imbalance, we generate two different sets of rules with different load imbalance factors. One distributes the rules among 18 cores in a round-robin manner while the other is load-aware and tries to reduce the flow imbalance in terms of bytes received by every core. We calculated the number of packets received by each core for both cases and the maximum imbalance ratio of a core is 2.78× for the load-aware technique, while the round-robin technique causes 1.69× maximum load imbalance. The load-aware method has a higher load imbalance because we generate rules for the whole trace, but only replay a subset of it. Fig. 12 shows the 99th percentile latency of this chain for different load balancing methods (with different load imbalance ratio), specifically increasing DDIO capacity reduces the 99th percentile latency by ~21% when the load imbalance is higher. However, when the load imbalance is lower, these improvements reduce to ~2%. A higher load imbalance factor means that a core receives more packets than others, some of which could be evicted while enqueued in the LLC. Hence, it is crucial to realize a good balance to get the most out of DDIO. Furthermore, load imbalance is the root cause of many other performance degradations and is hard to prevent [8, 10].

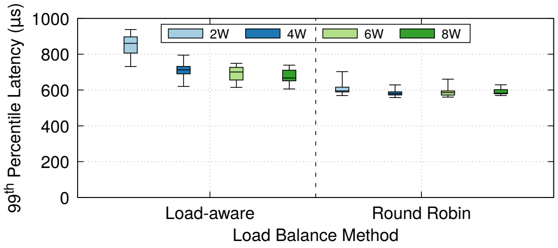

Figure 12: DDIO should be *carefully* tuned when the load imbalance factor is higher. The results shows 99th percentile latency of a stateful network function while 18 cores are processing mixed-size packets at 100 Gbps. The throughputs were 94 & 97 Gbps for load-ware (higher imbalance) & round-robin (lower imbalance) experiments, respectively.

7 Is DDIO Always Beneficial?

The previous section showed that performance could be improved by tuning DDIO for I/O intensive network functions operating at ~100 Gbps. However, these results *cannot* be generalized, as the improvements are highly dependent on the application's characteristics. Moreover, there may be some applications that do not benefit from DDIO tuning. To investigate this, we measure the sensitivity of different applications to DDIO by enabling/disabling it (see §4.4). Table 2 shows the results for four applications/benchmarks:

[*] We replay the first 400 k packets of a 28-minute campus trace fifty times. The full trace has ~800 M packets with an average size of 981 B.

Table 2: DDIO sensitivity changes for different applications.

DDIO / Application	Enabled				Disabled				Sensitivity
	Throughput	Median (μs)	Avg (μs)	99^{th} (μs)	Throughput	Median (μs)	Avg (μs)	99^{th} (μs)	
Memcached (TCP)	1003058 TPS	N/A	477.62	N/A	994387 TPS	N/A	481.62	N/A	Low
Memcached (UDP)	638763 TPS	N/A	750.12	N/A	631354 TPS	N/A	758.75	N/A	Low
NVMe (Full Write)	4427.2 MiB/s	44879.4	44437.6	46452.4	4434.2 MiB/s	44827	44374.68	46452.4	Low
NVMe (Random Read)	3372.4 MiB/s	582	589.67	765.7	3233.7 MiB/s	601.8	614.46	805.7	High
NVMe (Random Write)	1498.3 MiB/s	1307.8	1324.73	1991.2	1499.9 MiB/s	1309.5	1323.38	1971.4	Low
L2 Forwarding	98.01 Gbps	500.82	662	1055.98	87.02 Gbps	1058.15	862	1229.62	High
Stateful Service Chain (without offloading)	63.92 Gbps	665	657	923	63.25 Gbps	672	666	931	Low
Stateful Service Chain (with round-robin offloading)	97.35 Gbps	499	505	595	87.46 Gbps	531	924	1981	High

(i) DPDK-based implementation of Memcached developed by Seastar [5], (ii) an NVMe benchmarking tool (i.e., fio [4]), (iii) L2 forwarding application, (iv) a stateful service chain, used in §6, which performs IP filtering in software rather than offloading it to the NIC, and (v) the stateful service chain with round-robin offloading used in §6. We define sensitivity as "Low" if the maximum impact on the performance of an application is $\leq 5\%$. For Memcached, we use the method recommended by Seastar [2] with 8 instances of memaslap clients running for 120 s and a Memcached instance with 4 cores. For NVMe benchmarks, we tested a Toshiba NVMe (KXG50PNV1T02) with 4×1024-GB SSDs according to [3], where we report the average of 10 runs. The L2 forwarding application forwards mixed-size packets, while using 4 cores with a total of 4096 RX descriptors. The stateful service chain without offloading uses RSS to distribute packets among 18 cores (to increase the throughput) with 18×256 RX descriptors. The results demonstrate that different applications have different levels of sensitivity to DDIO, which can be exploited by system developers to optimize their system in a multi-tenant environment, where multiple I/O applications co-exist, see §8.1. The most sensitive application is L2 forwarding, which is the most I/O intensive application among these applications and can run at line rate. Some applications (e.g., Memcached) experience less benefit from DDIO, as their performance may be bounded by other bottlenecks. A more detailed sensitivity analysis of different applications remains as our future work.

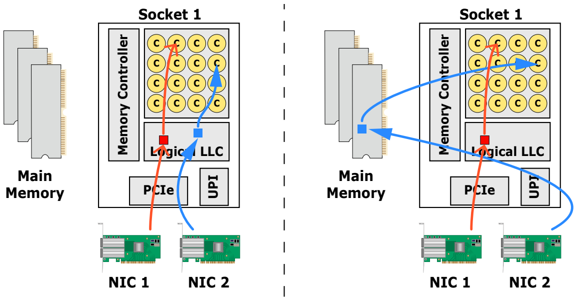
8 Future Directions for DCA

Tuning DDIO occupancy was shown to substantially improve the performance of some applications. However, increasing the portion of the cache used for I/O is only a temporary solution for two reasons: (i) I/O is only a part of packet processing and (ii) to achieve suitable performance many networking applications require a large amount of cache memory for *code/data*. Moreover, many network functions would benefit from performing in-cache flow classification [92]; hence, there is a trade-off between allocating cache to I/O vs. code/data and this trade-off depends on the application's characteristics & cache size. Additionally, since DDIO is way-based, the granularity of partitions is quite coarse in recent Intel processors, due to low set-associativity. Therefore, it is harder to partition the cache fairly between code/data & I/O. These reasons, together with the recent trend in Intel processors of decreasing per-core LLC, eventually make the current implementation of DCA a major bottleneck to achieving low-latency service times. Hence, DCA needs to deliver better performance even with a small fraction of the cache. This makes it necessary to *rethink* the current DCA designs with an eye toward realizing network services running at multi-hundred gigabits per second. Some possible directions/proposals for future DCA are: ① Fine-grained placement: adopting CacheDirector [15] methodology (i.e., sending packets to the appropriate LLC slices) and only sending the relevant parts of these packets to the L2 cache, L1 cache, or *potentially* CPU registers [26]; ② Selective DMA/DCA: only DMA relevant parts of the packet (as required by an application) to the cache and buffer the rest in either main memory, the NIC, or Top-of-Rack switch; and ③ I/O isolation: extend CAT to include I/O prioritization in addition to Code and Data Prioritization (CDP) technology [60] to alleviate I/O contention. These ideas could be simulated in a cycle accurate simulator (e.g., gem5 [6, 12]), which remains as our future work. Next, we examine one potential solution in the current systems to better take advantage of DDIO.

8.1 Bypassing Cache

§3.1 explained that one way to prevent unnecessary memory accesses and the leaky DMA problem is to reduce the number of descriptors. However, this could increase packet loss and generate more PAUSE frames at high link rates. Unfortunately, both can have a severe impact on the service time as they postpone the service time by at least a couple of microseconds. Taking these consequences into account, we believe future DCA technologies should perform cache injection more effectively: *DMA should not be directed to the cache if this would cause I/O evictions*; thus, buffering packets in local memory (at a cost of only several hundreds of nanoseconds) is preferable to dropping or enqueuing packets in previous nodes. Additionally, bypassing cache would be beneficial in a multi-tenant scenario where performance isolation is desired. For instance, low-priority and/or low-DDIO-sensitive applications could bypass cache to make room for high-priority and/or high-DDIO-sensitive applications. In addition, one could prioritize [7] different traffic flows, thus only a subset of received traffic (and hence cores) would use cache for I/O. Implementing a system to prioritize DDIO for different flows either in a programmable switch or modern NICs (e.g., Mellanox Socket Direct Adapters) remains as our future work.

Evaluation. To evaluate the benefits of bypassing the cache, we use two methods: (i) disabling DDIO and (ii) exploiting DMA via a remote socket (see §4.3). We set up a 200-Gbps testbed, see Fig. 13. We first connect two 100-Gbps NICs to the same socket. Next, we connect one of these NICs to a remote socket. We run two instances of L2 forwarding application located on the first socket, each of which uses 4 cores and one NIC to forward mixed-size packets. We chose four cores per NIC because our earlier experiments (see Fig. 10) showed that DDIO can achieve an acceptable performance while receiving 1500-B packets with four cores. To reduce the contention for cache and memory bandwidth, we apply CAT & MBA to each application (similar to ResQ [83]). We assume that one of the applications has a higher priority, and we measure its latency in five different scenarios: **(i)** without the presence of the low-priority application, **(ii)** when the low-priority application pollutes the cache via 2-way DDIO (see Fig. 13a), **(iii)** when the low-priority application pollutes the cache via 4-way DDIO, **(iv)** when the low-priority application bypasses the cache by DMA-ing packets via a remote socket (see Fig. 13b), **(v)** when the low-priority application bypasses the cache via disabled DDIO. Fig. 14 shows the 99^{th} percentile latency of the high-priority application–other percentiles show a similar trend with a smaller difference. These results demonstrate that bypassing cache via a remote socket (i.e., case iv) achieves the same latency as when there is no low-priority application (i.e., case i). However, when both applications are receiving traffic via DDIO (i.e., case ii), the 99^{th} percentile latency degrades ~30%. We observe that bypassing cache has the same benefits as increasing DDIO capacity (i.e., case iii vs. case iv). Furthermore, comparing cases (iv) and (v) indicates that disabling DDIO *slightly* pollutes the cache (as opposed to bypassing via a remote socket). We speculate that disabling DDIO only affects the packets, not the descriptors. Therefore, we conclude that bypassing cache can result in less variability in performance and potentially better performance isolation. Additionally, it is clearly necessary to tune DDIO capacity when moving toward 200 Gbps.



(a) Through local socket.

(b) Through remote socket.

Figure 13: Receiver setup to achieve 200 Gbps. On the right setup, the second NIC is connected to the remote socket. It sends packets through UPI link directly to the main memory.

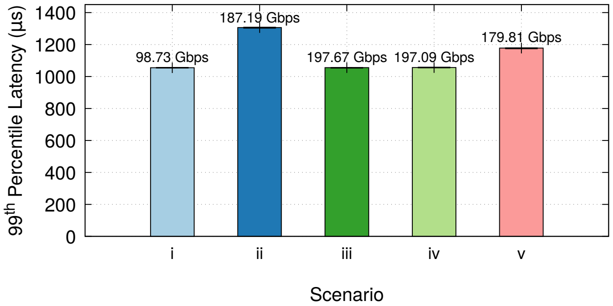


Figure 14: Bypassing cache and tuning DDIO at 200 Gbps mitigate I/O contention and improve the tail latency of the high-priority application up to 30%. Scenarios: (i) 100 Gbps with no contention; (ii) contention at 200 Gbps; (iii) tuning DDIO at 200 Gbps; (iv) bypassing cache via a remote socket; and (v) bypassing cache via disabled DDIO. The total achieved throughput of the receiver is written on the bars.

9 Lessons Learned: Optimization Guidelines

This section summarizes our key findings, which could help system designers/developers to optimize DDIO for their applications. Furthermore, our study should inspire computer architects to improve DCA's performance by offering increasing control. Although we focused on packet processing, our work is not limited to network functions. Our investigations could be equally useful in other contexts (e.g., HPC) that require high-bandwidth I/O when transferring data via RDMA and processing with GPUs. We showed that current approaches to avoid DDIO becoming a bottleneck are only temporary solutions and they are inapplicable to multi-hundred-gigabit network applications. We proposed a benchmarking method to understand the unknown & little-discussed details of DDIO. Later, we characterized the performance of DDIO in different scenarios and showed the benefits of bypassing the cache. We concluded that there is *no* one-size-fits-all approach to utilize DDIO. Our study reveals:

- The locations of LLC to which DDIO injects data (§4.1).
- Co-locating an application's code/data with I/O in the cache could adversely impact its performance (§4.2).
- The way that DDIO behavior changes for different system parameters and workload characteristics (§5).
- If an application is I/O bound, adding excessive cores could degrade its performance (Fig. 10).
- If an application is I/O bound, *carefully* sizing the DDIO capacity can improve its performance and could lead to the

same improvements as adding more cores (Fig. 11).

- If an application starts to become CPU bound, adding more cores can increase its throughput, but then it has to balance load among cores to *maximize* DDIO benefits (Fig. 12).
- If an application is *truly* CPU/memory bound, DDIO tuning is less efficient (Fig. 9). However, it can be beneficial to buffer in DRAM incoming requests/packets which cannot be processed in time, rather than having the NIC issue PAUSE frames or drop packets.
- Going beyond ~75 Gbps can cause DDIO to become a bottleneck (Fig. 8). Therefore, it is essential to *bypass cache* to realize performance isolation. Bypassing cache could be done for low-priority traffic or applications that do not benefit from DDIO (§8.1).
- Different applications have different levels of sensitivity to DDIO (§7). Identifying this level is essential to utilize system resources more efficiently, provide performance isolation, and improve performance.

10 Related Work

The most relevant work to our study is ResQ [83], which we discussed thoroughly in §3.1 and §8.1. This section discusses other efforts relevant to our work.

Injecting I/O into the cache. The idea of loading I/O data directly to the processor's cache was initially proposed using cache injection techniques [52, 63]. Later, it was used to enhance network performance on commodity servers and was referred to as DCA [25]. Amit Kumar et al. [42] investigated the role of coherency protocol in DCA. Their results indicated that the benefit of DCA would be limited when the network processing rate cannot match the I/O rate. In addition, [75] showed that DCA could cause cache pollution; hence they proposed an alternative cache injection mechanism to mitigate the problem. A. Kumar et al. [43] characterized DCA for 10-Gbps Ethernet links. Other works have discussed that DCA is insufficient due to architectural limitations [40, 46, 71]. For example, the work in [46] proposed a new I/O architecture that decouples and offloads I/O descriptor management from the NIC to an on-chip network engine. Similarly, the work in [40] proposed a flexible network DMA interface which can support DCA. Last but not least, Wen Su et al. [71] proposed an improvement to combine DCA with an integrated NIC to reduce latency.

Efforts toward realizing 100 Gbps. Many have tried to tackle challenges to achieve suitable performance for fast networks, mostly in the context of NFV [49] and key-value stores [19, 45]. Some research has exploited new features in modern/smart/programmable NICs (e.g., [38, 47, 84, 94]) & switches (e.g., [36]) or proposed new features (e.g., [70]) to offload costly software processing. A number of works investigate packet processing models (e.g., [9, 39, 93]). CacheBuilder [80] and CacheDirector [15] have discussed the importance of cache management in realizing 100-Gbps networks. HALO [92] exploited the non-uniform cache architecture (NUCA) characteristics of LLC to perform in-cache flow classification. Last but not least, IOctopus [68] proposed a new NIC design and wiring for servers to avoid non-uniform DMA penalties. Our work is complementary to these works.

Cache partitioning. Many have tried to overcome cache contention by performing cache partitioning [53]. These efforts can be split into two main categories: (i) software techniques and (ii) hardware techniques. The former group principally relies on physical addresses to partition cache based on sets [22, 48, 67] or slices [15]. This way of cache partitioning does not require any hardware support, but it is not very commonly used, due to its drawbacks (e.g., OS/App modification and costly re-partitioning). The latter group mostly exploits way-partitioning (e.g., CAT) to partition the cache among different applications [13, 18, 62, 89, 90, 91]. In addition to these techniques, Wang et al. [85] proposed a hybrid approach that combines both techniques to achieve finer granularity for partitioning. To the best of our knowledge, there are only two works (ResQ [83] and CacheDirector [15]) that have specifically tried to exploit cache partitioning techniques to improve packet processing. ResQ proposes to isolate a percentage of LLC that is used for I/O and CacheDirector exploits the NUCA used in Intel processors to distribute I/O more efficiently among different LLC slices. Our work is complementary to these works, as most of them do not consider I/O when partitioning the cache.

11 Conclusion

DCA technologies were introduced to improve the performance of networking applications. However, we systematically showed that the latest implementation of DCA in Intel processors (i.e., DDIO) cannot perform as needed with increasing link speeds. We demonstrated that better I/O management is required to meet the critical latency requirements of future networks. Our main goal is to emphasize that networking is, now more than before, tightly coupled with the capability of the current hardware. Consequently, realizing time-critical multi-hundred-gigabit networks is only possible by (i) increasingly well-documented control over the hardware and (ii) improved holistic system design optimizations.

sRDMA — Efficient NIC-based Authentication and Encryption for Remote Direct Memory Access

Konstantin Taranov, Benjamin Rothenberger, Adrian Perrig, and Torsten Hoefler
Department of Computer Science, ETH Zurich

Abstract

State-of-the-art remote direct memory access (RDMA) technologies have shown to be vulnerable against attacks by in-network adversaries, as they provide only a weak form of protection by including access tokens in each message. A network eavesdropper can easily obtain sensitive information and modify bypassing packets, affecting not only secrecy but also integrity. Tampering with packets can have drastic consequences. For example, when memory pages with code are changed remotely, altering packet contents enables remote code injection. We propose sRDMA, a protocol that provides efficient authentication and encryption for RDMA to prevent information leakage and message tampering. sRDMA uses symmetric cryptography and employs network interface cards to perform cryptographic operations. Additionally, we provide an implementation for sRDMA using programmable network adapters.

1 Introduction

Despite numerous state-of-the-art systems [8, 11, 30] leveraging remote direct memory access (RDMA) primitives to achieve high performance guarantees and resource utilization, current RDMA technologies lack any form of cryptographic authentication or encryption. Instead RDMA mechanisms provide a weak form of protection by including access tokens in each message. Given that RDMA networks are mainly used in data-center environments and at large-scale deployments, detecting bugged wires is seemingly impossible. But not only in-network adversaries are an issue, also malicious end hosts can affect the security of an RDMA network. If an adversary is able to obtain control over a machine in an RDMA network (e.g., by escaping its virtual machine or hypervisor confinement in a cloud service [42]), it can fabricate and inject arbitrary packets. If the adversary can guess or obtain the protection domain and memory protection tokens (which are transmitted in plaintext), it can read and write memory locations that have been exposed using RDMA on *any machine in the network*, leading to a powerful attack vector for lateral movement in a data center network.

Given these threats, the security of current RDMA data center networks highly depends on isolation. However, even isolation cannot defend against in-network attackers. Thus, RDMA networks require cryptographic authentication and encryption. Unfortunately, application-level encryption (e.g., *TLS* [34]) is not possible, since RDMA read and write can operate as purely one-sided communication routines. Furthermore, such an approach requires employing a temporal buffer for incoming encrypted messages. The message would then be decrypted by the CPU and copied to the desired location, which would cause high overhead—negating RDMA's advantages. Additionally, cryptographic protection using *IPSec* [10] does not support RDMA traffic as the protocol is unaware of the underlying RDMA headers and achieves no source authentication (see Section 7).

In our work, we introduce a secure RDMA (sRDMA) design using a secure reliable connection (SRC) queue pair (QP) that uses symmetric cryptography for source and data authentication and employs Network Interface Cards (NICs) to perform cryptographic operations. Symmetric cryptography reduces the computational overhead compared to asymmetric cryptography by 3–5 orders of magnitude. Thus, it is suitable for high-performance and low-latency applications based on RDMA, e.g., [8, 17, 39]. Since symmetric cryptography introduces per-connection memory overhead and memory on NICs is constrained, we augment our proposed mechanisms using protection domain level keys and efficient dynamic key derivation, which eliminates the need for storing QP-level keys and drastically reduces the memory overhead on RDMA-capable NICs (RNICs). Additionally, we propose extended memory protection mechanisms that enable delegation of memory access to other trusted peers without requiring additional communication with the accessed host (e.g., an access control proxy for databases [29]).

In summary, we make the following contributions:

- we design a SRC QP that effectively prevents attacks in an RDMA network, with minimal changes to the current

InfiniBand Architecture (IBA) standard (Section 4.2);

- we improve our design by introducing PD-level keys to reduce the memory overhead on the RNIC (Section 4.5), and augment IBA with extended memory protection that enables delegation of memory accesses to third parties without the need of direct communication to the target entity (Section 4.6);
- we provide an implementation of our design using modern programmable network adapters equipped with ARM multi-core processors [7, 40] (Section 5);
- we extensively evaluate our design using artificial and real-world traces. Additionally, we modified the RDMA-based key value store, HERD [17], to make use of sRDMA (Section 6).

2 Remote Direct Memory Access

RDMA is a mechanism allowing one machine to directly access data in remote machines across the network.

Memory accesses are performed using dedicated hardware without any CPU intervention or context switches, which decreases CPU usage on both the initiator and the target. When an application performs an RDMA read or write request, the application data is delivered directly to the network, reducing latency and enabling fast message transfer. RDMA also exhibits the concept of one-sided operations when the CPU at a target node is not notified of incoming RDMA requests.

Several network architectures support RDMA: InfiniBand (IB) [4] , RDMA over Converged Ethernet (RoCE) [5], and internet Wide Area RDMA Protocol (iWARP) [33]. InfiniBand is a network architecture fully designed to enable reliable RDMA with its own hardware and protocol specification. RoCE is an extension to Ethernet to enable RDMA over an Ethernet network. Finally, iWARP is a protocol that allows using RDMA over TCP/IP. In this work, we focus on the InfiniBand architecture (IBA) and RoCE as they are the most widely used interconnect for RDMA, but the proposed ideas can be easily extended to other RDMA architectures.

2.1 InfiniBand Transport

Several transport types are supported by the IBA to communicate between endpoints: reliable connection (RC), unreliable connection, unreliable datagram, extended reliable connection, and raw packet. In this paper, we only consider the RC transport type, since it is the only type that supports both RDMA read and write requests.

The RC transport type establishes a *queue pair (QP)* between the two communicating parties. QPs are bi-directional message transport engines used to send and receive data in InfiniBand. Endpoints of a single RC QP can only communicate with each other but not with any other QP in the same or any other target adapter. Each QP endpoint has a queue pair number (QPN) assigned by the RNIC which uniquely identifies the QP within the RNIC.

The RC transport uses several techniques to ensure reliability. The target must respond to each request packet with a positive acknowledge packet or a negative acknowledge packet. The acknowledgement-based protocol permits the requester to verify that all packets are delivered to the target. To ensure the integrity of a packet, each packet contains two checksums that are verified by the target node. Finally, the RNIC counts received and sent packets using a packet sequence number (PSN), which is included in each packet. Thus, endpoints of a QP must know the PSN of each other to enforce in-order delivery and detect duplicate and lost packets.

2.2 IBA Memory Protection

The IBA protection mechanisms provide protection from unauthorized access to the local memory by network controllers. The local memory can also be protected against prohibited memory accesses. Three mechanisms exist to enforce memory access restrictions: Memory Regions, Protection Domains (PD), and Memory Windows.

Memory Regions. To get access to host memory, the RNIC must first allocate a corresponding memory region. This process involves copying page table entries of the corresponding memory to the memory management unit of the RNIC. When a memory region is created, the RNIC generates keys for local and remote accesses, namely *l_key* and *r_key*. The memory region can be accessed by any local QP which has the *l_key* as long as they are in the same PD, and by their remote QP endpoints which have the *r_key*. The endpoints must prove the possession of this key by including it in every RDMA request, such as RDMA Write and Read. *r_key* is not used in any form of cryptographic computation, but rather is used as access tokens that are transmitted in plaintext.

Protection Domain. PDs provide protection from unauthorized or inadvertent use of memory regions. PDs group IB resources such as QP connections and memory regions that can work together: QP connections created in one PD cannot access memory regions allocated in another PD. In other words, a memory region can be accessed by any QP from its PD. All QPs and memory regions must have a PD and can be a member of one PD only.

Memory Windows. Memory windows extend protection of memory regions by allowing remote QPs to have different access rights within a memory region and grant access to only a slice of the memory region.

3 Problem Definition

This section describes the adversary model we consider, outlines different types of attacks, and the security properties we strive to achieve.

3.1 Desired Security Properties

The current IBA protection mechanisms do not suffice to ensure secure communication between endpoints, allowing adversaries numerous attacks. Thus, the primary goal of our work is to *secure RDMA protocols against attacks* by providing source and data authentication along with data secrecy and data freshness. Source authentication denotes the verification of the source address of a host that sends a packet and is designed to determine whether a packet originated from the claimed source. Data authentication ensures that the packet content has not been modified. Data secrecy ensures that the data remains hidden from a network eavesdropper. Data freshness ensures that data has not been recorded and replayed by a network attacker. Additionally, our proposal should require *minimal changes to the protocol*, and introduce only a *minor performance overhead*. This does not only include latency and processing overhead for RDMA requests but also memory state overhead on the RNIC.

3.2 Adversary Model

In our adversary model we consider end hosts that are equipped with RNICs and interact with each other through RDMA, and an adversary with the following parameters.

Location. We assume that the adversary can reside at *arbitrary locations* within the network. Thus, we consider both network-based adversaries (e.g., rogue cloud provider, rogue administrator, malicious bump-in-the-wire device) and adversaries located at end hosts (e.g., compromise of an end host). This includes compromise of the machines of communicating parties. However, we assume that RNICs are *trusted* by their host. This could be achieved using remote attestation, whereby a trusted party checks the internal state of a potentially compromised network device. We further assume that the internal bus is trusted, such that the CPU can securely communicate with the RNIC.

Capabilities. A network-based adversary can passively eavesdrop on messages, but also actively tamper with the communication. Since RDMA communication is performed in plaintext, an adversary that is located on the path between communicating parties can obtain any information in all IB and Ethernet headers. Furthermore, he can also alter any of these values, as this only requires recalculation of packet checksums, whose algorithms and seeds are known and specified by the IBA.

Given these capabilities, the adversary can also fabricate packets and send them towards a destination of its choice using spoofed QP numbers, *r_key*s, and PSNs (e.g., to modify a memory region without authorization to influence the behavior of applications running on the remote host).

Cryptography. The adversary has no efficient way of breaking cryptographic primitives. For pseudorandom function families, this means that no efficient algorithm can distinguish between an output of a function chosen randomly from the pseudorandom function family (PRF) and a random value.

Table 1: Notation used in this paper.

$\|\|$	Bitstring concatenation
$PRF_K(\cdot)$	Pseudorandom function using key K
$MAC_K(\cdot)$	Message authentication code using key K
A, B	Endpoints uniquely identified by the combination of the adapter port address (APA) and Queue Pair Numbers (QPN)
$K_{A,B}$	Symmetric key shared between node A and B
$nonce_{A \rightarrow B}$	cryptographic nonce used for communication in the direction from node A to node B
K_{PD}, K_{MR}, K_{SR}	Symmetric key used for protection domain, memory region, or sub memory region

4 Secure RDMA System Design

We propose a new transport type for reliable communication based on the IBA. We introduce a secure reliable connection (SRC) QP that uses symmetric cryptography for source and data authentication, and thus provides guarantees for the origin of a packet, data authenticity and payload secrecy.

To require minimal changes to the current IBA specification, our proposed design of the SRC QP consists of two main changes: 1) we add symmetric key initialization for QPs, and 2) we propose a new packet header called secure transport header (STH) which contains a message authentication code (MAC) providing integrity of the packet content. The STH must be included in all requests and response packets corresponding to RDMA reads and writes.

Besides basic QP-channel protection, we also propose *PD level protection* eliminating the need for storing cryptographic keys for each QP, which drastically reduces the memory overhead on RNICs. Additionally, it enables *extended memory protection* that provides memory access control based on encryption and the ability of delegating memory access to other trusted entities without additional communication to the accessed host. All QPs and memory regions created in a secure PD will be inherently secured by it.

Table 1 lists the security-related notation used in this paper.

4.1 Assumptions

Trust in RNIC. We assume that the RNIC is trusted by its host. It can not only perform authentication of outgoing packets, but is also trusted to perform en-/decryption of the packet payload. We further assume that the internal bus is trusted, such that the CPU can securely communicate with the RNIC.

QP-level Key Establishment. Our system enables the establishment of a QP-level symmetric key. To guarantee interoperability, our design is agnostic of this underlying mechanism. IBA could use for instance a (D)TLS [34] or QUIC [15] handshake as a mechanism to obtain a QP-level symmetric key.

Key Validity. As the validity period of a QP-level symmetric key is bound to the lifetime of a QP, key rollover can be performed by closing and reopening a QP between the communicating entities. Thus, key lifetime can be managed on the application level.

Size (bits)	0	96	128	160	224	256	384	512
Value	0x0	0x1	0x2	0x3	0x4	0x5	0x6	0x7

Table 2: Possible sizes of STH, depending on the 3 bit value indicated in the Base Transport Header of an IB packet.

4.2 Secure Reliable Connection Queue Pair

We propose new transport type—Secure Reliable Connection (SRC) QP—that uses symmetric cryptography for source and data authentication. The introduction of SRC requires minimal changes to the current specification. Specifically, the QP initialization requires specifying a protection algorithm and a symmetric key. This allows us to bootstrap secrecy and authentication for QP-based communication.

Secure Transport Header. Secure Transport Header (STH) consists of MAC to provide header and packet authentication. The STH must be included in all request and response packets of sRDMA. Depending on the authentication mode installed to the secure QP, the MAC either authenticates only the packet header or the entire packet. To specify the length of the STH, we use 3 (out of 7) reserved invariant bits in the Base Transport Header. Based on the 3 bit value (see Table 2), the size of the MAC changes: minimum 96 bits, and maximum 512 bits. If the reserved 3 bits are all zero, then the STH is not present in the packet, thereby enabling support of both classical and secure QP connections.

Reusing PSN as a Per-Packet Nonce. sRDMA prevents replay attacks by including a unique nonce in the MAC computation of each packet (Section 4.3). Nonces are used as initialization vectors for ciphers to ensure that every packet is unique. They must *only be used once*, but their choice can be *predictable* and they can be *transmitted in clear* [19, 37]. In case a nonce is reused, the cryptographic properties of a cipher are affected (e.g., "sudden death" property of Poly1305 [6]).

A naive solution is to transmit a nonce as cleartext with each packet (e.g., as in TLS up to version 1.2 [36]). However, this would incur an additional transmission overhead of at least 64 bits, and additional 64 bits memory overhead on RNICs memory to store the nonce.

To avoid the overhead of transmitting the nonce, our protocol takes advantage of the sequential nature of IB packets. It uses the sequence number as nonces as they are tracked by end points and can never be reused. The approach resembles how TLS 1.3 [35] exploits the packet number as a nonce; however, the size of the PSN in the IB packet is only 24 bits, which would cause a reuse of a nonce after 80 ms assuming that an RNIC is able to send 200 million packets per second [28].

sRDMA extends the local PSN counters for inbound and outbound packets on the RNIC to 64 bits each, and reuse them as a per-packet nonce, thereby introducing only 40 bits overhead for each nonce. However, the size of the PSN transmitted on the wire remains unchanged (24 bits) and contains the least significant bits of the 64 bit counter. sRDMA is able to infer the 64 bit nonce used to secure the packet using only the 24 bit PSN specified in the header. Under the same assumption on the packet rate, the reuse of nonce occurs after 3,000 years.

Table 3: Overheads of sRDMA for *N* RC QP connections with AES-128 cipher in 4 different protection modes. Here, *pd-prot* and *ext-mem* stand for PD-level protection and extended memory protection, and are described in Section 4.5 and 4.6.

AES-128 protection	Key overhead	Nonce	Header
basic	16B * *N*	10B * *N*	16B
pd-prot	16B	10B * *N*	16B
ext-mem	16B * *N* + 16B	10B * *N*	16B
pd-prot + *ext-mem*	16B + 16B	10B * *N*	16B

To ensure that the nonce never gets reused by both endpoints, we use the most significant bit to identify the direction of communication between the entities *A* and *B* using their endpoint identifiers: the combination of adapter port address and Queue Pair Number (QPN).

4.3 Header Authentication

To perform header authentication, sRDMA uses the established symmetric keys and calculates a MAC for each packet:

$$mac_{hdr} = MAC_{K_{A,B}}(nonce_{A\to B} \parallel RH \parallel BTH)$$

Here, *RH* denotes the routing header, which defines the adapter port address, and *BTH* the base transport header, which includes destination QPN. Note that these headers uniquely identify the sender and receiver RNIC, and limit the input size of the MAC computation (only the packet header instead of the entire packet with arbitrary payload length). Thus, assuming an block-cipher-based MAC is used, a fixed number invocations of the block-cipher are required to calculate a MAC.

The RNIC of the receiving node will recompute the MAC for each packet and compare it to the MAC appended in the STH. Fields that are modified during the packet's transmission are replaced with ones during the MAC computation (same as for invariant checksum).

Header authentication prevents not only source-address-spoofing attacks, but also unauthorized access to memory regions by augmenting the existing IBA memory-protection mechanisms (i.e., *r_key* and memory windows).

4.4 Packet Authentication and Encryption

For packet authentication and payload encryption, we assume that the RNIC is trusted. Thus, the host is allowed to offload all cryptographic operations to the RNIC. We use authenticated encryption with associated data (AEAD), to simultaneously obtain secrecy and authenticity for the payload. The authentication tag is transmitted using the MAC field in the STH.

4.5 PD-level Protection

Introducing QP-level keys requires storing a 16 byte key per QP (see Table 3). As an RNIC might have a large number of QPs simultaneously, this can lead to a significant memory overhead on the RNIC. Memory on RNICs is a constrained resource, and a large part is consumed by IB connection contexts and page-table entries for registered memory. Multiple works report significant performance degradation of RDMA operations when the amount of memory registered or the number of QPs is increased [11, 18]. This is due to the RNIC running out of memory for storing page-table entries and starting to fetch them from system memory across the PCI bus. For instance, Dragojevic et al. [11] observe ~4x throughput drop in their evaluation when 4,096 memory pages are registered within the RNIC compared to a single-page experiment. Thus, we aim to mitigate the memory overheads introduced by QP-level keys.

To reduce the memory overhead and eliminate the need of storing a symmetric key per QP, we introduce PD-level protection. In this mechanism, we assign a symmetric key K_{PD} to each protection domain PD and use this key to derive QP-level keys using efficient key derivation [14]. PD-level keys are exchanged using the same mechanism as QP-level keys (see Section 4.1). The derivation process works as follows:

$$K_{A,B} = PRF_{K_{PD}}(APA_A \parallel QPN_A \parallel APA_A \parallel QPN_B)$$

PRF denotes a pseudorandom function with a PD-level key K_{PD} and a pair of unique end point identifiers (i.e., adapter port address (APA) and queue pair number (QPN)) as input. When an RDMA request targets a QP that is located within a protection domain PD, the RNIC uses the corresponding symmetric key K_{PD} to derive the QP-level key on-the-fly. The QP-level key is then used to perform authentication and encryption. Thus, instead of storing a symmetric key per QP, the RNIC is only required to store a key per PD. To minimize the processing overhead, the RNIC can cache the derived QP-level keys (e.g., after the first packet of a message arrives). K_{PD} is initialized upon creation of the PD and thus the lifetime of K_{PD} is bound to the lifetime of the PD. In order to perform a key rollover, a new protection domain must be created.

4.6 Extended Memory Protection

Using encryption of memory regions enables an even stronger mechanism for access control, as only entities in possession of the required key are able to read the content of a memory region. For this purpose, we use PD-level memory protection and derive memory level keys from K_{PD} for memory regions that are created within the protection domain. The derivation process works as follows:

$$K_{MR} = PRF_{K_{PD}}(START_{MR} \parallel END_{MR} \parallel r\_key_{MR})$$

Alternatively, the K_{MR} can be provided by the application to protect memory from unauthorized accesses.

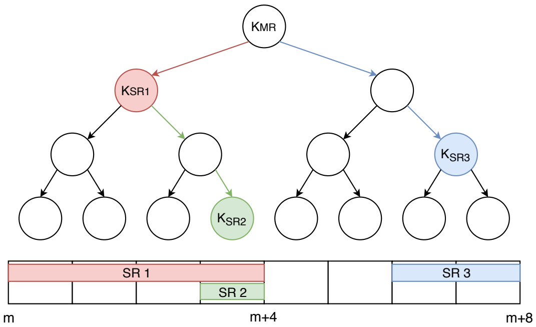

Figure 1: Access Sub-Delegation with one-way tree.

When remote parties want to access a subregion (SR) of the region MR, they need to prove the possession of the K_{MR} by computing a key to the SR:

$$K_{SR} = PRF_{K_{MR}}(START_{SR} \parallel END_{SR}) \quad (1)$$

Nonce for Key Derivation. To avoid replay attacks, our system must use a separate nonce for each memory region. However, it is not possible to use a memory access counter as nonce, as multiple QPs can access the same memory region. Therefore, this would require the RNIC to include a random nonce in each packet, which must be unique among all nonces used to access the memory region. Given that multiple parties have access to the region, this property is hard to achieve. Additionally, we want to avoid transferring a separate MAC for memory access in the packet header. Thus, we suggest to reuse the MAC of the header by overwriting it as follows:

$$mac_{hdr} = MAC_{K_{A,B}}(K_{SR}||mac_{hdr})$$

Such design allows sRDMA to reuse the per-packet nonce used in computation of mac_{hdr} and ensure the possession of K_{MR} to access memory. This construction is secure since the key is unknown to an adversary.

4.7 Sub-Delegation of Access to Memory

To allow sub-delegation of access to memory regions, we further extend the proposed extended memory protection with a binary one-way function tree [26]. The one-way function tree is built top-down where the memory region key K_{MR} is represented by the root of the binary tree and all child nodes are generated by applying the PRF:

$$K_{MR_{child}} = PRF_{K_{MR_{parent}}}(START_{MR_{child}} \parallel END_{MR_{child}})$$

Each memory block represents a leaf of the binary one-way tree (see Figure 1). Thus, the height of the tree depends on the size of the region and on the memory block size. Delegating access to a subregion works by sending the key of an intermediate node to a remote party. Given the key for a memory region, the subregion offset and subregion size uniquely identify which inner node is required for delegation.

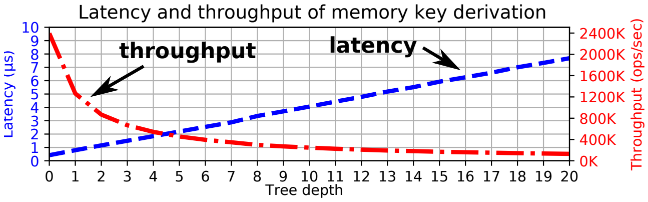

Figure 2: Performance of K_{MR} derivation for different tree depths. The derivation is performed sequentially, thus latency grows linearly and the throughput decreases exponentially.

An example of the delegation process is illustrated in Figure 1. To obtain a key for subregion 3, the entity must derive an intermediate key first, which can then be used to derive K_{SR_3}. To delegate access for subregion 2 to another host, a host in possession of K_{SR_1} derives K_{SR_2} and then shares this key with the delegated host. This allows access to subregion 2, but not to any other part of the memory region.

Only logarithmically many derivations are needed to obtain a key for memory access. For example, a key for accessing a 1 MiB subregion of a 16 MiB memory region can be obtained in at most 4 steps, which takes 2 μs on our RNIC (see Figure 2). Additionally, to prevent long key derivation chains, sRDMA allows users to limit the number of steps in the key derivation process. The sub-delegation is optional and can be disabled by restricting the tree depth to zero. In this case, the key derivation works as in Equation 1.

Advantages. This approach offers multiple advantages: 1) It trivially enables sub-delegation, as the delegated party can also calculate inner nodes of the subtree that is rooted at the subregion key. 2) The block size and thus the tree size is variable and can be adjusted for each memory region, e.g., depending on window size, depth of sub-delegation, or computational power of the corresponding nodes. This also allows limiting the depth of the tree to restrict the computational overhead. 3) The RNIC is required to compute only a single branch of the tree to verify. 4) The larger the delegate memory space, the smaller is the computational overhead on the RNIC. 5) The packet size remains constant as accessing a memory subregion requires only the start and size of the region, the offset and the size of subregion, and a MAC computed using the appropriate key.

Restrictions. We restrict delegation to powers of two to ensure that a single key is sufficient to delegate access to any sub-region. Alternatively, a solution based on segment trees would overcome this limitation, but require the exchange of multiple keys.

5 Implementation

Towards our goal of supporting secure QP connections, this section describes how we implement the sRDMA protocol using modern programmable network adapters equipped with ARM multi-core processors [7,40]. sRDMA core primitives are implemented in 3,500 lines of C++ code and rely on various libraries: libibverbs, an implementation of the RDMA verbs; librdmacm, an implementation of the RDMA connection manager; Openssl 1.1.1a, a general-purpose cryptography library; and libev, a high-performance event loop. Our implementation supports more than 20 different cryptographic algorithms, such as the AES cipher and SHA hash families, to enable authentication and data secrecy for secure QPs. The implementation, all tests, and benchmark scripts are available in the open-source release.*

5.1 Notation and Experimental Setup

In the rest of the paper, we refer to a programmable network adapter as a *SmartNIC*. Our SmartNIC is capable of running a full Linux stack, supports RDMA over RoCEv2 and has crypto acceleration enabled. When RDMA requests are initiated on the SmartNIC and target the local host we refer to them as DMA requests as they only pass across the PCIe bus.

Our implementation is bi-directional, i.e., sRDMA writes and reads can be sent in both directions passing through both SmartNICs of the initiator and the target. Therefore, we distinguish between three roles as depicted in Figure 4: *Initiator*, *SmartNIC*, and *Target*, and the initiator always communicates with the target via two SmartNICs. Such a design allows full offloading of cryptographic computations from the initiator and the target to their respective SmartNICs.

5.2 Implementation of the Secure QP

We provide a library that models a secure QP connection between an initiator and a target as three standard RC QPs: one DMA connection between the SmartNIC and the host on *each* endpoint, and one connection between the SmartNICs.

Connection Establishment. Our secure QP library encapsulates connection establishment, which is performed in three stages as for a classical RC QP. When an application wants to establish a secure QP, it first creates a local QP in the INIT state. In this state, the connection between the host and the SmartNIC is created, and all necessary symmetric keys are copied to the SmartNIC. Then the QP must be transitioned to the RTR state by passing information about the target such as the QPN, the LID, and the PSN. To perform this transition we establish an RC QP connection between the two SmartNICs and create a special connection context on each SmartNIC. Finally, to send messages we transit the secure QP to the RTS state by passing the local send PSN. The application workers on the SmartNIC are responsible for packet counting, key derivation, and cryptographic algorithms.

Memory Registration. When a memory region should be secured with extended memory protection, the library intercepts a memory registration request and sends memory region information to a thread on the local SmartNIC.

*https://spcl.inf.ethz.ch/Research/Security/sRDMA/

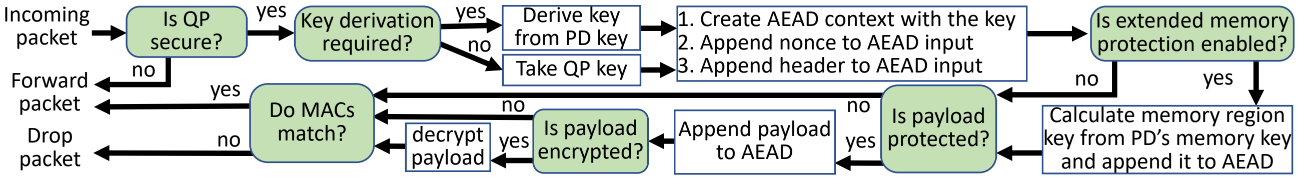

Figure 3: RNIC packet processing on receive.

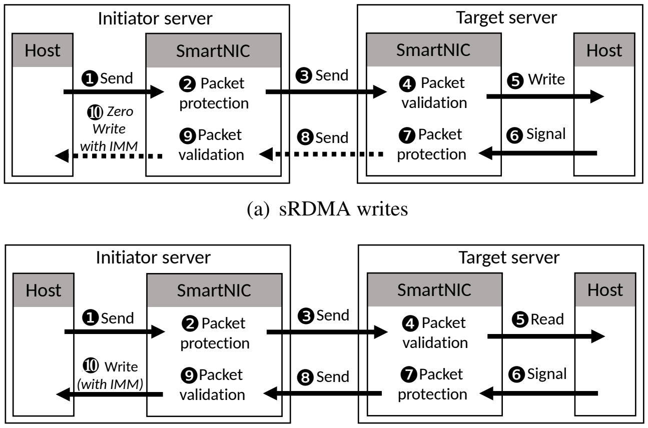
Secure QP communication. The initiator uses IB Send to deliver packets for both sRDMA reads and writes to its SmartNIC. The SmartNIC uses IB Receive to receive incoming packets from DMA connections and from remote SmartNICs. The SmartNIC secures all incoming packets from a DMA connection according to the cryptographic mechanism agreed on with the target. To secure a packet, the SmartNIC appends the IB transport and RDMA headers along with the generated MAC to the packet header. In our implementation, we use IB scatter/gather entries to attach an additional header before the main payload provided by the initiator. Scatter/gather entries allow building up an outgoing message from multiple buffers. After that, the packets are forwarded to the SmartNIC of the target QP. The target's SmartNIC verifies the security header as depicted in Figure 3, and decides on initiating an RDMA Read or RDMA write depending on the type of the request towards the target's host. The replies from the target are secured by its SmartNIC and forwarded back to the initiator.

sRDMA request completion. If the initiator expects an acknowledgment for a signaled request, the SmartNIC is responsible for acknowledging the initiator about the completion of the request. We use IB requests with immediate data to generate completion events on the host. The secure QP library is able to intercept completion events to distinguish between classical IB completions and sRDMA completions. The intercepted sRDMA completions are modified to inform the initiator about the sRDMA completion instead of the classical IB completion.

Packet security. The whole process of packet verification and key generation is shown in Figure 3. The SmartNIC performs header authentication, packet authentication, or payload encryption depending on which security protocol has been set up for the QP and which packet is processed. The SmartNIC will derive the QP's key if the QP is initialized in a secure PD, and also verify extended memory protection if the registered memory region has extended memory protection set up. On receiving, the SmartNIC also checks whether the QP is indeed a secure QP, as our implementation also supports classical insecure RC QPs. For insecure RC QPs, packets do not carry a MAC and are always trusted by SmartNICs.



(a) sRDMA writes

(b) sRDMA reads

Figure 4: Implementation of RDMA operations.

5.3 sRDMA requests

Figure 4(a) depicts the implementation of an sRDMA write. The initiator ❶ sends a packet to the local SmartNIC containing the payload and the remote memory address. The local SmartNIC ❷ appends the IB header and the STH and ❸ sends the secured packet to the remote SmartNIC. The remote SmartNIC ❹ processes the header and ❺ initiates a signaled DMA write to the host memory specified in the header. Upon ❻ the completion of the DMA write, the SmartNIC, depending on whether the sRDMA write is signaled, ❼❽ sends an authenticated Ack packet to the initiator's SmartNIC. The SmartNIC of the initiator then ❾ verifies the packet and ❿ performs an empty RDMA write with immediate data to its host, which consumes one posted receive at the host application. Finally, the secure QP interface intercepts such completions and modifies them to notify the application about the secure request completion.

sRDMA also implements secure Send operations which are similar to sRDMA writes, but they always generate the completion on the target and do not require knowing destination buffers. Since a Send request does not contain the header with destination buffer, it does not support memory protection.

sRDMA read has a similar structure as an sRDMA write as depicted in Figure 4(b) but there are some subtle differences. The initiator ❶ sends the message containing remote and local memory addresses and their *r_key*s to the local SmartNIC. The initiator's SmartNIC creates a special local read completion context with the initiator's memory address where the remote data must be copied to. Then the local SmartNIC ❷❸ sends the authenticated read request to the remote SmartNIC, which ❹ verifies the request and ❺ initiates a signaled DMA read from the target host memory to one of the SmartNIC's buffers. When ❻ the completion of a DMA read is generated, the SmartNIC ❼❽ sends an authenticated read response with read data to the initiator's SmartNIC. The initiator's SmartNIC ❾ verifies the MAC of response packets and decides whether to ❿ write their content to the memory address specified in the matched local read completion context using a DMA write request. The DMA write will be with immediate data if the sRDMA read is signaled.

6 Evaluation

We conduct a series of benchmarks to thoroughly profile our system. To evaluate the overall sRDMA performance and the impact of cryptographic operations, we first evaluate the performance of each cryptographic algorithm. Secondly, we evaluate the latency and bandwidth of sRDMA writes and reads to assess the overheads of secure QPs over insecure QPs. Subsequently, we study the impact of bulk sRDMA operations by measuring the achievable bandwidth for different read/write ratios. Later, we evaluate the performance of the HERD key-value store [17] to examine the impact of sRDMA.

Test settings. The experiments are conducted on two servers directly connected to each other using the RoCEv2 protocol. These servers run Ubuntu 18.04.1 LTS with a 4.15.0-43-generic Linux kernel. Each server is equipped with a Broadcom PS225 25 Gbit/s programmable network controller. Both network adapters have eight-core 64-bit ARM Cortex-A72 3.0 GHz processors and 8 GiB of dual-channel DDR4 DRAM.

6.1 Authentication performance

We first study the performance of the cryptographic engine installed in the SmartNICs. We evaluate 7 different cryptographic algorithms of the openssl 1.1.1a library for message authentication: *aes-128*, *aes-192*, *aes-256*, *chacha20-poly1305*, *sha1-160*, *sha2-256*, *sha2-512*.

Figure 5 depicts the achievable throughput in Gbit/s of those algorithms for different numbers of threads and block sizes. The line rate of the tested RNIC over the RoCEv2 protocol is 20.6 Gbit/s, which is goodput of 25 Gbit/s link. AES algorithms are the fastest for small blocks and achieve 8 Gbit/s for 64 byte blocks using single thread. Thus, our sRDMA library uses the AES128 algorithm as the PRF function needed for key derivation. For larger blocks hash-based methods perform almost as fast as cipher-based algorithms. We observe that chacha20-poly1305 is ~4x slower on average than the AES algorithms. The data also reveals that we cannot achieve the line rate for packet authentication with SHA512.

For varying key sizes of AES algorithms, we have not noticed significant differences in performance and hereafter report results exclusively for the AES128 algorithm. As SHA1-based authentication provides similar performance as SHA256 in all tests, we omit its data in all plots. Additionally, we label chacha20-poly1305 in Figures as *poly1305*.

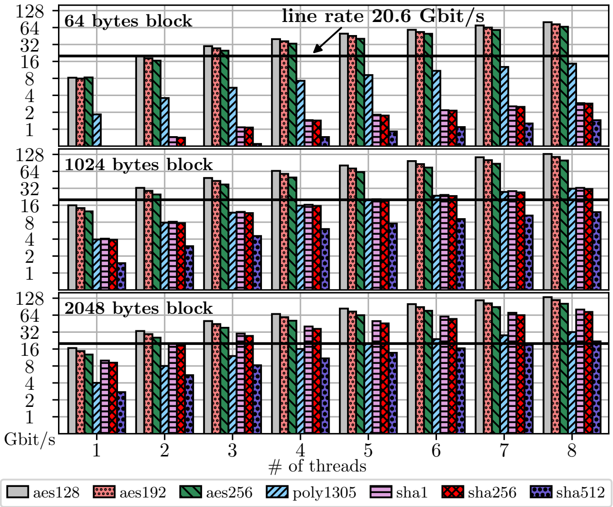


Figure 5: Authentication performance using openssl.

6.2 Evaluation modes

All evaluations have been performed with no security enabled (*NO security*) and in four protection modes:

No security. In *No security* mode RDMA reads and writes are performed as described in Section 5.3 but with skipping packet protection and validation (❷❹❼❾ in Figure 4).

Basic mode. In *basic* mode the key is attached to the secure QP connection directly, so the key is in the RNIC's cache when an incoming packet must be processed.

Pd-prot mode. The secure QP is created without an individual key, but in the secure PD (*pd-prot*) with a key derivation algorithm. We consider the case when the RNIC does not cache derived keys, and therefore, every time a packet arrives, the RNIC must derive the QP key from the PD key. In these experiments we want to show the performance of the system with constant cache misses. Using the cache we expect the same performance as in basic mode without key derivation.

Ext-mem mode. In this mode, the QP is created with an individual key and with extended memory protection (*ext-mem*) enabled. Extended memory protection requires derivation of memory level keys from a PD-level key. In this case, when a packet arrives, the RNIC must generate a key to access memory specified in the RDMA header from the PD-level key and include the generated key in MAC calculation. For this test we also consider that the initiator has the primary memory key which grants access to whole memory region, so the memory key can be derived in one step (depth 0 in Figure 1).

Pd-prot + ext-mem mode. The last mode combines our two protection methods: secure PD and extended memory protection (*pd-prot + ext-mem*). Therefore, the RNIC is responsible for generating both keys when a packet should be processed.

6.3 Latency

To evaluate the overall sRDMA performance and the impact of cryptographic operations, we split latency tests in two cate-

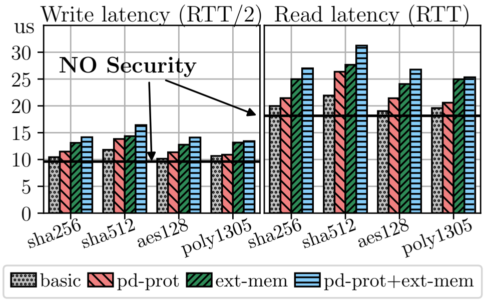

Figure 6: Source authentication latency of reads and writes carrying 32 Bytes payload.

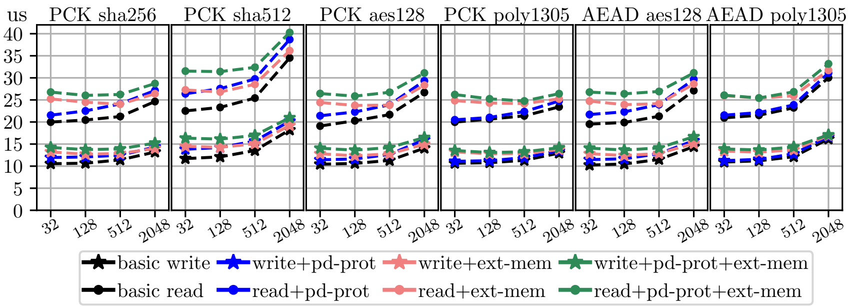

Figure 7: Latency of packet authentication (*PCK*) and encryption (*AEAD*) as a function of payload sizes.

gories: header authentication only and full packet security.

Header authentication. Figure 6 presents the median latency of sRDMA reads and writes in all four protection modes for header authentication. The figure reports the median only as for all measurements deviation from the median is less than 0.4 μs. All measurements are done for packets carrying the payload of 32 bytes. sRDMA write latency is measured for a half round trip, whereas sRDMA reads are for a full round trip. The latency of sRDMA writes without security is 9.55 μs and of sRDMA reads is 18.2 μs which build the baseline for our experiments.

Figure 6 shows that all tested security algorithms in the first mode add about 0.9 μs for sRDMA writes which is approximately 9% more than the insecure version. Another interesting observation is that the QP key derivation is more expensive than memory key derivation. The difference stems from the fact that a key-derivation process involves reinitialization of cryptographic contexts and different algorithms have different reinitialization performance (e.g., AES generates round keys [9]). The same phenomenon occurs for sRDMA reads. As expected, the highest latency is achieved for sRDMA operations with both key derivation and extended memory protection.

Packet security. We evaluate the latency of packet authentication (*PCK*) and packet encryption (*AEAD*) for different payload sizes and in four protection modes. Figure 7 illustrates the median latency of sRDMA reads and writes for SHA256, SHA512, AES128, and POLY1305. In each subplot, the top four lines illustrate sRDMA read round-trip latency, and the bottom four lines half-round-trip latency of sRDMA writes.

Figure 7 highlights that payload authentication is more expensive than header authentication. It takes 15 μs to write and secure 2 KiB payload in the first mode in comparison to header authentication of the same packet with the median of 12 μs. The graph also illustrates that latency increases for both reads and writes with payload size as more data must be authenticated. For AEAD, latency goes up even faster with respect to payload size since more data is en-/decrypted. As anticipated, SHA512 has the highest latency as the most expensive algorithm. We observe that for smaller payload sizes payload authentication and payload encryption achieves approximately the same performance in terms of latency.

6.4 Bandwidth

We measure performance separately for sRDMA reads and writes. As for latency benchmarks, all evaluations are performed in four protection modes. Our implementation is multithreaded where each thread can process requests from a single secure QP. The number of threads represents the number of connections between endpoints. For n threads, each host establishes n secure connections with its SmartNIC, and SmartNICs establish n connections between each other. Thread workers on a SmartNIC do not share any resources and are pinned to distinct cores. In all evaluations the initiator issues requests continuously to the target, but with a limited number of outstanding requests (96 per connection). Once the initiator receives the signal for an sRDMA request completion it posts new requests to maintain 96 outstanding requests. The payload size is 2,048 bytes and bandwidth is measured in Gbit/s of goodput. We also assume the worst case scenario for the secure PD mode (*pd-prot*): the RNIC derives the QP key from the PD key for each packet. In other words, we consider the case when the RNIC does not cache derived keys. The main reason for that is that *pd-prot* mode with caching has the same performance as *basic* mode.

Figure 8 depicts communication bandwidth for sRDMA writes with different cryptographic algorithms. The black line (*NO*) in the header column stands for sRDMA writes with no security enabled. We observe that the single-threaded test with no security achieves only 8 Gbit/s while the highest RDMA goodput bandwidth achievable on our interconnect is 20.6 Gbit/s. The slowdown is caused by processing and parsing headers of messages by the general purpose ARM CPUs of the SmartNICs. Even if no security is enabled, a thread worker reads and parses headers of incoming packets and, depending on the operation code, initiates RDMA requests according to our implementation described in Section 5.3. In our tests we treat performance of secure operations with no security as the baseline. The highest achievable goodput bandwidth with no security is 20.5 Gbit/s which is line rate.

Figure 8 illustrates that sRDMA writes with header authentication can achieve line rate in all four protection modes

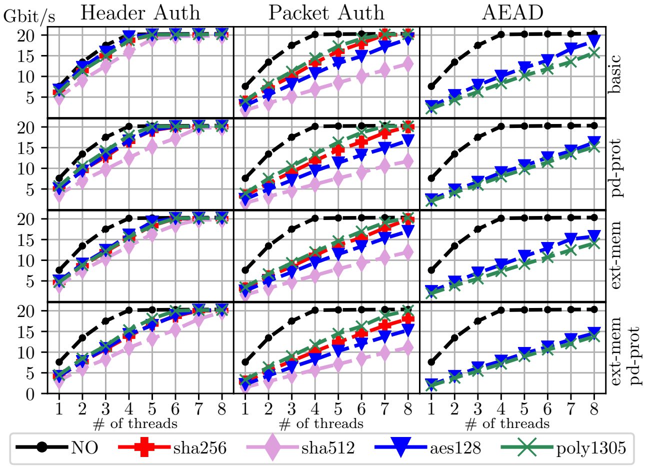

Figure 8: Bandwidth of sRDMA Writes in four different protection modes, and with *NO* security enabled.

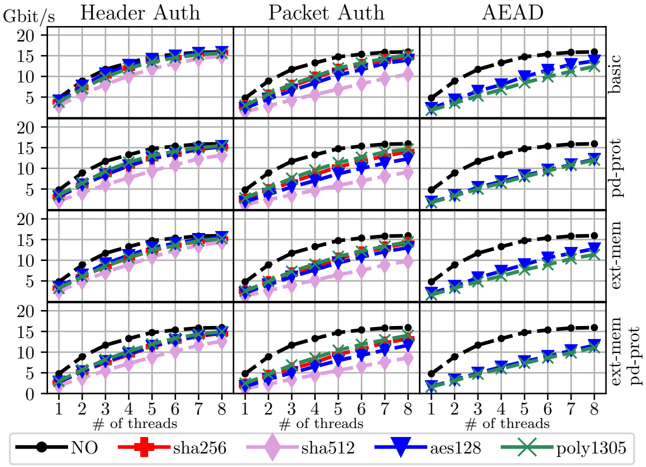

Figure 9: Bandwidth of sRDMA Reads in four different protection modes, and with *NO* security enabled.

if we use all 8 threads. The slowest header authentication is observed for SHA512 due to hashing performance. For full packet authentication SHA512 reaches only a goodput of 13 Gbit/s which is even slower than AEAD algorithms. In the payload encryption mode, our implementation can also achieve line rate for the SHA256 and POLY1305 algorithms. AES128 based authentication achieves 19.6 Gbit/s which is 95% of the line rate. The data also demonstrates that key derivation algorithms slow down sRDMA writes by 2 Gbit/s on average. However, in header authentication mode all algorithms can achieve 20 Gbit/s without performance loss when all 8 threads are used. Another interesting observation is that POLY1305 is faster than AES128 in packet-authentication mode, but slower in packet-encryption one. In AEAD mode, the highest write bandwidth of 19 Gbit/s is observed for the AES128 algorithm.

We have performed a similar benchmark for sRDMA reads in various protection modes. Results of our evaluations are depicted in Figure 9. Again, the black line (*NO*) stands for no security installed and represents the baseline for sRDMA reads. sRDMA reads are more expensive than writes despite the fact that they transfer the same amount of protected bytes as signaled sRDMA writes. Both sRDMA operations require six hops for a full round trip, and they both transfer the same payload size but in different directions. For writes, data is sent from the initiator to the target, and for reads from the target to the initiator. The differences in performance stem from the fact that an sRDMA read is a more complex operation than an sRDMA write and requires to create a special read context and matching it at initiator's SmartNIC (see Section 5.3). In addition, receive buffers on SmartNICs for reads and writes have different lifetimes. For example, a receive buffer can be released on the target SmartNIC once the completion of the RDMA write is received (❻ in Figure 4(a)), however, for reads the buffer on the target SmartNIC can be released once the completion of ❽ is received from Figure 4(b). According to the data, the highest achievable sRDMA read bandwidth is 16.71 GBit/s for 8 threads and about 4.7 Gbit/s for single-threaded test. Overall, our measurements indicate that reads are 16% slower than writes for all tests due to the complexity of sRDMA reads.

CPU Usage in Bandwidth Experiments. In our experiments, sRDMA introduces no overhead on the host CPU usage as packet processing is fully offloaded to the SmartNIC. The host application only needs to submit an RDMA request to the SmartNIC, which performs all cryptographic computations as described in Section 5.3. The SmartNIC, on the other hand, has full CPU usage in almost all experiments, which can be observed in the inability of the majority of security schemes to achieve line rate. The main reason for that is the SmartNIC needs to load the incoming packets from its DRAM to the L1 cache of its CPU cores in order to process the packets depending on the installed security level. Thus, all protection levels which require the CPU to read the whole packet have 800% CPU usage for 8 worker threads, even though in authentication performance experiment (see Figure 5) all authentication algorithms achieves the line rate for 2 KiB blocks. It comes from the fact that the packet authentication and AEAD are memory-bound problems, and, therefore, CPU works at full capacity to copy the data to its caches.

Header authentication requires reading only the header to authenticate the packet. Thus, header authentication algorithms could achieve 100% of line-rate, although, the performance still suffers from cache misses. The lowest CPU usage is observed for AES128 authentication scheme, which is 440% CPU usage for the bandwidth experiment with sRDMA Write requests. The sRDMA reads, on other hand, consume almost 750% on the target SmartNIC.

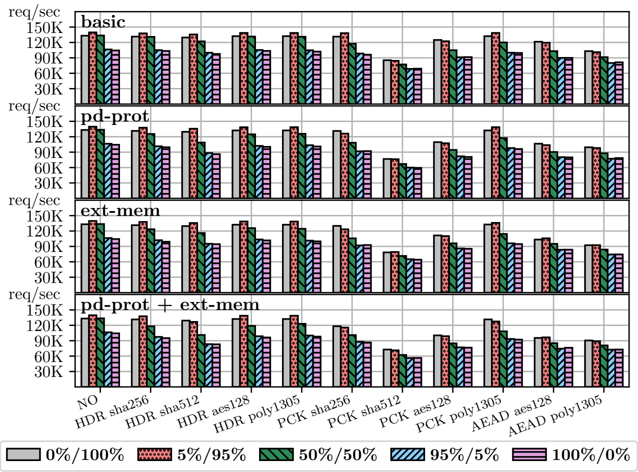

Figure 10: Throughput of mixed read/write benchmark.

6.5 Mixed write/read workload

The results of Figure 8 and Figure 9 are valid for either read-only or write-only workloads, which are uncommon for read-world applications. Therefore, we measure the throughput of sRDMA in a more realistic scenario as used in key-value stores that exploit one-sided RDMA operations. Figure 10 shows the throughput for workloads with different (read/write) ratios, including write only (0%/100%), write mostly (5%/95%), equal-shares (50%/50%), read-mostly (95%/5%) and read-only (100%/0%). The read-heavy workload is representative for applications such as photo tagging. The update-heavy workload is typical for applications such as an advertisement log that records recent user activities. In this benchmark the payload size is 2,048 bytes, and sRDMA is deployed with all 8 workers. We also consider the worst case scenario for the secure PD mode (*pd-prot*), when the RNIC derives the QP key for each packet. The *pd-prot* mode with QP key caching has the same performance as *basic* mode.

Figure 10 illustrates that (5%/95%) workload performs better than (0%/100%) one. The reason for that is better utilization of the bi-directional connection between endpoints since sRDMA writes send data from the initiator to the target, whereas sRDMA reads from the target to the initiator. Therefore, in that case we achieve a better utilization of the connection in the direction of the initiator. In theory, a (50%/50%) ratio would lead to the highest throughput as both links would be loaded evenly; however the lower performance of sRDMA reads overwhelms benefits of the network utilization. For the same reason, the throughput decreases for higher read ratios.

6.6 Key-value store workload

HERD [17] is an RDMA-accelerated key-value store which uses a mix of RDMA write and IB send verbs. HERD uses MICA's [25] algorithm for both GETs and PUTs: each GET requires up to two random memory lookups, and each PUT requires one. In HERD, clients transmit their request to the server's memory using RDMA writes, and get responses via unreliable datagram QPs. To comply with our sRDMA design, we made some changes to the original HERD implementation. First of all, we replace all unreliable datagram QPs with RC QPs as they are not reliable and not point-to-point and thus incompatible with sRDMA. That is, the server replies to clients via RC QPs, but still uses IB Send verbs. For that, we also implement secure SEND operations which are similar to sRDMA writes, but they always generate the completion on the target and do not require knowing destination buffers. Since an IB Send request does not contain the header with destination buffer, it does not support extended memory protection. The second change is that clients send requests via reliable sRDMA writes instead of unreliable writes.

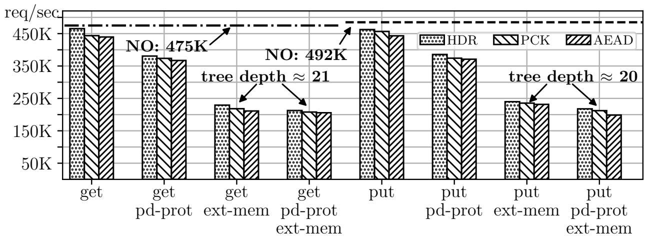

Figure 11: Throughput of the HERD kvs over sRDMA.

Key-value-store (KVS) experiments use one server machine and one client machine. The server machine has only one worker process when the client machine has 8 processes. Each client process establishes an sRDMA connection to the server. The key size is 16 bytes and the value size is 32 bytes. Therefore, clients send and receive small messages of less than 40 bytes. The KVS contains 8,388,608 keys and occupies 1 GiB of memory. Figure 11 depicts the throughput for puts and gets in different protections modes based on the AES128 cipher. We also measure HERD's throughput with NO protection which is 475K req/sec for gets and 492K req/sec for puts. Puts are faster than gets because they cause fewer lookups in internal memory structures.

According to the data in Figure 11, basic packet authentication without key-derivation algorithms achieves almost the same throughput as the unprotected version. Interestingly, even the AEAD mode decreases the throughput by 7.3%. In the setting with a secure PD when the key must be generated for each request, we observe a 21% slow down in both puts and gets. It is worth mentioning that we intentionally derive the QP keys for each request in the secure PD mode (*pd-prot*) to see the effect of constant misses in QP keys. In real settings, an RNIC would have a cache with generated keys to reduce computation. In such case, the *pd-prot* mode has the same performance as *basic* mode.

A drastic decrease in performance can be observed for evaluations with enabled extended memory protection. The reason for this is that HERD's clients WRITE their GET

Table 4: Comp. of sRDMA to IPSec and TLS over RoCE.

Protocol	Sec. comm.	IBA supp.	One-sided comm.	Hdr overhead.
RDMA	✗	✓	✓	-
IPSec	✓	✗	✗	50-80 B
(d)TLS	✓	✗	✗	25-40 B
[23, 24]	✗	✗	✓	12-16 B
sRDMA	✓	✓	✓	12-64 B

requests of 17 bytes and PUT requests of 40 bytes to the contiguous memory region of 16 MiB on the server machine. Therefore, it takes on average 20 steps for PUTs and 21 steps for GETs to derive the memory MAC using our binary tree approach, which causes such significant drop in performance. To alleviate the problem, the depth of the tree can be limited to 0, and then the *ext-mem* would achieve the same performance as the *pd-prot* case.

7 Related Work on Securing IBA

RFC 5042 [32] analyzes the security issues around uses of RDMA protocols. It reviews various attacks against resources including spoofing, tampering, information disclosure, and DoS. As a countermeasure the authors suggest to employ IPsec authentication and encryption [10]. However, IPSec currently does not support RDMA traffic, because it is unaware of the encapsulated RDMA headers and thus cannot distinguish QP endpoints. A naive application of IPSec to RoCE packets would not achieve source authentication as all RoCE traffic is destined to the same UDP port (and not the QPN). Thus, the use of IPsec would incur changes in the packet format, whereas sRDMA is supported by native IBA and RoCE. Additionally, the complexity of IPsec and its high processing overheads [31] make it ill-suited for high-performance and low-latency applications and would introduce a header overhead of 50-80 bytes [21]. While the IPsec-enabled Cavium LiquidIO II [2] and Mellanox Innova [3] NICs support RoCE, they do not support IPsec-based protection of RoCE packets.

Lee et al. [23,24] discuss security vulnerabilities in IBA and show that they could be exploited by an adversary with moderate overhead. The authors suggest to replace the Invariant CRC field with a MAC to achieve packet authentication. Unfortunately, this might lead to routers dropping packets with invalid ICRC, making the proposed solution incompatible with legacy routers. Additionally, they discuss how IBA could reduce its key exposure risk by introducing partition- and queue-level key distributions. However, modifying partition-level keys can lead to packets being dropped as they might be used by routers and switches to enforce partitioning. Furthermore, their design uses the 24 bit PSN as a nonce which cause a reuse of a PSN after 80 ms on modern RNICs [28]. Finally, the authors provide no implementation of their system, but rather simulate the performance of symmetric ciphers to show that they are suitable for high performance networking.

RDMA Side-Channel Attack. Kurth et al. [22] have shown that the Intel DDIO [1] and RDMA features facilitate a side-channel attack named NetCAT. Intel DDIO technology allows RDMA reads and writes access not only the pinned memory region but also parts of the last level cache of the CPU. NetCAT remotely measures cache activity caused by a victim SSH connection to perform a keystroke timing analysis. An attacker can make use of the attack to recover words typed by a victim client in the SSH session from another computer.

Tsai et al. [41] implemented a set of RDMA-based remote sidechannel attacks that allow an attacker on one client machine to learn how victims on other client machines access data. They further extend their work by building side-channel attacks on Crail [38].

Using sRDMA a large attack surface could be removed by permitting only trusted entities to initiate RDMA requests.

8 Conclusion

Using NIC-based authentication and encryption enables secure communication for systems that require high performance guarantees such as RDMA mechanisms. sRDMA provides strong authenticity and secrecy, and prevents several forms of DoS attacks. Thus, safety- and security-critical applications that rely on RDMA must use sRDMA to prevent attacks by malicious entities within the same network.

Our software implementation on the SmartNIC causes a high load due to data movement overheads. The datapath could be optimized with a different architecture using specialized programmable packet processing units [13,20]. Furthermore, sRDMA could also be hardened into fixed logic as the area and power consumption overhead are marginal compared to regular input/output processing [12,16,27]. Additionally, sRDMA minimizes memory consumption on the RNIC using PD-level protection.

Acknowledgment

UREQA: Leveraging Operation-Aware Error Rates for Effective Quantum Circuit Mapping on NISQ-Era Quantum Computers

Tirthak Patel, Baolin Li, Rohan Basu Roy, and Devesh Tiwari
Northeastern University

Abstract

Noisy Intermediate-Scale Quantum (NISQ) computers are enabling development and evaluation of real quantum algorithms, but due to their highly erroneous nature, careful selection of qubits to map the algorithm on to real hardware is required to minimize the error rate of the algorithm output. In this paper, we propose UREQA, a new approach that introduces quantum-operation-aware error rate prediction to minimize of output errors of quantum algorithms running on NISQ devices.

1 Introduction

Noisy Intermediate-Scale Quantum (NISQ) computers are enabling development and evaluation of quantum algorithms in various domains including chemistry and physics simulations, combinatorial and black-box optimization, and quantum cryptography [16, 20]. A major challenge toward increasing the practicality and wide-adoption of quantum computing is the high error rate observed on current NISQ devices, often orders of magnitude higher than the classical computing systems [16,20]. This challenge is likely to remain prevalent in the near-term, and requires innovative techniques to mitigate the side-effects of quantum errors [6, 12, 16, 20]. Next, we provide a brief background of quantum computers, errors, and algorithm execution.

Background and Problem Statement. In quantum computers, a *qubit* is the fundamental unit, analogous to a classical bit. A qubit state ($|\Psi\rangle$) can be expressed as a superposition of the two basis states: $|0\rangle$ and $|1\rangle$. More formally, $|\Psi\rangle = a|0\rangle + b|1\rangle$, where a and b are complex numbers such that $||a||^2 + ||b||^2 = 1$. Due to the quantum physical behavior of qubits, upon measurement, this superposition collapses, and the qubit is found either in state $|0\rangle$ (with probability $||a||^2$) or in state $|1\rangle$ (with probability $||b||^2$). Multiple operations can be sequentially performed on a set of qubits on a computer to run a quantum algorithm. Upon the completion of the execution of a quantum algorithm, the qubit state is measured for all qubits and the output is analyzed.

The qubit operations, referred to as *quantum operations*, are of three types: 1-qubit gates, 2-qubit gates and readout. 1-qubit gates operates on a single qubit and change the superposition state of the qubit. 2-qubit gates entangle two qubits and can change the state of the "target" qubit depending on the state of the "control" qubit (Sec. 2 provides more details on these operations). The readout operation simply refers to measuring a qubit's state. The readout operation is applied only at the end of the execution as it destroys the qubit's state. A *quantum algorithm* is expressed as a sequence of gate operations operating on multiple qubits. The mapping of a logical quantum algorithm on the physical qubits of a quantum computer is referred to as a *quantum circuit* — a set of quantum operations and the corresponding qubits on which the operation is being performed. An example of the execution of a quantum circuit is shown in Fig. 1. This example circuit has three qubits all initialized to the ground state $|0\rangle$. A few quantum gates are applied to them (details provided in Sec. 2) and their states are measured at the end and transferred over to a classical computer. It is important to note that a *single* quantum algorithm can map to *multiple* circuits in different ways on the same computer, much like how a classical algorithm can be executed on any permutation of transistors.

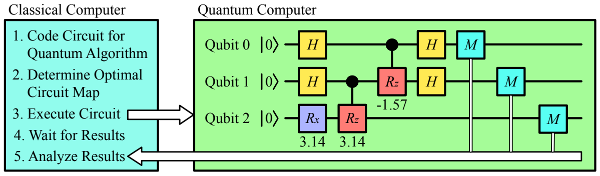

Figure 1: Execution flow of Quantum Phase Estimation (QPE) algorithm mapped to a quantum circuit. Each horizontal line represents a qubit, and each box represents a quantum operation. The time order of operations flows from left to right.

Unfortunately, qubits and operations on NISQ machines are highly error-prone and hence, quantum circuits have erroneous output. State-of-the-art approaches carefully choose the qubits and operations with the lowest overall error rate for determining the best circuit map [3, 15, 18, 25–28, 31, 33]. Error rate of each operation is estimated based on the historical information (e.g., IBM calibrates and publishes error rate for all qubits of a machine on a twice-a-day basis). Based on these error rates, a "good" circuit map is chosen to obtain an outcome that has a high probability of being close to the correct output. Estimating error rate correctly is the key to choosing the optimal circuit map for a given quantum algorithm. For example, if the estimated error rate of each qubit is significantly different than the actual error rate when the circuit map is executed, then these differences add up over the circuit map execution and result in a significantly inaccurate outcome. *Therefore, previous works have focused on estimating the error rates accurately and using that to find the optimal circuit map [3, 15, 18, 25, 26, 28].*

What is Missing from Existing Solutions? Current approaches use a single number to characterize the error rate of a given qubit irrespective of the different quantum operations being performed on the qubit [25, 26, 28, 31]. For the first time, we show that error rate is not only qubit-specific, but also operation-specific (as explained in Sec. 2, a 1-qubit gate can perform different types of quantum operations on a single qubit). We show that quantum error rates can vary significantly depending on the specific quantum operation that is being performed, even if other conditions are kept constant (i.e., the physical qubit and the machine). Some qubits with low aggregate average error rate might experience high error rate for specific quantum operations. Hence, these qubits should be avoided for a circuit-map selection if a particular circuit consists of many such specific quantum operations. The reason for this phenomena is the unstable nature of current NISQ technology where qubits are erroneous and do not have consistent properties as different qubits interact differently with external control and the environmental features. *This is the first work to discover and leverage the above insight to choose better circuit maps that lower the impact of quantum errors, and push the state-of-the-art in improving the efficiency of quantum algorithm execution on NISQ computers.*

UREQA Solution. UREQA[1] builds a data driven model for correctly estimating the error rates of operations on different qubits of a quantum computer, and then, leverages this information to find the most optimized circuit for a quantum algorithm. UREQA builds its error rate prediction model by performing a large number of experiments on real IBM NISQ computers. Our evaluation shows that these error rate prediction methods are more accurate than current state-of-the-art approaches of simply using a general error rate number periodically published by the quantum computing platform provider.

To demonstrate UREQA's effectiveness, we evaluate UREQA for a diverse set of quantum benchmarks, conducting experiments over more than 50 days on four different quantum computers in the IBM QX cloud. Our results show that our operation-aware solution achieves a small median prediction error rate of 1%. Using these operation error-rate prediction models, UREQA's optimized circuit map selection achieves up to 15% reduction in error rate for a quantum algorithm, compared to the current approaches which rely on a single aggregated number for error rate estimation based on historical data.

2 UREQA: The Solution

Background. This study is performed on the IBM Quantum Experience (QX) - a public cloud service. We use the IBM QX machines listed in Table 1. They cover a diverse range of quantum architectures in terms of error-rates, topology, and time of introduction (Fig. 2).

Quantum operations on these computers include both the gate and readout operations. Primary 1-qubit gates include the Hadamard (H) gate which puts the two basis states into equal superposition and the x-, y-, and z-rotation gates (R_x, R_y, and R_z, respectively) which rotate the qubit about the x-axis, y-axis and z-axis on the Bloch Sphere, respectively. The Bloch Sphere is a unit sphere with the $|0\rangle$ state represented as a vector pointing toward the positive z-axis and the $|1\rangle$ state is represented on the negative z-axis. The other two axis represent the qubit phase. The qubit state vector can point anywhere on the Bloch Sphere, but upon readout, it collapses to the positive ($|0\rangle$) or negative ($|1\rangle$) z-axis. As an example, Fig. 3 uses the Bloch Sphere to show the state changes after applying a H gate followed by a R_z gate with π rotation to a single qubit. When the H gate is applied, the qubit state vector points toward the positive x-axis and the qubit is equally probable to be measured as $|0\rangle$ or $|1\rangle$. This probability of measurement remains the same even after a R_z rotation is applied, except the qubit has a negative phase.

All 1-qubit gates have 2-qubit variants (CH, CR_x, CR_y and CR_z) where one qubit is the control and the other is the target. The respective 1-qubit gate is applied to the target qubit depending on the superposition of the control qubit. In Fig. 1, the connection between qubit 0 and R_z gate of qubit 1 means it is a CR_z gate with qubit 0 as control and qubit 1 as target.

These qubit operations can be erroneous. IBM's qubits are fixed-frequency superconducting Transmon qubits

[1] UREQA (Eureka) stands for utilizing operation-aware error rate predictions (for better circuit mapping) on quantum computers.

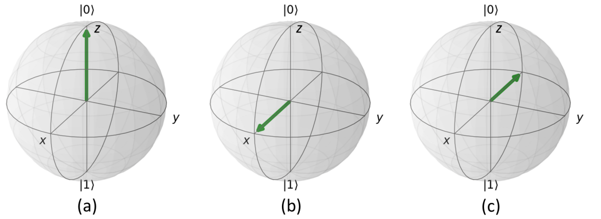

Figure 3: A qubit (green arrow tip) on a Bloch sphere. The qubit in (a) first gets manipulated by an H gate to state in (b), then by a R_z gate to state in (c).

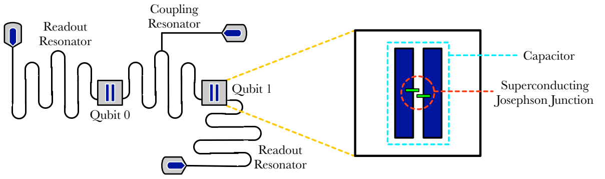

Figure 4: Design of IBM's superconducting qubits technology.

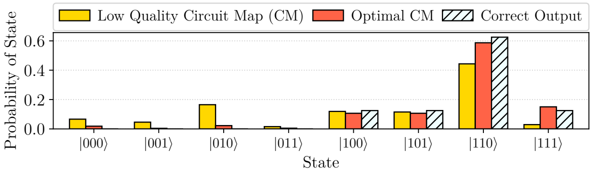

Figure 5: Choice of circuit map can greatly impact overall output error: different circuit maps for the QPE algorithm.

based on Josephson Junctions, and the Transmon frequency is referred to as the **qubit frequency**. On IBM's quantum computers, the qubits are implemented using Josephson Junctions created by separated superconducting electrodes and capacitors as shown in Fig. 4. 1-qubit gates are performed by applying external controls in the form of microwave pulses. Errors in applying these pulses cause **1-qubit gate errors**. Entanglement between two qubits is performed using coupling resonators. These coupling resonators can be highly erroneous causing **2-qubit gate errors**. Lastly, readout operation (or qubit state measurement) is performed using readout resonators as shown in Fig. 4. The readout resonators are also highly error-prone and cause **readout errors** when qubit states are measured. In fact, other factors can also affect error rates. Once initialized, a qubit can only retain its state for a limited time (coherence time). There are two types of coherence times: (1) The **T1 coherence time** is associated with amplitude damping due to the qubit's natural energy decay to the ground state. (2) The **T2 coherence time** is associated with phase damping due to environmental factors.

IBM's computers are calibrated twice a day, and the qubit coherence times change after each calibration. We note that the error rates are determined when calibration tasks are performed for all the operations of a quantum computer. Calibration is the task of determining qubit frequency and accordingly, setting the properties of the microwave tone which changes the state of a qubit. During calibration, operation characteristics such as the frequency of a qubit and the optimal microwave tone amplitude are determined based on new properties of the qubit. These characteristics are then used to perform all the operations. These new characteristics determine the error rate of the operation. The effect of environmental factors (such as the electromagnetic interference, fluctuating temperature, or mechanical vibrations) is already captured in the operation error rates. Coherence times are also measured immediately after calibration is performed. Note that regular circuits (jobs) cannot run on machines when calibration is being performed. Thus, it is impractical to constantly keep calibrating the machines, and hence, this practical constraint forces the calibration to be performed typically twice daily.

Current Efforts in Circuit Mapping. IBM posts a single error number for all 1-qubit and 2-qubit gates for each qubit twice a day. One solution to the aforementioned circuit mapping problem can be to map quantum operations on qubits which have the minimum operation error rates according to these posted numbers [10, 25, 26, 28]. The idea is to maximize the Estimated Success Probability (*ESP*) of a quantum circuit [25]. The ESP is calculated as $\prod_{i=1}^{N_{gates}} g_i * \prod_{j=1}^{N_{readout}} m_j$, where g is the success rate of gates and m is the success rate of readout (success rate = 1 - error rate). The circuit map with highest ESP is the optimal circuit map. Fig. 5 shows the impact of choosing a low quality circuit map vs. an optimal circuit map for executing the quantum phase estimation (QPE) algorithm. The correct output of QPE has states $|100\rangle$, $|101\rangle$, and $|111\rangle$ with probability 0.125, and state $|110\rangle$ with probability 0.625. On real-systems, executing a circuit map results in state probabilities that are different than the correct probabilities. Using the correct probabilities as reference, the optimal circuit map has an overall error of 6% (sum of errors of all states divided by 2), while the low quality circuit has an overall error of 28%. Thus, estimating the ESP of a circuit map accurately (and hence, in turn estimating the error rate of quantum operations) is critical for mitigating the side-effects of erroneous quantum operations. However, current approach of using the published numbers to estimate the error rates implicitly assumes that all 1-qubit operations have uniform errors and that all 2-qubit operations also have uniform errors. This is far from the actual behavior of errors as we show next.

Different quantum operations exhibit significant variation in observed error rates. Fig.6 shows that quantum errors are correlated with the specific type of operation being performed (on the same qubit; results are averaged over all available qubits and platforms for simplicity). For example, on IBM computers R_z is imple-

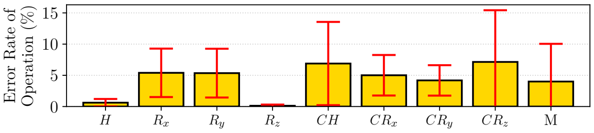

Figure 6: Different quantum operations can have significant different error rates with a high degree of variance.

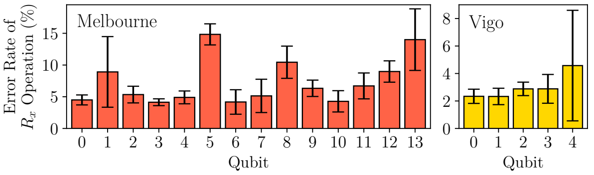

Figure 7: Error rate of a quantum operation varies across machines and among qubits within the same machine.

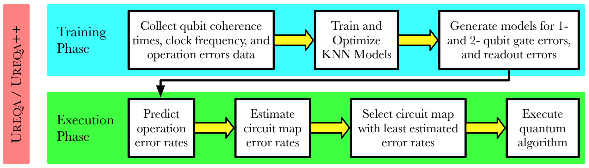

UREQA / UREQA++
Training Phase
Collect qubit coherence times, clock frequency, and operation errors data
Train and Optimize KNN Models
Generate models for 1- and 2- qubit gate errors, and readout errors
Execution Phase
Predict operation error rates
Estimate circuit map error rates
Select circuit map with least estimated error rates
Execute quantum algorithm

Figure 8: Key steps in UREQAworkflow.

Table 2: Predictive features of different operations.

Operation	**Predictive Features**
1-Qubit Gate	Computer ID, Qubit T1 Coherence Time, Qubit T2 Coherence Time, Qubit Frequency, Gate Type (H, R_x, R_y, R_z)
2-Qubit Gate	Computer ID, Control Qubit T1 Coherence Time, Control Qubit T2 Coherence Time, Control Qubit Frequency, Target Qubit T1 Coherence Time, Target Qubit T2 Coherence Time, Target Qubit Frequency, Gate Type (CH, CR_x, CR_y, CR_z)
Measurement (Readout)	Computer ID, Qubit T1 Coherence Time, Qubit T2 Coherence Time, Qubit Frequency

mented as a simple frame change with no physical computation; hence, it has close to 0 error rate. The H gate also has a low error rate; however, the error rates of the other two 1-qubit gates R_x and R_y are much higher. 2-qubit gates like CH and CR_z also have high error rates. It is a conventional belief that 2-qubit gates have a higher error rate than 1-qubit gates [10, 23, 27]. However, our analysis reveals that while on average 2-qubit gates have higher error rates than 1-qubit gates, certain types of 1-qubit gates such as R_x and R_y have error rates comparable to 2-qubit error rates and readout (M) error rate.

A potential reason for varying error rates among different quantum operations can be the difference in microwave tones that are applied to implement the operation on a gate. For example, an R_x gate with a π rotation (on a single qubit) is applied using a Gaussian microwave pulse of a certain calibrated amplitude A. On the other hand, the H gate (also, on a single qubit) is implemented using a Gaussian microwave pulse of half the amplitude ($A/2$) and pre- and post- pulse frame changes. It can lead to a lower error rate because its pulse has half the amplitude of the R_x gate and the frame changes have zero error. Overall, this finding of operation-specific error rates motivates the need for accounting for the operation type when estimating the error rates.

Errors rates also vary temporally and spatially across computers and qubits. In Fig. 6, the error bars show the high standard deviation (variation) of operation error rates across time. This situation is further exacerbated by the fact that error rates for the same operation also vary across different computers and qubits, as shown in Fig. 7 for the R_x gate. The variation in the error rates for R_x across different qubits is considerable and has not decreased even in the newest IBM quantum computer, Vigo. The error rates vary across qubits and across operations performed on the same qubit.

UREQA Overview. While using published errors does offer simplicity, accurate estimation of ESP needs better prediction of operation error rates. The high degree of instability and uncertainty makes it difficult to model the behavior of these errors using analytical or rule-based models. Therefore, UREQA takes a data-driven machine-learning-based approach, as shown in Fig. 8. We develop a data-driven model which helps perform accurate predictions of error rates of individual operations. Then, when executing quantum algorithms, these pre-trained models can be used to estimate circuit map error rates and the best circuit map can thus be selected to execute the algorithm with minimal errors.

UREQA Model Development. To collect the error rate data for different types of operations, we developed micro benchmarks that perform a specific operation on every qubit of all available quantum computers. For example, to get the readout error, every qubit was measured in its initialization state of $|0\rangle$ without running any gate operation. To get the error of H, R_x, R_y, R_z, CH, CR_x, CR_y, and CR_z, the corresponding gate-operation was performed, and result was measured and compared against the ground truth. Our automated workflow collected over 20,000 samples. Each run consisted of 1024 trials — multiple trials need to be conducted because the output of a quantum circuit is probabilistic. Other data such as coherence times and frequencies of individual qubits were obtained from IBM's daily calibration results.

The goal of model development is to predict the error rate of a given operation given a set of predictive features. A complete list of these features is provided in Table 2 for the three types of quantum operations. For example, given qubit 0 on Melbourne computer's T1 coherence time, T2 coherence time, and frequency after today's calibration, predict its readout error rate. The predictive features are chosen based on their availability on the IBM QX machines and based on their relevance to the qubit operation (e.g., T1 coherence time of qubit 1 is relevant to the 1-qubit error rate of the same qubit but not to other qubits on the machine). Principle Component Analysis (PCA) was performed to determine the features

Table 3: Optimal parameters tuned for KNN learners.

Operation	Number of Neighbors	Distance Metric	Distance Weight
1-Qubit Gate	13	Euclidean	Squared Inverse
2-Qubit Gate	31	Correlation	Inverse
Readout	68	Jaccard	Inverse

which contribute the most to the variance of the dataset and the features shown in Table 2 were found to account for more than 95% of all variance in the dataset.

After thorough experimentation and hyper-parameter tuning, we assessed that k Nearest Neighbors (k-NN) classification learner [1] was the best learning model for error rate prediction – it has the lowest mis-classification error. The output of a k-NN learner is a membership to a class (class here refers to a particular error rate). A sample is classified by a plurality vote of its neighbors given a set of predictors. The sample gets assigned the class most common among its k nearest neighbors.

The hyper-parameter optimization of the k-NN learners was performed using Bayesian Optimization [21] which builds a stochastic model of the parameter space by progressively sampling parameters which have the highest expected improvement based on the constructed model. The parameters optimized include number of nearest neighbors involved in the voting process, distance metric (e.g., Euclidean, Manhattan, etc.), and distance weight (e.g., Equal, Inverse, etc.). Table 3 shows the optimal parameters obtained after performing Bayesian-Optimization-based hyper-parameter tuning for the three error rate learners. 90% of the dataset was used for training and 10% was used for testing. Data was randomized so as to ensure that all quantum computers, qubits, and operation characteristics were included in the training dataset. The training was performed using 5-fold cross validation [32] to avoid machine-learning methodology pitfalls such as over-fitting the model.

Finally, we note that UREQA is practically feasible. The model building and training can be completed within a few days. This process needs to be invoked or refreshed when significant architectural/operational changes are introduced to a particular machine. UREQA's result quality is not highly sensitive to the number of samples (e.g., an incremental improvement in result quality over 10,000 samples is limited). Note that the investment of one-time 20,000 sample based training can potentially be amortized over multiple months in choosing better circuit mappings which reduce the error rate.

3 UREQA: Evaluation and Analysis

Quantum Algorithms and Circuits. Real quantum benchmark algorithms were programmed using *Qiskit*, IBM's python-based language for quantum circuits [2], and executed on different IBM computers (benchmarks are listed in Table 4). The results from these circuits are used to assess the improvement in circuit mapping due to improved prediction power. *Note that the training data of individual operation execution and the assessment data of execution of real quantum circuits were generated at disjoint sets of time periods to avoid biasing the results.*

Table 4: Quantum benchmarks used for evaluation.

Benchmark ID	Benchmark description
$BV2$	2-Qubit Bernstein-Vazirani [5]
$BV3$	3-Qubit Bernstein-Vazirani [5]
QPE	Quantum Phase Estimation [8]
SIA	Simon's algorithm [13]
HR_x^8H	Circuit to stress X gate errors (expected output $\|0\rangle$)
$R_xHR_x^8H$	Circuit to stress X gate errors (expected output $\|1\rangle$)

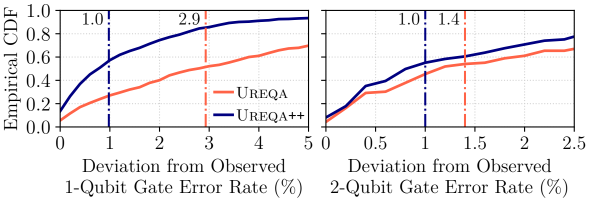

Figure 9: The prediction quality is much better when operation-aware predictor is used in UREQA++.

The benchmarks are chosen to cover a diverse set of quantum algorithm characteristics. For example, the Bernstein-Vazirani (BV) benchmarks heavily use H and R_z gates and the QPE benchmark has high number of 2-qubit gates such as the CR_z gates. Finally, two home-grown benchmarks HR_x^8H (H gate followed by 8 R_x gates followed by H gate) and $R_xHR_x^8H$ are used. These benchmarks are designed to generate and test large 1-qubit gate errors with a long sequence of R_x gates.

Evaluation Metrics. The prediction quality of a model is assessed using *deviation of the predicted value from the observed value of the operation error rate*. The effectiveness of a method's prediction on real quantum algorithms is assessed using the *overall output error rate when a circuit map is selected for an algorithm using the prediction provided by a model/method.*

Evaluated Techniques. (1) The base method: Best circuit map is selected by maximizing the ESP using the operation errors posted by IBM as used in current approaches [10,25,26,28]. (2) UREQA: Best circuit map is selected by predicting operation errors using k-NN models trained without using operation-specific information. (3) UREQA++: Best circuit map is selected by predicting operation errors using k-NN models trained with all features including operation-specific information.

Including operation-specific information in the prediction improves the prediction quality significantly. Fig. 9 shows that when operation-specific information (type of 1-qubit or 2-qubit gate) is included as the predictor, the prediction error is much lower on average. For 1-qubit gates, the median deviation from observed error rate is only 1% with UREQA++ compared to 2.9% with

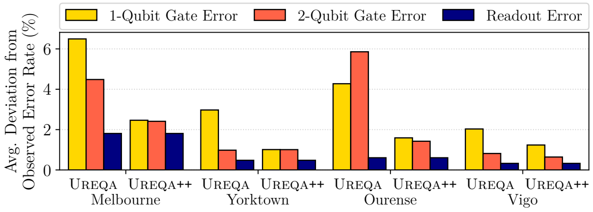

Figure 10: The prediction quality is good across different computers with UREQA++.

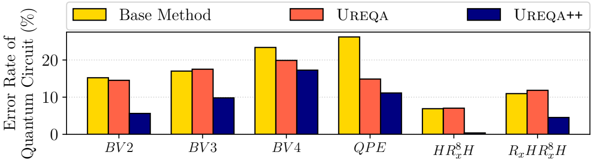

Figure 11: Circuit maps selected using UREQA++ perform much better as compared to other methods.

UREQA. We note that the CDF of UREQA++ has a much steeper rise, indicating that the prediction error is smaller for a large majority of test samples. Similarly, for 2-qubit gates, the median deviation from observed error rate is only 1% with UREQA++ and it is 1.4% with UREQA. As our results show later, even this seemingly small difference has a compounded impact when these predictions are used to estimate the error rate of an entire circuit because multiple operations are used in real quantum algorithms. Note that both UREQA and UREQA++ are hyperparameter optimized using the Bayesian-Optimization-based procedure described earlier. Thus, both models are optimal for their given set of predictor features. Yet, UREQA++ performs better as it is trained in an operation-aware manner.

The deviation from observed value is small across different quantum computers when using UREQA and UREQA++. Fig. 10 shows that UREQA and UREQA++ have another desirable result: the deviation from the observed value is low across the four computers for all the three types of operation errors. Melbourne has slightly higher deviation from the observed error rates than other computers because it has older and more unstable technology which makes error rates vary considerably. This makes prediction difficult. For the other three computers, the average deviation is less than 2% with UREQA++.

Quantum circuit error rate drops significantly when the circuit map is chosen using predictions provided by UREQA++. Fig. 11 shows error rates when the best circuit maps to execute a quantum algorithm are selected using different methods. UREQA achieves similar or significantly better results in some cases (e.g., more than 10% in QPE) compared to the base method. The similar results are mostly due to the fact that both methods do not consider operation-specific information. On the other hand, UREQA++ performs much better across different quantum algorithms, generally resulting in over 5-15% improvement in the error rate compared to the base method (e.g., $BV2$, QPE, HR_x^8H). UREQA++ is able to achieve this low circuit error by producing output state probabilities close to the correct output. Fig. 12 provides an example of this for QPE, where evidently, the circuits produced by the base method and UREQA have more error from the correct output (Table 5) than UREQA++. This demonstrates that the improved prediction quality with UREQA++ when using operation-specific information results in the selection of better circuit maps, which ultimately reduces the side-effect of erroneous quantum operations on current real quantum hardware.

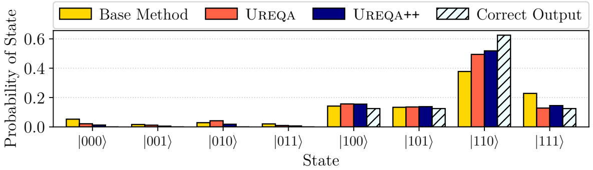

Figure 12: Overall output is much less erroneous with UREQA++ and UREQA than with the base method.

Table 5: State error results for the QPE output in Fig. 12.

Method	Error of Each State from the Correct Output (%)								Overall
	$\|000\rangle$	$\|001\rangle$	$\|010\rangle$	$\|011\rangle$	$\|100\rangle$	$\|101\rangle$	$\|110\rangle$	$\|111\rangle$	Error (%)
Base	5.3	1.6	2.9	2.0	1.7	0.9	24.7	10.3	$\sum/2=24.7$
UREQA	2.1	1.2	4.2	1.0	3.2	1.1	13.1	0.3	$\sum/2=13.1$
UREQA++	1.3	0.5	1.8	0.7	3.0	1.3	10.7	2.0	$\sum/2=10.7$

4 Related Work and Conclusion

Quantum Error Correction. Previous works have proposed algorithms for error correction in qubits which rely on heavy computational requirements which are unavailable in the current NISQ computers [4, 7, 11, 14, 24, 29, 30]. Thus, these methods are not applicable to NISQ technology, while UREQA++ helps reduce the error rate of quantum algorithms executed on NISQ hardware.

Minimization of Error Rates. Many recent works have employed approaches to mitigate the effects of error rates in quantum circuits via both online and offline methods [3, 9, 10, 12, 15, 17–19, 22, 23, 23, 26, 27, 31, 33, 34]. These include optimizing circuit maps to minimize error rates [23], migrating circuits to less-erroneous qubits [34], and minimizing error-prone operations [31]. UREQA's operation-aware circuit mapping technique achieves up to 15% reduction in error rate for quantum programs, compared to the current approaches. UREQA's open-source contribution pushes the state-of-the-art in quantum error rate prediction to minimize erroneous output, which can be leveraged by the quantum computing systems community.

Abstract

Modern storage systems leverage flash caching to boost I/O performance, and enhancing the space efficiency and endurance of flash caching remains a critical yet challenging issue in the face of ever-growing data-intensive workloads. Deduplication and compression are promising data reduction techniques for storage and I/O savings via the removal of duplicate content, yet they also incur substantial memory overhead for index management. We propose AustereCache, a new flash caching design that aims for memory-efficient indexing, while preserving the data reduction benefits of deduplication and compression. AustereCache emphasizes austere cache management and proposes different core techniques for efficient data organization and cache replacement, so as to eliminate as much indexing metadata as possible and make lightweight in-memory index structures viable. Trace-driven experiments show that our AustereCache prototype saves 69.9-97.0% of memory usage compared to the state-of-the-art flash caching design that supports deduplication and compression, while maintaining comparable read hit ratios and write reduction ratios and achieving high I/O throughput.

1 Introduction

High I/O performance is a critical requirement for modern data-intensive computing. Many studies (e.g., [1, 6, 9, 11, 20, 21, 24, 26, 31, 34, 35, 37]) propose solid-state drives (SSDs) as a flash caching layer atop hard-disk drives (HDDs) to boost performance in a variety of storage architectures, such as local file systems [1], web caches [20], data centers [9], and virtualized storage [6]. SSDs offer several attractive features over HDDs, including high I/O throughput (in both sequential and random workloads), low power consumption, and high reliability. In addition, SSDs have been known to incur much less cost-per-GiB than main memory (DRAM) [27], and such a significant cost difference still holds today (see Table 1). On the other hand, SSDs pose unique challenges over HDDs, as they not only have smaller available capacity, but also have poor endurance due to wear-out issues. Thus, in order to support high-performance workloads, caching as many objects as possible, while mitigating writes to SSDs to avoid wear-outs, is a paramount concern.

We explore both deduplication and compression as data reduction techniques for removing duplicate content on the I/O path, so as to mitigate both storage and I/O costs. Deduplication and compression target different granularities of data reduction and are complementary to each other: while deduplication removes chunk-level duplicates in a coarse-grained but lightweight manner, compression removes byte-level duplicates within chunks for further storage savings. With the ever-increasing growth of data in the wild, deduplication and/or compression have been widely adopted in primary [18, 23, 36] and backup [40, 42] storage systems. In particular, recent studies [24, 26, 37] augment flash caching with deduplication and compression, with emphasis on managing variable-size cached data in large replacement units [24] or designing new cache replacement algorithms [26, 37].

Type	Brand	Cost-Per-GiB ($)
DRAM	Crucial DDR4-2400 (16 GiB)	3.75
SSD	Intel SSD 545s (512 GiB)	0.24
HDD	Seagate BarraCuda (2 TiB)	0.025

Table 1: Cost-per-GiB of DRAM, SSD, and HDD based on the price quotes in January 2020.

Despite the data reduction benefits, existing approaches [24,26,37] of applying deduplication and compression to flash caching inevitably incur substantial memory overhead due to expensive index management. Specifically, in conventional flash caching, we mainly track the logical-to-physical address mappings for the flash cache. With both deduplication and compression enabled, we need dedicated index structures to track: (i) the mappings of each logical address to the physical address of the non-duplicate chunk in the flash cache after deduplication and compression, (ii) the cryptographic hashes (a.k.a. fingerprints (§2.1)) of all stored chunks in the flash cache for duplicate checking in deduplication, and (iii) the lengths of all compressed chunks that are of variable size. It is desirable to keep all such indexing metadata in memory for high performance, yet doing so aggravates the memory overhead compared to conventional flash caching. The additional memory overhead, which we refer to as *memory amplification*, can reach at least 16× (§2.3) and unfortunately compromise the data reduction effectiveness of deduplication and compression in flash caching.

In this paper, we propose AustereCache, a memory-efficient flash caching design that employs deduplication and compression for storage and I/O savings, while substantially mitigating the memory overhead of index structures in similar designs. AustereCache advocates *austere* cache management on the data layout and cache replacement policies to limit the memory amplification due to deduplication and compression. It builds on three core techniques: (i) *bucketization*, which achieves lightweight address mappings by deterministically mapping chunks into fixed-size buckets; (ii) *fixed-size compressed data management*, which avoids tracking chunk lengths in memory by organizing variable-size compressed chunks as fixed-size subchunks; and (iii) *bucket-based cache replacement*, which performs memory-efficient cache replacement on a per-bucket basis and leverages a compact sketch data structure [13] to track deduplication and recency patterns in limited memory space for cache replacement decisions.

We implement an AustereCache prototype and evaluate it through testbed experiments using both real-world and synthetic traces. Compared to CacheDedup [26], a state-of-the-art flash caching system that also supports deduplication and compression, AustereCache uses 69.9-97.0% less memory than CacheDedup, while maintaining comparable read hit ratios and write reduction ratios (i.e., it maintains the I/O performance gains through flash caching backed by deduplication and compression). In addition, AustereCache incurs limited CPU overhead on the I/O path, and can further boost I/O throughput via multi-threading.

The source code of our AustereCache prototype is available at: **http://adslab.cse.cuhk.edu.hk/software/austerecache**.

2 Background

We first provide deduplication and compression background (§2.1). We then present a general flash caching architecture that supports deduplication and compression (§2.2), and show how such an architecture incurs huge memory amplification (§2.3). We finally argue that state-of-the-art designs are limited in mitigating the memory amplification issue (§2.4).

2.1 Deduplication and Compression

Deduplication and compression are data reduction techniques that remove duplicate content at different granularities.

Deduplication. We focus on *chunk-based deduplication*, which divides data into non-overlapping data units called *chunks* (of size KiB). Each chunk is uniquely identified by a *fingerprint (FP)* computed by some cryptographic hash (e.g., SHA-1) of the chunk content. If the FPs of two chunks are identical (or distinct), we treat both chunks as duplicate (or unique) chunks, since the probability that two distinct chunks have the same FP is practically negligible. Deduplication stores only one copy of duplicate chunks (in physical space), while referring all duplicate chunks (in logical space) to the copy via small-size pointers. Also, it keeps all mappings of FPs to physical chunk locations in an index structure used for duplicate checking and chunk lookups.

Chunk sizes may be fixed or variable. While content-based variable-size chunking generally achieves high deduplication savings due to its robustness against content shifts [42], it also incurs high computational overhead. On the other hand, fixed-size chunks fit better into flash units and fixed-size chunking often achieves satisfactory deduplication savings [26]. Thus, this work focuses on fixed-size chunking.

Compression. Unlike deduplication, which provides coarse-grained data reduction at the chunk level, *compression* aims for fine-grained data reduction at the byte level by transforming data into more compact form. Compression is often applied to the unique chunks after deduplication, and the output compressed chunks are of variable-size in general. For high performance, we apply sequential compression (e.g., Ziv-Lempel algorithm [43]) that operates on the bytes of each chunk in a single pass.

2.2 Flash Caching

We focus on building an SSD-based flash cache to boost the I/O performance of HDD-based primary storage, by storing the frequently accessed data in the flash cache. Flash caching has been extensively studied and adopted in different storage architectures (§7). Existing flash caching designs, which we collectively refer to as *conventional flash caching*, mostly support both *write-through* and *write-back* policies for read-intensive and write-intensive workloads, respectively [22]; the write-back policy is viable for flash caching due to the persistent nature of SSDs. For write-through, each write is persisted to both the SSD and the HDD before completion; for write-back, each write is completed right after it is persisted to the SSD. To support either policy, conventional flash caching needs an SSD-HDD translation layer that maps each *logical block address (LBA)* in an HDD to a *chunk address (CA)* in the flash cache.

In this work, we explore how to augment conventional flash caching with deduplication and compression to achieve storage and I/O savings, so as to address the limited capacity and wear-out issues in SSDs. Figure 1 shows the architecture of a general flash caching system that deploys deduplication and compression. We introduce two index structures: (i) *LBA-index*, which tracks how each LBA is mapped to the FP of a chunk (the mappings are many-to-one as multiple LBAs may refer to the same FP), and (ii) *FP-index*, which tracks how each FP is mapped to the CA and the length of a compressed chunk (the mappings are one-to-one). Thus, each cache lookup triggers two index lookups: it finds the FP of an LBA via the LBA-index, and then uses the FP to find the CA and the length of a compressed chunk via the FP-index. We also maintain a *dirty list* to track the list of LBAs of recent writes in write-back mode.

We now elaborate the I/O workflows of the flash caching system in Figure 1. For each write, the system partitions the written data into fixed-size chunks, followed by deduplication and compression: it first checks if each chunk is a duplicate; if not, it further compresses the chunk and writes the compressed chunk to the SSD (the compressed chunks can be packed into large-size units for better flash performance and endurance [24]). It updates the entries in both the LBA-index and the FP-index accordingly based on the FP of the chunk; in write-through mode, it also stores the fixed-size chunk in the HDD in uncompressed form. For each read, the sys-

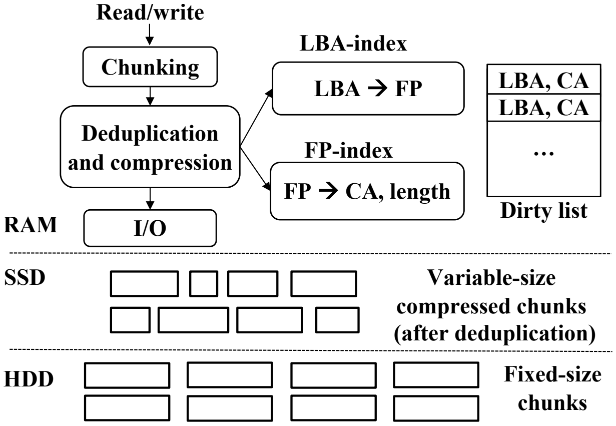

Figure 1: Architecture of a general flash caching system with deduplication and compression.

tem checks if the LBA is mapped to any existing CA via the lookups to both the LBA-index and the FP-index. If so (i.e., cache hit), the system decompresses and returns the chunk data; otherwise (i.e., cache miss), it fetches the chunk data from the HDD into the SSD, while it applies deduplication and compression to the chunk data as in a write.

2.3 Memory Amplification

While deduplication and compression intuitively reduce storage and I/O costs in flash caching by eliminating redundant content on the I/O path, both techniques inevitably incur significant memory costs for their index management. Specifically, if both index structures are entirely stored in memory for high performance, the memory usage is significant and much higher than that in conventional flash caching; we refer to such an issue as *memory amplification* (over conventional flash caching), which can negate the data reduction benefits of deduplication and compression.

We argue this issue through a simple analysis on the following configuration. Suppose that we deploy a 512 GiB SSD as a flash cache atop an HDD that has a working set of 4 TiB. Both the SSD and the HDD have 64-bit address space. For deduplication, we fix the chunk size as 32 KiB and use SHA-1 (20 bytes) for FPs. We also use 4 bytes to record the compressed chunk length. In the worst case, the LBA-index keeps 4 TiB / 32 KiB $= 128 \times 2^{20}$ (LBA, FP) pairs, accounting for a total of 3.5 GiB (each pair comprises an 8-byte LBA and a 20-byte FP). The FP-index keeps 512 GiB / 32 KiB $=$ 16×2^{20} (FP, CA) pairs, accounting for a total of 512 MiB (each pair comprises a 20-byte FP, an 8-byte CA, and a 4-byte length). The total memory usage of both the LBA-index and the FP-index is **4 GiB**. In contrast, conventional flash caching only needs to index 16×2^{20} (LBA, CA) pairs and the memory usage is **256 MiB**. This implies that flash caching with deduplication and compression amplifies the memory usage by **16**×. If we use a more collision-resistant hash function, the memory amplification is even higher; for example, it becomes **22.75**× if each FP is formed by SHA-256 (32 bytes). Note that our analysis does not consider other metadata for deduplication and compression (e.g., reference counts for deduplication), which further aggravates memory amplification over conventional flash caching.

In addition to memory amplification, deduplication and compression also add *CPU overhead* to the I/O path. Such overhead comes from: (i) the FP computation of each chunk, (ii) the compression of each chunk, and (iii) the lookups to both the LBA-index and the FP-index.

2.4 State-of-the-Art Flash Caches

We review two state-of-the-art flash caching designs, Nitro [24] and CacheDedup [26], both of which support deduplication and compression. We argue that both designs are still susceptible to memory amplification.

Nitro [24]. Nitro is the first flash cache that deploys deduplication and compression. To manage variable-size compressed chunks (a.k.a. extents [24]), Nitro packs them in large data units called *Write-Evict Units (WEUs)*, which serve as the basic units for cache replacement. The WEU size is set to align with the flash erasure block size for efficient garbage collection. When the cache is full, Nitro evicts a WEU based on the least-recently-used (LRU) policy. It manages index structures in DRAM (or NVRAM for persistence) to track all chunks in WEUs. If the memory capacity is limited, Nitro stores a *partial* FP-index in memory, at the expense that deduplication may miss detecting and removing some duplicates.

In addition to the memory amplification issue, organizing the chunks by WEUs may cause a WEU to include *stale chunks*, which are not referenced by any LBA in the LBA-index as their original LBAs may have been updated. Such stale chunks cannot be recycled immediately if their hosted WEUs also contain other valid chunks that are recently accessed due to the LRU policy, but instead occupy the cache space and degrade the cache hit ratio.

CacheDedup [26]. CacheDedup focuses on cache replacement algorithms that reduce the number of *orphaned entries*, which refer to either the LBAs that are in the LBA-index but have no corresponding FPs in the FP-index, or the FPs that are in the FP-index but are not referenced by any LBA. It proposes two deduplication-aware cache replacement policies, namely D-LRU and D-ARC, which augment the LRU and adaptive cache replacement (ARC) [29] policies, respectively. It also proposes a compression-enabled variant of D-ARC, called CD-ARC, which manages variable-size compressed chunks in WEUs as in Nitro [24]; note that CD-ARC suffers from the same stale-chunk issue as described above. CacheDedup maintains the same index structures as shown in Figure 1 (§2.2), in which the LBA-index stores LBAs to FPs, and the FP-index stores FPs to CAs and compressed chunk lengths. If it keeps both the LBA-index and the FP-index in memory for performance concerns, it still suffers from the same memory amplification issue. A follow-up work CDAC [37] improves the cache replacement of CacheDedup by incorporating ref-

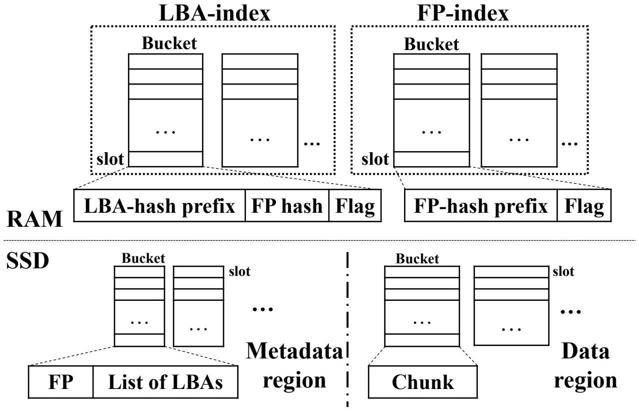

Figure 2: Bucketized data layouts of AustereCache in the LBA-index, the FP-index, as well as the metadata and data regions in flash.

erence counts and access patterns, but incurs even higher memory overhead for maintaining additional information.

3 AustereCache Design

AustereCache is a new flash caching design that leverages deduplication and compression to achieve storage and I/O savings as in prior work [24,26,37], but puts specific emphasis on reducing the memory usage for indexing. It aims for austere cache management via three key techniques.

- **Bucketization (§3.1).** To eliminate the overhead of maintaining address mappings in both the LBA-index and the FP-index, we leverage deterministic hashing to associate chunks with storage locations. Specifically, we hash index entries into equal-size partitions (called *buckets*), each of which keeps the *partial* LBAs and FPs for memory savings. Based on the bucket locations, we further map chunks into the cache space.
- **Fixed-size compressed data management (§3.2).** To avoid tracking chunk lengths in the FP-index, we treat variable-size compressed chunks as fixed-size units. Specifically, we divide variable-size compressed chunks into smaller fixed-size *subchunks* and manage the subchunks without recording the compressed chunk lengths.
- **Bucket-based cache replacement (§3.3).** To increase the likelihood of cache hits, we propose cache replacement on a per-bucket basis. In particular, we incorporate recency and deduplication awareness based on *reference counts* (i.e., the counts of duplicate copies referencing each unique chunk) for effective cache replacement. However, tracking reference counts incurs non-negligible memory overhead. Thus, we leverage a fixed-size compact sketch data structure [13] for reference count estimation in limited memory space with bounded errors.

3.1 Bucketization

Figure 2 shows the bucketized data layouts of AustereCache in both index structures and the flash cache space. We now do not consider compression, which we address in §3.2.

AustereCache partitions both the LBA-index and the FP-index into equal-size *buckets* composed of a fixed number of equal-size *slots*. Each slot corresponds to an LBA and an FP in the LBA-index and the FP-index, respectively. In addition, AustereCache divides the flash cache space into a *metadata region* and a *data region* that store metadata information and cached chunks, respectively; each region is again partitioned into buckets with multiple slots. Note that both regions are allocated the same numbers of buckets and slots as in the FP-index, such that each slot in the FP-index is a one-to-one mapping to the same slots in the metadata and data regions.

To reduce memory usage, each slot stores only the *prefix* of a key, rather than the full key. AustereCache first computes the hashes of both the LBA and the FP, namely *LBA-hash* and *FP-hash*, respectively. It stores the prefix bits of the LBA-hash and the FP-hash as the primary keys in one of the slots of a bucket in the LBA-index and the FP-index, respectively. Keeping only partial keys leads to hash collisions for different LBAs and FPs. To resolve hash collisions, AustereCache maintains the full LBA and FP information in the metadata region in flash, and any hash collision only leads to a cache miss without data loss. Also, by choosing proper prefix sizes, the collision rate should be low. AustereCache currently fixes 128 slots per bucket, mainly for efficient cache replacement (§3.3). For 16-bit prefixes as primary keys, the hash collision rate is only $1-(1-\frac{1}{2^{16}})^{128} \approx 0.2\%$, which is sufficiently low.

Write path. To write a unique chunk identified by an $(\mathrm{LBA},\mathrm{FP})$ pair to the flash cache, AustereCache updates both the LBA-index and the FP-index as follows. For the LBA-index, it uses the suffix bits of the LBA-hash to identify the bucket (e.g., for 2^k buckets, we check the k-bit suffix). It scans all slots in the corresponding bucket to see if the LBA-hash prefix has already been stored; otherwise, it stores the entry in an empty slot or evicts the least-recently-accessed slot if the bucket is full (see cache replacement in §3.3). It writes the following to the slot: the LBA-hash prefix (primary key), the FP-hash, and a valid flag that indicates if the slot stores valid data. Similarly, for the FP-index, it identifies the bucket and the slot using the FP-hash, and writes the FP-hash prefix (primary key) and the valid flag to the corresponding slot.

Based on the bucket and slot locations in the FP-index, AustereCache identifies the corresponding buckets and slots in the metadata and data regions of the flash cache. For the metadata region, it stores the complete FP and the list of LBAs; note that the same FP may be shared by multiple LBAs due to deduplication. We now fix the slot size as 512 bytes. If the slot is full and cannot store more LBAs, we evict the oldest LBA using FIFO to accommodate the new one. For the data region, AustereCache stores the chunk in the corresponding slot, which is also the CA.

Deduplication path. To perform deduplication on a written chunk identified by an $(\mathrm{LBA},\mathrm{FP})$ pair, AustereCache first identifies the bucket of the FP-index using the suffix bits of the FP-hash, and then searches for any slot that matches the same FP-hash prefix. If a slot is found, AustereCache checks the corresponding slot in the metadata region in flash and verifies if the input FP matches the one in the slot. If so, it means that a duplicate chunk is found, so AustereCache appends the LBA to the LBA list if the LBA does not exist before; otherwise, it implies an FP-hash prefix collision. When such a collision occurs, AustereCache invalidates the collided FP in the metadata region in flash and writes the chunk as described above (recall that the collision is unlikely from our calculation).

Read path. To read a chunk identified by an LBA, AustereCache first queries the LBA-index for the FP-hash using the LBA-hash prefix, followed by querying the FP-index for the slot that contains the FP-hash prefix. It then checks the corresponding slot of the metadata region in flash if an LBA is found in the LBA list. If so, the read is a cache hit and AustereCache returns the chunk from the data region; otherwise, the read is a cache miss and AustereCache accesses the chunk in the HDD via the LBA.

Analysis. We show via a simple analysis that the bucketization design of AustereCache has low memory usage. Suppose that we use a 512 GiB SSD as the flash cache with a 4 TiB working set of an HDD. We fix the chunk size as 32 KiB. Since each bucket has 128 slots, the LBA-index needs at most 2^{20} buckets to reference all chunks in the HDD, while the FP-index needs at most 2^{17} buckets to reference all chunks in the SSD. In addition, we store the first 16 prefix bits of both the LBA-hash and the FP-hash as the partial keys in the LBA-index and the FP-index, respectively. Since we use suffix bits to identify a bucket, we need 20 and 17 suffix bits to identify a bucket in the LBA-index and the FP-index, respectively. Thus, we configure an LBA-hash with $16+20=36$ bits and an FP-hash with $16+17=33$ bits.

We now compute the memory usage of each index structure, to which we apply bit packing for memory efficiency. For the LBA-index, each slot consumes 50 bits (i.e., a 16-bit LBA-hash prefix, a 33-bit FP-hash, and a 1-bit valid flag), so the memory usage of the LBA-index is $2^{20} \times 128 \times 50$ (bits) $=$ 800 MiB. For the FP-index, each slot consumes 17 bits (i.e., a 16-bit FP-hash prefix and a 1-bit valid flag), so the memory usage of the FP-index is $2^{17} \times 128 \times 17$ (bits) $=$ 34 MiB. The total memory usage of both index structures is 834 MiB, which is only around 20% of the 4 GiB memory space in the baseline (§2.3). While we do not consider compression, we emphasize that even with compression enabled, the index structures incur no extra overhead (§3.2).

Comparisons with other data structures. We may construct the LBA-index and the FP-index using other data structures for further memory savings. As an example, we consider the B+-tree [12], which is a balanced tree structure that organizes all leaf nodes at the same level. Suppose that we store index mappings in the leaf nodes that reside in flash, while the non-leaf nodes are kept in memory for referencing the leaf nodes. We evaluate the memory usage of the LBA-index and the FP-index as follows.

Suppose that each leaf node is mapped to a 4 KiB SSD page. For the LBA-index, each leaf node stores at most $\lfloor \frac{4096}{8+20} \rfloor = 146$ (LBA, FP) pairs (for an 8-byte LBA and a 20-byte FP). Referencing each leaf node takes 16 bytes (including an 8-byte LBA key and an 8-byte pointer). As there are 128×2^{20} (LBA, FP) pairs, the memory usage of the LBA-index is $\frac{128\times 2^{20}}{146} \times 16 \approx 14.0$ MiB (note that we exclude the memory usage for referencing non-leaf nodes). For the FP-index, each leaf node stores at most $\frac{4096}{20+8+4} = 128$ (FP, CA) pairs (for a 20-byte FP, an 8-byte CA, and a 4-byte length). Referencing each leaf node takes 28 bytes (including a 20-byte FP key and an 8-byte pointer). As there are 16×2^{20} (FP, CA) pairs, the memory usage of the FP-index is 3.5 MiB. Both the LBA-index and the FP-index incur much less memory usage than our current bucketization design (see above).

We can further use an in-memory Bloom Filter [8] to query for the existence of index mappings. For an error rate of 0.1%, each mapping uses 14.4 bits in a Bloom Filter. To track both 128×2^{20} (LBA, FP) pairs in the LBA-index and 16×2^{20} (FP, CA) pairs in the FP-index, we need an additional memory usage of 259.2 MiB.

We can conduct similar analyses for other data structures. For example, for the LSM-tree [32], we can maintain an in-memory structure to reference the on-disk LSM-tree nodes (a.k.a. *SSTables* [33]) that store the index mappings for the LBA-index and the FP-index. Then we can accordingly compute the memory usage for the LBA-index and the FP-index.

Even though these data structures support memory-efficient indexing, they incur additional flash access overhead. First, using B+-trees or LSM-trees for both the LBA-index and the FP-index incurs two flash accesses (one for each index structure) for indexing each chunk, while AustereCache issues only one flash access in the metadata region. Also, both the B+-tree and the LSM-tree have high write amplification [33] that degrades I/O performance. For these reasons, and perhaps more importantly, the synergies with compressed data management and cache replacement (see the following subsections), we settle on our proposed bucketized index design.

3.2 Fixed-Size Compressed Data Management

AustereCache can compress each unique chunk after deduplication for further space savings. To avoid tracking the length of the compressed chunk (which is of variable-size) in the index structures, AustereCache slices a compressed chunk into fixed-size *subchunks*, while the last subchunk is padded to fill a subchunk size. For example, for a subchunk size of 8 KiB, we store a compressed chunk of size 15 KiB as two subchunks, with the last subchunk being padded.

AustereCache allocates the same number of consecutive slots as that of subchunks in the FP-index (and hence the metadata and data regions in flash) to organize all subchunks

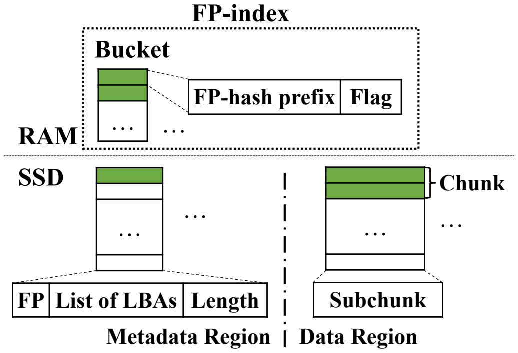

Figure 3: Fixed-size compressed data management, in which multiple consecutive slots are used for handling multiple fixed-size subchunks of a compressed chunk.

of a compressed chunk; note that the LBA-index remains unchanged, and each of its slots still references a chunk. Figure 3 shows an example in which a chunk is stored as two subchunks. For the FP-index, each of the two slots stores the corresponding FP-hash prefix, with an additional 1-bit valid flag indicating that the slot stores valid data. For the metadata region, it also allocates two slots, in which the first slot stores not only the full FP and the list of LBAs (§3.1), but also the length of the compressed chunk, while the second slot can be left empty to avoid redundant flash writes. For the data region, it allocates two slots for storing the two subchunks. Note that our design incurs no memory overhead for tracking the length of the compressed chunk in any index structure.

The read/write workflows with compression are similar to those without compression (§3.1), except that AustereCache now finds consecutive slots in the FP-index for the multiple subchunks of a compressed chunk. Note that we still keep 128 slots per bucket. However, since each slot now corresponds to a smaller-size subchunk, we need to allocate more buckets in the FP-index as well as the metadata and data regions in flash (the number of buckets in the LBA-index remains unchanged since each slot in the LBA-index still references a chunk). As we allocate more buckets for the FP-index, the memory usage also increases. Nevertheless, AustereCache still achieves memory savings for varying subchunk sizes (§5.4).

3.3 Bucket-Based Cache Replacement

Implementing cache replacement often requires priority-based data structures that decide which cached items should be kept or evicted, yet such data structures incur additional memory overhead. AustereCache opts to implement per-bucket cache replacement, i.e., the cache replacement decisions are based on only the entries within each bucket. It then implements specific cache replacement policies that incur no or limited additional memory overhead. Since each bucket is now configured with 128 slots, making the cache replacement decisions also incurs limited performance overhead.

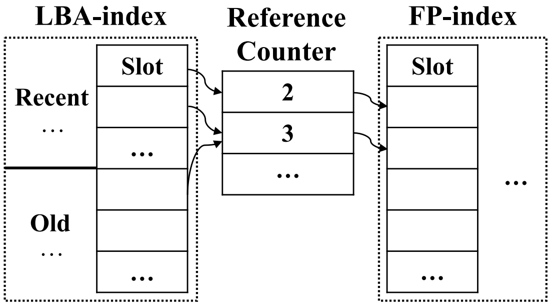

Figure 4: Cache replacement in the FP-index. When a bucket in the FP-index is full, the slot with the least reference counts (e.g. the slot with reference count 2) will be evicted.

For the LBA-index, AustereCache implements a bucket-based least-recently-used (LRU) policy. Specifically, each bucket sorts all slots by the recency of their LBAs, such that the slots at the lower offsets correspond to the more recently accessed LBAs (and vice versa). When the slot of an existing LBA is accessed, AustereCache shifts all slots at lower offsets than the accessed slot by one, and moves the accessed slot to the lowest offset. When a new LBA is inserted, AustereCache stores the new LBA in the slot at the lowest offset and shifts all other slots by one; if the bucket is full, the slot at the highest offset (i.e., the least-recently-accessed slot) is evicted. Such a design does not incur any extra memory overhead for maintaining the recency information of all slots.

For the FP-index, as well as the metadata and data regions in flash, we incorporate both deduplication and recency awareness into cache replacement. First, to incorporate deduplication awareness, AustereCache tracks the reference count for each FP-hash (i.e., the number of LBAs that share the same FP-hash). For each LBA being added to (resp. deleted from) the LBA-index, AustereCache increments (resp. decrements) the reference count of the corresponding FP-hash. When inserting a new FP to a full bucket, it evicts the slot that has the lowest reference count among all the slots in the same bucket. It also invalidates the corresponding slots in both the metadata and data regions in flash.

Simple reference counting does not address recency. To also incorporate recency awareness, AustereCache divides each LBA bucket into *recent slots* at lower offsets and *old slots* at higher offsets (now being divided evenly by half), as shown in Figure 4. Each LBA in the recent (resp. old) slots contributes to a count of two (resp. one) to the reference counting. Specifically, each newly inserted LBA is stored in the recent slot at the lowest offset in the LBA-index (see above), so AustereCache increments the reference count of the corresponding FP-hash by two. If an LBA is demoted from a recent slot to an old slot or is evicted from the LBA-index, AustereCache decrements the reference count of the corresponding FP-hash by one; similarly, if an LBA is promoted from an old slot to a recent slot, AustereCache increments the reference count of the corresponding FP-hash by one.

Maintaining reference counts for all FP-hashes, however, incurs non-negligible memory overhead. AustereCache addresses this issue by maintaining a Count-Min Sketch [13] to track the reference counts in a fixed-size compact data structure with bounded errors. A Count-Min Sketch is a two-dimensional counter array with r rows of w counters each (where r and w are configurable parameters). It maps each FP-hash (via an independent hash function) to one of the w counters in each of the r rows, and increments or decrements the mapped counters based on our reference counting mechanism. AustereCache can estimate the reference count of an FP-hash using the minimum value of all mapped counters of the FP-hash. Depending on the values of r and w, the error bounds can be theoretically proven [13].

Currently, our implementation fixes $r = 4$ and w equal to the total number of slots in the LBA-index. We justify via a simple analysis that sketch-based reference counting achieves significant memory savings. Referring to the analysis in §3.1, each FP-hash has 33 bits. If we track the reference counts of all FP-hashes, we need 2^{33} counters. On the other hand, if we use a Count-Min sketch, we set $r = 4$ and $w = 2^{27}$ (the total number of slots in the LBA-index), so there are $r \times w = 2^{29}$ counters, which consume only 1/16 of the memory usage of tracking all FP-hashes.

Our bucket-based cache replacement design works at the slot level. By using reference counting to make cache replacement decisions, AustereCache can promptly evict any stale chunk that is not referenced by an LBA, as opposed to the WEU design in Nitro and CD-ARC of CacheDedup (§2.4).

4 Implementation

We implement an AustereCache prototype as a user-space block device in C++ on Linux; the user-space implementation (as in Nitro [24]) allows us to readily deploy fast algorithms and multi-threading for performance speedups. Specifically, our AustereCache prototype issues reads and writes to the underlying storage devices via `pread` and `pwrite` system calls, respectively. It uses SHA-1 from the Intel ISA-L Crypto library [3] for chunk fingerprinting, LZ4 [4] for lossless stream-based compression, and XXHash [5] for fast hash computations in the index structures. We also integrate the cache replacement algorithms in CacheDedup [26] into our prototype for fair comparisons (§5). Our prototype now contains around 4.5 K LoC.

We leverage multi-threading to issue multiple read/write requests in parallel for high performance. Specifically, we implement bucket-level concurrency, such that each read/write request needs to acquire an exclusive lock to access a bucket in both the LBA-index and the FP-index, while multiple requests can access different buckets simultaneously.

5 Evaluation

We experiment AustereCache using both real-world and synthetic traces. We consider two variants of AustereCache: (i) AC-D, which performs deduplication only without compression, and (ii) AC-DC, which performs both deduplication and compression. We compare AustereCache with the three cache replacement algorithms of CacheDedup [26]: D-LRU, D-ARC, and CD-ARC (§2.4) (recall that CD-ARC combines D-ARC with the WEU-based compressed chunk management in Nitro [24]). For consistent naming, we refer to them as *CD-LRU-D*, *CD-ARC-D*, and *CD-ARC-DC*, respectively (i.e., the abbreviation of CacheDedup, the cache replacement algorithm, and the deduplication/compression feature). We summarize our evaluation findings as follows.

- Overall, AustereCache reduces memory usage by 69.9-97.0% compared to CacheDedup (Exp#1). It achieves the memory savings via different design techniques (Exp#2).
- AC-D achieves higher read hit ratios than CD-LRU-D and comparable read hit ratios as CD-ARC-D, while AC-DC achieves higher read hit ratios than CD-ARC-DC (Exp#3).
- AC-DC writes much less data to flash than CD-LRU-D and CD-ARC-D, while writing slightly more data than CD-ARC-DC due to padding (§3.2) (Exp#4).
- AustereCache maintains its substantial memory savings for different chunk sizes and subchunk sizes (Exp#5). We also study how it is affected by the sizes of both the LBA-index and the FP-index (Exp#6).
- AustereCache achieves high I/O throughput for different access patterns (Exp#7), while incurring small CPU overhead (Exp#8). Its throughput further improves via multi-threading (Exp#9).

Traces	Working Set (GiB)	Unique Data (GiB)	Write-to-Read Ratio
WebVM	2.71	69.37	3.24
Homes	19.19	240.00	10.81
Mail	59.01	983.78	5.09

Table 2: Basic statistics of FIU traces in 32 KiB chunks.

5.1 Traces

Our evaluation is driven by two traces.

FIU [23]. The FIU traces are collected from three different services with diverse properties, namely *WebVM*, *Homes*, and *Mail*, for the web, NFS, and mail services, respectively. Each trace describes the read/write requests on different chunks (of size 4 KiB or 512 bytes each), each of which is represented as an MD5 fingerprint of the chunk content.

To accommodate different chunk sizes, we take each trace of 4 KiB chunks and perform two-phase trace conversion as in [24]. In the first phase, we identify the initial state of the disk by traversing the whole trace and recording the LBAs of all chunk reads; any LBA that does not appear is assumed to have a dummy chunk fingerprint (e.g., all zeroes). In the second phase, we regenerate the trace of the corresponding chunk size based on the LBAs and compute the new chunk fingerprints. For example, we form a 32 KiB chunk by concatenating eight contiguous 4 KiB chunks and calculating a

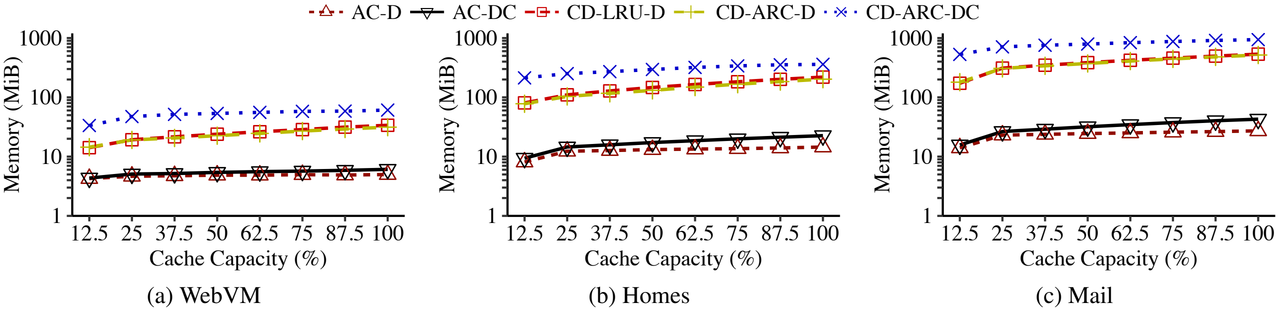

Figure 5: Exp#1 (Overall memory usage). Note that the y-axes are in log scale.

new SHA-1 fingerprint for the 32 KiB chunk. Table 2 shows the basic statistics of each regenerated FIU trace on 32 KiB chunks.

The original FIU traces have no compression details. Thus, for each chunk fingerprint, we set its *compressibility ratio* (i.e., the ratio of raw bytes to the compressed bytes) following a normal distribution with mean 2 and variance 0.25 as in [24].

Synthetic. For throughput measurement (§5.5), we build a synthetic trace generator to account for different access patterns. Each synthetic trace is configured by two parameters: (i) *I/O deduplication ratio*, which specifies the fraction of writes that can be removed on the write path due to deduplication; and (ii) *write-to-read ratio*, which specifies the ratios of writes to reads.

We generate a synthetic trace as follows. First, we randomly generate a working set by choosing arbitrary LBAs within the primary storage. Then we generate an access pattern based on the given write-to-read ratio, such that the write and read requests each follow a Zipf distribution. We derive the chunk content of each write request based on the given I/O deduplication ratio as well as the compressibility ratio as in the FIU trace generation (see above). Currently, our evaluation fixes the working set size as 128 MiB, the primary storage size as 5 GiB, and the Zipf constant as 1.0; such parameters are all configurable.

5.2 Setup

Testbed. We conduct our experiments on a machine running Ubuntu 18.04 LTS with Linux kernel 4.15. The machine is equipped with a 10-core 2.2 GHz Intel Xeon E5-2630v4 CPU, 32 GiB DDR4 RAM, a 1 TiB Seagate ST1000DM010-2EP1 SATA HDD as the primary storage, and a 128 GiB Intel SSDSC2BW12 SATA SSD as the flash cache.

Default setup. For both AustereCache and CacheDedup, we configure the size of the FP-index based on a fraction of the working set size (WSS) of each trace, and fix the size of the LBA-index four times that of the FP-index. We store both the LBA-index and the FP-index in memory for high performance. For AustereCache, we set the default chunk size and subchunk size as 32 KiB and 8 KiB, respectively. For CD-ARC-DC in CacheDedup, we set the WEU size as 2 MiB (the default in [26]).

5.3 Comparative Analysis

We compare AustereCache and CacheDedup in terms of memory usage, read hit ratios, and write reduction ratios using the FIU traces.

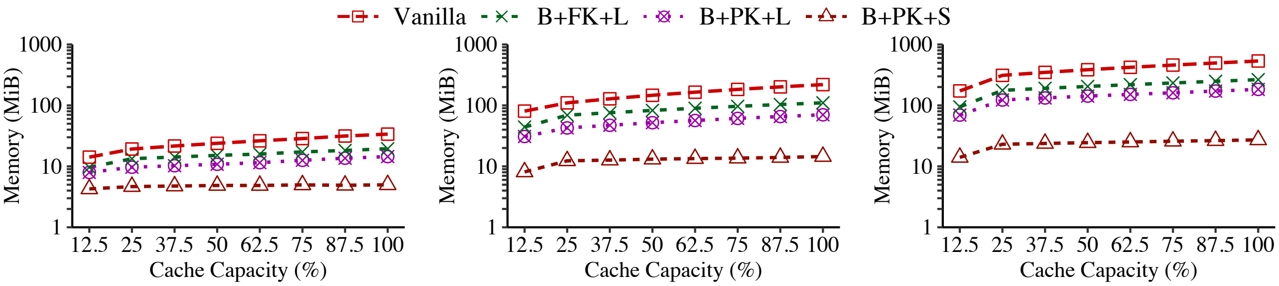
Exp#1 (Overall memory usage). We compare the memory usage of different schemes. We vary the flash cache size from 12.5% to 100% of WSS of each FIU trace, and configure the LBA-index and the FP-index based on our default setup (§5.2). To obtain the actual memory usage (rather than the allocated memory space for the index structures), we call `malloc_trim` at the end of each trace replay to return all unallocated memory from the process heap to the operating system, and check the residual set size (RSS) from `/proc/self/stat` as the memory usage.

Figure 5 shows that AustereCache significantly saves the memory usage compared to CacheDedup. For the non-compression schemes (i.e., AC-D, CD-LRU-D, and CD-ARC-D), AC-D incurs 69.9-94.9% and 70.4-94.7% less memory across all traces than CD-LRU-D and CD-ARC-D, respectively. For the compression schemes (i.e., AC-DC and CD-ARC-DC), AC-DC incurs 87.0-97.0% less memory than CD-ARC-DC.

AustereCache achieves higher memory savings than CacheDedup in compression mode, since CD-ARC-DC needs to additionally maintain the lengths of all compressed chunks, while AC-DC eliminates such information. If we compare the memory overhead with and without compression, CD-ARC-DC incurs 78-194% more memory usage than CD-ARC-D across all traces, implying that compression comes with high memory usage penalty in CacheDedup. On the other hand, AC-DC only incurs 2-58% more memory than AC-D.

Exp#2 (Impact of design techniques on memory savings). We study how different design techniques of AustereCache help memory savings. We mainly focus on bucketization (§3.1) and bucket-based cache replacement (§3.3); for fixed-size compressed data management (§3.2), we refer readers to Exp#1 for our analysis.

We choose CD-LRU-D of CacheDedup as our baseline and compare it with AC-D (both are non-compressed versions), and add individual techniques to see how they contribute to the memory savings of AC-D. We consider four variants:



(a) WebVM (b) Homes (c) Mail

Figure 6: Exp#2 (Impact of design techniques on memory savings).

- *Vanilla*. It refers to CD-LRU-D. It maintains the LRU lists that track the LBAs and FPs being accessed in the LBA index and the FP index, respectively.
- *B+FK+L*. It deploys bucketization (B), but keeps the full keys (FK) (i.e., LBAs and FPs) in each slot. Each bucket implements the LRU policy (L) independently and keeps an LRU list of the slot IDs being accessed.
- *B+PK+L*. It deploys bucketization (B) and now keeps the prefix keys (PK) in both the LBA-index and the FP-index. It still implements the LRU policy as in B+FK+L.
- *B+PK+S*. It deploys bucketization (B) and keeps the prefix keys (PK). It maintains reference counts in a sketch (S). Note that it is equivalent to AC-D.

Figure 6 presents the memory usage versus the cache capacity, where the memory usage is measured as in Exp#1. Compared to Vanilla, B+FK+L saves the memory usage by 30.6-50.6%, while B+PK+L further increases the savings to 43.9-68.0% due to keeping prefix keys in the index structures. B+FK+S (i.e., AC-D) increases the overall memory savings to 69.9-94.9% by keeping reference counts in a sketch as opposed to maintaining LRU lists with full LBAs and FPs.

Exp#3 (Read hit ratio). We evaluate different schemes with the *read hit ratio*, defined as the fraction of read requests that receive cache hits over the total number of read requests.

Figure 7 shows the results. AustereCache generally achieves higher read hit ratios than different CacheDedup algorithms. For the non-compression schemes, AC-D increases the read hit ratio of CD-LRU-D by up to 39.2%. The reason is that CD-LRU-D is only aware of the request recency and fails to clean stale chunks in time (§2.4), while AustereCache favors to evict chunks with small reference counts. On the other hand, AC-D achieves similar read hit ratios to CD-ARC-D, and in particular has a higher read hit ratio (up to 13.4%) when the cache size is small in WebVM (12.5% WSS) by keeping highly referenced chunks in cache. For the compression schemes, AC-DC has higher read hit ratios than CD-ARC-DC, by 0.5-30.7% in WebVM, 0.7-9.9% in Homes, and 0.3-6.2% in Mail. Note that CD-ARC-DC shows a lower read hit ratio than CD-ARC-D although it intuitively stores more chunks with compression, mainly because it cannot quickly evict stale chunks due to the WEU-based organization (§2.4).

Exp#4 (Write reduction ratio). We further evaluate different schemes in terms of the *write reduction ratio*, defined as the fraction of reduction of bytes written to the cache due to both deduplication and compression. A high write reduction ratio implies less written data to the flash cache and hence improved performance and endurance.

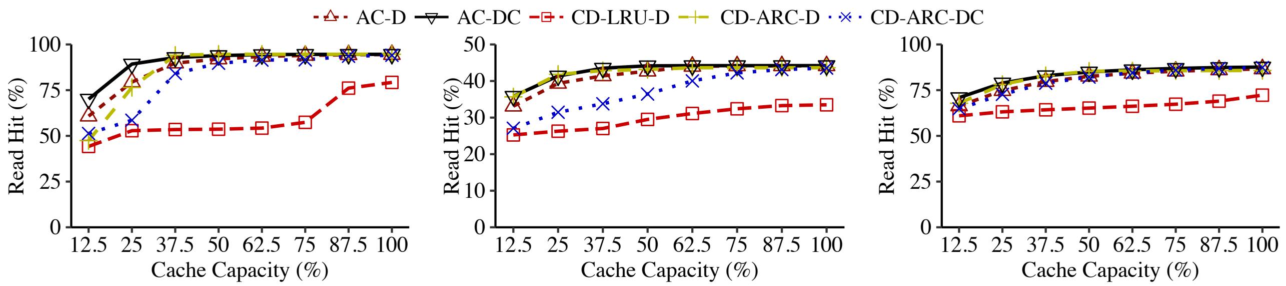
Figure 8 shows the results. For the non-compression schemes, AC-D, CD-LRU-D, and CD-ARC-D show marginal differences in WebVM and Homes, while in Mail, AC-D has lower write reduction ratios than CD-LRU-D by up to 17.5%. We find that CD-LRU-D tends to keep more stale chunks in cache, thereby saving the writes that hit the stale chunks. For example, when the cache size is 12.5% of WSS in Mail, 17.1% of the write reduction in CD-LRU-D comes from the writes to the stale chunks, while in WebVM and Homes, the corresponding numbers are only 3.6% and 1.1%, respectively. AC-D achieves lower write reduction ratios than CD-LRU-D, but achieves much higher read hit ratios by up to 39.2% by favoring to evict the chunks with small reference counts (Exp#3).

For the compression schemes, both CD-ARC-DC and AC-DC have much higher write reduction ratios than the non-compression schemes due to compression. However, AC-DC shows a slightly lower write reduction ratio than CD-ARC-DC by 7.7-14.5%. The reason is that AC-DC pads the last subchunk of each variable-size compressed chunk, thereby incurring extra writes. As we show later in Exp#5 (§5.4), a smaller subchunk size can reduce the padding overhead, although the memory usage also increases.

5.4 Sensitivity to Parameters

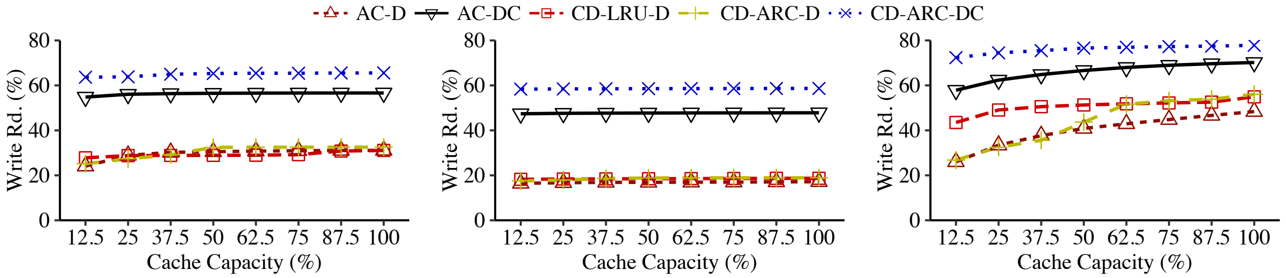
We evaluate AustereCache for different parameter settings using the FIU traces.

Exp#5 (Impact of chunk sizes and subchunk sizes). We evaluate AustereCache on different chunk sizes and subchunk sizes. We focus on the Homes trace and vary the chunk sizes and subchunk sizes as described in §5.1. For varying chunk sizes, we fix the subchunk size as one-fourth of the chunk size; for varying subchunk sizes, we fix the chunk size as 32 KiB. We focus on comparing AC-DC and CD-ARC-DC by fixing the cache size as 25% of WSS. Note that CD-ARC-DC is unaffected by the subchunk size.



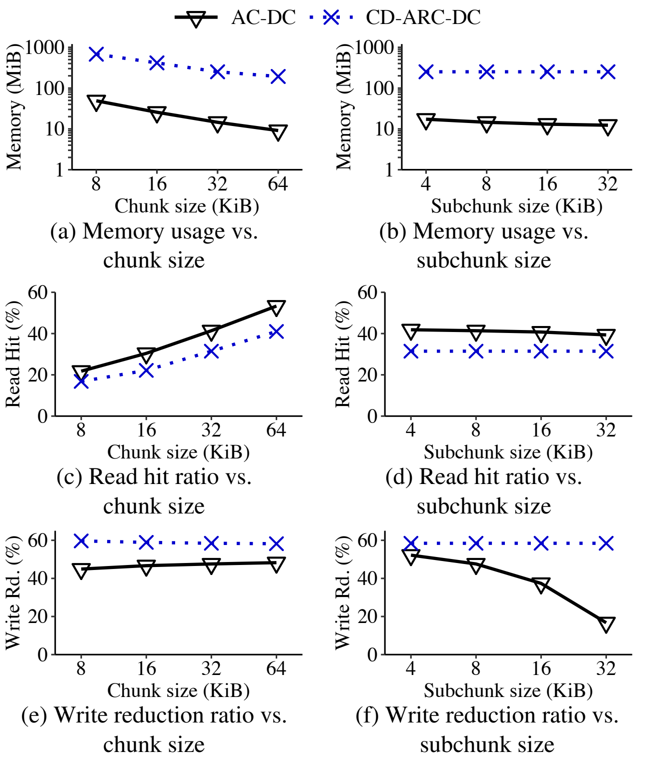
(a) WebVM (b) Homes (c) Mail

Figure 7: Exp#3 (Read hit ratio).



(a) WebVM (b) Homes (c) Mail

Figure 8: Exp#4 (Write reduction ratio).



(a) Memory usage vs. chunk size

(b) Memory usage vs. subchunk size

(c) Read hit ratio vs. chunk size

(d) Read hit ratio vs. subchunk size

(e) Write reduction ratio vs. chunk size

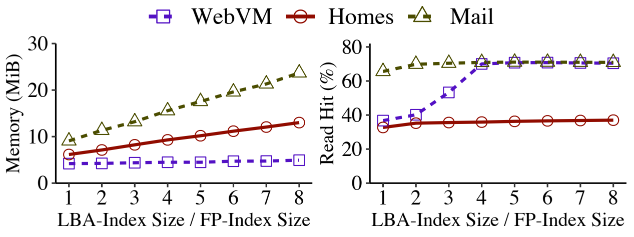
(f) Write reduction ratio vs. subchunk size

Figure 9: Exp#5 (Impact of chunk sizes and subchunk sizes). We focus on the Homes trace and fix the cache size as 25% of WSS in Homes.

AC-DC maintains the significant memory savings compared to CD-ARC-DC, by 92.8-95.3% for varying chunk sizes (Figure 9(a)) and 93.1-95.1% for varying subchunk sizes (Figure 9(b)). It also maintains higher read hit ratios than CD-ARC-DC, by 5.0-12.3% for varying chunk sizes (Figure 9(c)) and 7.9-10.4% for varying subchunk sizes (Figure 9(d)). AC-DC incurs a (slightly) less write reduction ratio than CD-ARC-DC due to padding, by 10.0-14.8% for varying chunk sizes (Figure 9(e)); the results are consistent with those in Exp#4. Nevertheless, using a smaller subchunk size can mitigate the padding overhead. As shown in Figure 9(f), the write reduction ratio of AC-DC approaches that of CD-ARC-DC when the subchunk size decreases. When the subchunk size is 4 KiB, AC-DC only has a 6.2% less write reduction ratio than CD-ARC-DC. Note that if we change the subchunk size from 8 KiB to 4 KiB, the memory usage increases from 14.5 MiB to 17.3 MiB (by 18.8%), since the number of buckets is doubled in the FP-index (while the LBA-index remains the same).

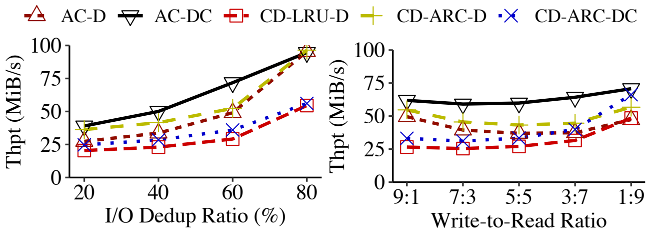
Exp#6 (Impact of LBA-index sizes). We study the impact of LBA-index sizes. We vary the LBA-index size from 1× to 8× of the FP-index size (recall that the default is 4×), and fix the cache size as 12.5% of WSS.

Figure 10 depicts the memory usage and read hit ratios; we omit the write reduction ratio as there is nearly no change for varying LBA-index sizes. When the LBA-index size increases, the memory usage increases by 17.6%, 111.5%, and 160.9% in WebVM, Homes and Mail, respectively (Figure 10(a)), as we allocate more buckets in the LBA-index. Note that the increase in memory usage in WebVM is less than those in Homes and Mail, mainly because the WSS of WebVM is small and incurs a small actual increase of the total memory usage. Also, the read hit ratio increases with



(a) Memory usage (b) Read hit ratio

Figure 10: Exp#6 (Impact of LBA-index sizes).



(a) Throughput vs. I/O dedup ratio (write-to-read ratio 7:3)

(b) Throughput vs. write-to-read ratio (I/O dedup ratio 50%)

Figure 11: Exp#7 (Throughput).

the LBA-index size, until the LBA-index reaches 4× of the FP-index size (Figure 10(b)). In particular, for WebVM, the read hit ratio grows from 36.7% (1×) to 70.4% (8×), while for Homes and Mail, the read hit ratios increase by only 4.3% and 5.3%, respectively. The reason is that when the LBA-index size increases, WebVM shows a higher increase in the total reference counts of the cached chunks than Homes and Mail, implying that more reads can be served by the cached chunks (i.e., higher read hit ratios).

5.5 Throughput and CPU Overhead

We measure the throughput and CPU overhead of AustereCache. We conduct the evaluation on synthetic traces for varying I/O deduplication ratios and write-to-read ratios. We focus on the write-back policy (§2.2), in which AustereCache first persists the written chunks to the flash cache and flushes the chunks to the HDD when they are evicted from the cache. We use direct I/O to remove the impact of page cache. We report the averaged results over five runs, while the standard deviations are small (less than 2.7%) and hence omitted.

Exp#7 (Throughput). We compare AustereCache and CacheDedup in throughput using synthetic traces. We fix the cache size as 50% of the 128 MiB WSS. Both systems work in single-threaded mode.

Figures 11(a) and 11(b) show the results for varying I/O deduplication ratios (with a fixed write-to-read ratio 7:3, which represents a write-intensive workload as in FIU traces) and varying write-to-read ratios (with a fixed I/O deduplication ratio 50%), respectively. For the non-compression schemes, AC-D achieves 18.5-86.6% higher throughput than CD-LRU-D for all cases except when the write-to-read ratio is 1:9 (slightly slower by 2.3%). Compared to CD-ARC-D, AC-D is slower by 1.1-24.5%, since both AC-D and CD-ARC-D have similar read hit ratios and write reduction ratios (§5.3), while AC-D issues additional reads and writes to the metadata region (CD-ARC-D keeps all indexing information in memory). AC-D achieves similar throughput to CD-ARC-D when there are more duplicate chunks (i.e., under high I/O deduplication ratios). For compression schemes, AC-DC achieves 6.8-99.6% higher throughput than CD-ARC-DC.

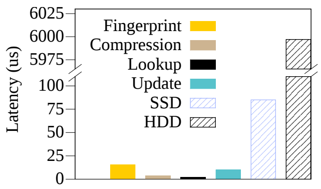


Figure 12: Exp#8 (CPU overhead).

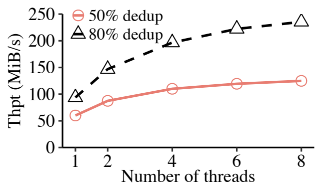

Figure 13: Exp#9 (Throughput of multi-threading).

Overall, AC-DC achieves the highest throughput among all schemes for two reasons. First, AustereCache generally achieves higher or similar read hit ratios compared to CacheDedup algorithms (§5.3). Second, AustereCache incorporates deduplication awareness into cache replacement by caching chunks with high reference counts, thereby absorbing more writes in the SSD and reducing writes to the slow HDD.

Exp#8 (CPU overhead). We study the CPU overhead of deduplication and compression of AustereCache along the I/O path. We measure the latencies of four computation steps, including fingerprint computation, compression, index lookup, and index update. Specifically, we run the WebVM trace with a cache size of 12.5% of WSS, and collect the statistics of 100 non-duplicate write requests. We also compare their latencies with those of 32 KiB chunk write requests to the SSD and the HDD using the `fio` benchmark tool [2].

Figure 12 depicts the results. Fingerprint computation has the highest latency (15.5 μs) among all four steps. In total, AustereCache adds around 31.2 μs of CPU overhead. On the other hand, the latencies of 32 KiB writes to the SSD and the HDD are 85 μs and 5,997 μs, respectively. Note that the CPU overhead can be suppressed via multi-threaded processing, as shown in Exp#9.

Exp#9 (Throughput of multi-threading). We evaluate the throughput gain of AustereCache when it enables multi-threading and issues concurrent requests to multiple buckets (§4). We use synthetic traces with a write-to-read ratio of 7:3, and consider the I/O deduplication ratio of 50% and 80%.

Figure 13 shows the throughput versus the number of threads being configured in AustereCache. When the number of threads increases, AustereCache shows a higher throughput gain under 80% I/O deduplication ratio (from 93.8 MiB/s to 235.5 MiB/s, or 2.51×) than under 50% I/O deduplication ratio (from 60.0 MiB/s to 124.9 MiB/s, or 2.08×). A higher I/O deduplication ratio implies less I/O to flash, and AustereCache benefits more from multi-threading on parallelizing the computation steps in the I/O path and hence sees a higher throughput gain.

6 Discussion

We discuss the following open issues of AustereCache.

Choices of chunk/subchunk sizes. AustereCache by default uses 32 KiB chunks and 8 KiB subchunks to align with common flash page sizes (e.g., 4 KiB or 8 KiB) in commodity SSDs, while preserving memory savings even for various chunk/subchunk sizes (Exp#5 in §5.4). Larger chunk/subchunk sizes reduce the chunk management overhead, at the expense of issuing more read-modify-write operations for small requests from upper-layer applications. Efficiently managing small chunks/subchunks in large-size I/O units in flash caching [24, 25], while maintaining memory efficiency in indexing, is future work.

Impact of indexing on flash endurance. AustereCache currently reduces its memory usage by keeping only limited indexing information in memory and full indexing details in flash (i.e., the metadata region). Since the indexing information generally has a smaller size than the cached chunks, we expect that the updates of the metadata region bring limited degradations to flash endurance, compared to the writes of chunks to the data region. An in-depth analysis of how AustereCache affects flash endurance is future work.

AustereCache assumes that the flash translation layer supports efficient flash erasure management (e.g., applying write combining before writing chunks to flash). To further mitigate the flash erasure overhead, one possible design extension is to adopt a log-structured data organization in flash in order to limit random writes, which are known to degrade flash endurance [30].

7 Related Work

Flash caching. Flash caching has been extensively studied to improve I/O performance. For example, Bcache [1] is a block-level cache for Linux file systems; FlashCache [20] is a file cache for web servers; Mercury [9] is a hypervisor cache for shared storage in data centers; CloudCache [6] estimates the demands of virtual machines (VMs) and manages cache space for VMs in virtualized storage.

Several studies focus on better flash caching management. For example, FlashTier [34] exploits caching workloads in cache block management; Kim *et al.* [21] exploit application hints to cache write requests; DIDACache [35] takes a software-hardware co-design approach to eliminate duplicate garbage collection. To improve the endurance of flash caching, Cheng *et al.* [11] propose erasure-aware heuristics to admit cache insertions; S-RAC [31] selectively evicts cache items based on temporal locality; Pannier [25] manages the flash cache in large-size units (called containers) with erasure awareness; Wang *et al.* [38] use machine learning to remove unnecessary writes to flash.

Deduplication and compression. AustereCache exploits deduplication and compression in flash caching. Extensive work has shown the effectiveness of deduplication and/or compression in storage and I/O savings in primary [18, 23, 36], backup [16, 40, 42], and memory storage [19, 39]. For flash storage, CAFTL [10] implements deduplication in the flash translation layer to reduce flash writes; SmartDedup [41] organizes in-memory and on-disk fingerprints for resource-constrained devices; FlaZ [28] applies transparent and online I/O compression for efficient flash caching. Prior studies [24, 26, 37] also exploit deduplication and compression in flash caching, but incur high memory overhead in metadata management (§2.4). On the other hand, AustereCache aims for memory efficiency without compromising the storage and I/O savings achieved by deduplication and compression.

Memory-efficient designs. Prior studies propose memory-efficient data structures for flash storage. ChunkStash [15] uses fingerprint prefixes to index fingerprints on SSDs in backup deduplication. SkimpyStash [14] designs a hash-table-based index that stores chained linked lists on SSDs for deduplication systems. SILT [27] uses partial-key hashing for efficient indexing in key-value stores. TinyLFU [17] uses Counting Bloom Filters to estimate item frequencies in cache admission. Our bucketization design (§3.1) is similar to the Quotient Filter (also used in flash caching [7]) in prefix-key matching. AustereCache specifically targets flash caching with deduplication and compression, and incorporates several techniques for high memory efficiency.

8 Conclusion

AustereCache makes a case of integrating deduplication and compression into flash caching while significantly mitigating the memory overhead due to indexing. It builds on three techniques to aim for austere cache management: (i) bucketization removes address mappings from indexing; (ii) fixed-size compressed data management removes compressed chunk lengths from indexing; and (iii) bucket-based cache replacement tracks reference counts in a compact sketch structure to achieve high read hit ratios. Evaluation on both real-world and synthetic traces shows that AustereCache achieves significant memory savings, with high read hit ratios, high write reduction ratios, and high throughput.

DADI Block-Level Image Service for Agile and Elastic Application Deployment

Huiba Li, Yifan Yuan, Rui Du, Kai Ma, Lanzheng Liu and Windsor Hsu
Alibaba Group

Abstract

Businesses increasingly need agile and elastic computing infrastructure to respond quickly to real world situations. By offering efficient process-based virtualization and a layered image system, containers are designed to enable agile and elastic application deployment. However, creating or updating large container clusters is still slow due to the image downloading and unpacking process. In this paper, we present DADI Image Service, a block-level image service for increased agility and elasticity in deploying applications. DADI replaces the waterfall model of starting containers (downloading image, unpacking image, starting container) with fine-grained on-demand transfer of remote images, realizing instant start of containers. DADI optionally relies on a peer-to-peer architecture in large clusters to balance network traffic among all the participating hosts. DADI efficiently supports various kinds of runtimes including cgroups, QEMU, etc., further realizing "build once, run anywhere". DADI has been deployed at scale in the production environment of Alibaba, serving one of the world's largest ecommerce platforms. Performance results show that DADI can cold start 10,000 containers on 1,000 hosts within 4 seconds.

1 Introduction

As business velocity continues to rise, businesses increasingly need to quickly deploy applications, handle unexpected surge, fix security flaws, and respond to various real world situations. By offering efficient process-based virtualization and a layered image system, containers are designed to enable agile and elastic application deployment. However, creating or updating large container clusters is still slow due to the image downloading and unpacking process. For example, Verma et al. in [37] report that the startup latency of containers is highly variable with a typical median of about 25s, and pulling layers (packages) accounts for about 80% of the total time.

Highly elastic container deployment has also become expected of modern cloud computing platforms. In serverless computing [23], high cold-start latency could violate responsiveness SLAs. Workarounds for the slow start are cumbersome and expensive, and include storing all images on all possible hosts. Therefore, minimizing cold-start latency is considered a critical system-level challenge for serverless computing [14, 23].

There has been recent work on reducing container startup time by accelerating the image downloading process with a peer-to-peer (P2P) approach [20, 22, 24, 30, 37]. We relied on a P2P download tool for several years to cope with the scalability problem of the Container Registry. However, the startup latency was still unsatisfactory. Another general approach to the problem is to read data on-demand from remote images [9, 16, 18, 19, 21, 33, 41]. Because container images are organized as overlaid layers of files and are presented to the container runtime as a file system directory, all of the previous work adhered to the file system interface, even though some of them actually used block stores as their backends.

Implementing a POSIX-complaint file system interface and exposing it via the OS kernel is relatively complex. Moreover, using file-based layers has several disadvantages. First, updating big files (or their attributes) is slow because the system has to copy whole files to the writable layer before performing the update operations. Second, creating hard links is similarly slow, because it also triggers the copy action as cross layer references are not supported by the image. Third, files may have a rich set of types, attributes, and extended attributes that are not consistently supported on all platforms. Moreover, even on one platform, support for capabilities such as hard links, sparse files, etc. tends to be inconsistent across file systems.

With the rapid growth of users running containers on public cloud and hybrid cloud, virtualized secure containers are becoming mainstream. Although it is possible to pass a file-based image from host to guest via 9p [1] or virtio-fs [10], there is usually a performance cost. There are also complications in handling heterogeneous containers such as Windows guest on Linux host, or vice versa. This means that some users may not be able to burst efficiently to public clouds, i.e. run their applications primarily on premise with an efficient container runtime, and scale them out under load to public clouds with a virtualized secure container runtime.

In this paper, we observe that the benefits of a layered image are not contingent on representing the layers as sets of file changes. More specifically, we can achieve the same effect with block-based layers where each layer still corresponds to a set of file changes but is physically the set of changes at the block level underneath a given file system. Such a design allows the image service to be file system and platform agnostic. The image service is solely responsible for managing and distributing physical images to the appropriate hosts. It is up to the individual host or container on the host to interpret

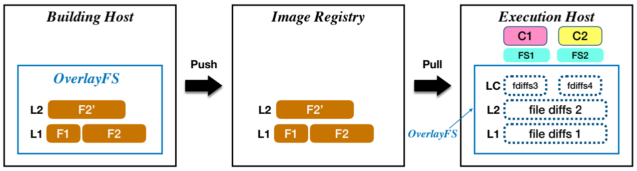

Figure 1: Layered Container Image. The image layers (L1, L2) are read-only shared by multiple containers (C1, C2) while the container layers (LC) are privately writable.

the image with an appropriate file system. This approach also allows dependency on the file system to be explicitly captured at image creation time, further enhancing consistency in the runtime environment of applications.

We have designed and implemented a complete system called *DADI Image Service* (*DADI* in short) based on this approach. The name *DADI* is an acronym for *Data Acceleration for Disaggregated Infrastructure* and describes several of our initiatives in enabling a disaggregated infrastructure. At the heart of the DADI Image Service is a new construct called Overlay Block Device (OverlayBD) which provides a merged view of a sequence of block-based layers. Conceptually, it can be seen as the counterpart of union file systems that are usually used to merge container images today. It is simpler than union file systems and this simplicity enables optimizations including flattening of the layers to avoid performance degradation for containers with many layers. More generally, the simplicity of block-based layers facilitates (1) fine-grained on-demand data transfer of remote images; (2) online decompression with efficient codecs; (3) trace-based prefetching; (4) peer-to-peer transfer to handle burst workload; (5) flexible choice of guest file systems and host systems; (6) efficient modification of large files (cross layer block references); (7) easy integration with the container ecosystem.

We have applied DADI to both cgroups [3] runtime and QEMU runtime. Support for other runtimes such as Firecracker [13], gVisor [5], OS^v [25], etc. should be technically straightforward. DADI has been deployed at scale in the production environment of Alibaba to serve one of the world's largest ecommerce platforms. Performance results show that DADI can cold start 10,000 containers on 1,000 hosts within 4 seconds. We are currently working on an edition of DADI for our public cloud service.

2 Background and Related Work

2.1 Container Image

Container images are composed of multiple incremental layers so as to enable incremental image distribution. Each layer is essentially a tarball of differences (addition, deletion or update of files) from a previous layer. The container system may apply the diffs in a way defined by its storage driver. The layers are usually much lighter than VM images that contain full data. Common layers are downloaded only once on a host, and are shared by multiple containers as needed. Each container has a dedicated writable layer (also known as container layer) that stores a private diff to the image, as shown in Figure 1. Writing to a file in the image may trigger a copy-on-write (CoW) operation to copy the entire file to the writable layer.

To provide a root file system to containers, the container engine usually depends on a union file system such as overlayfs, aufs, etc. These union file systems provide a merged view of the layers which are stored physically in different directories. The container system can also make use of Logical Volume Manager (LVM) thin-provisioned volumes, with each layer mapped to a snapshot.

The container system has a standard web service for image uploading and downloading called the Container Registry. The Container Registry serves images with an HTTP(S)-based protocol which, together with the incremental nature of layers, makes it a lot easier to distribute container images widely as compared to VM images.

2.2 Remote Image

The image distribution operation, however, consumes a lot of network and file system resources, and may easily saturate the service capacity allocated to the user/tenant, especially when creating or updating large container clusters. The result is long startup latencies for containers. After an image layer is received, it has to be unpacked. This unpacking operation is CPU, memory (for page cache) and I/O intensive at the same time so that it often affects other containers on the host and sometimes even stalls them.

To some extent, the current container image service is a regression to a decade ago when VM images were also downloaded to hosts. A similar problem has been solved once with distributed block stores [26, 28, 29, 38] where images are stored on remote servers, and image data is fetched over the network on-demand in a fine-grained manner rather than downloaded as a whole. This model is referred to as "remote image". There are several calls for this model in the container world (e.g. [18, 21]).

The rationale for remote image is that only part of the image is actually needed during the typical life-cycle of a container, and the part needed during the startup stage is even smaller. According to [19], as little as 6.4% of the image is used during the startup stage. Thus remote image saves a lot of time and resources by not staging the entire image in advance. And with the help of data prefetching (by OS) or asynchronous data loading (by applications themselves), the perceived time to start from a remote image can be effectively reduced further.

Remote image, however, requires random read access to the contents of the layers. But the standard layer tarball was designed for sequential reading and unpacking, and does not support random reading. Thus the format has to be changed.

2.3 File-System-Based Remote Image

CRFS [21] is a read-only file system that can mount a container image directly from a Container Registry. CRFS introduces an improved format called Stargz that supports random reads. Stargz is a valid tar.gz format but existing images need to be converted to realize remote image service. Instead of having the read-only file system read files directly from the layer, one could also extract the files in each layer and store them in a repository such as CernVM-FS [18] where they can be accessed on demand. CFS [27] is a distributed file system to serve unpacked layer files for hosts. Wharf [41], Slacker [19], Teleport [9] serve unpacked layer files through NFS or CIFS/SMB.

Due to the complexity of file system semantics, there are several challenges with file-system based image service. For example, passing a file system from host to guest across the virtualization boundary tends to limit performance. The I/O stack involves several complex pieces (including virtio-fs [10], FUSE [36], overlayfs [8], remote image itself) that need to be made robust and optimized. When compared to a block device, the file system also presents a larger attack surface that potentially reduces security in public clouds.

POSIX-compliant features are also a burden for non-POSIX workloads such as serverless applications, and an obstacle to Windows workloads running on Linux hosts (with virtualization). In addition, unikernel [5, 25, 39] based applications are usually highly specialized, and tend to prefer a minimalistic file system such as FAT [4] for efficiency. Some of them may even require a read-only file system. These different requirements are difficult to be satisfied by a file system that is predefined by the image service.

Furthermore, some desirable features of popular file systems such as XFS [11], Btrfs [2], ZFS [12], etc., are missing in current file-system-based image services, and are not likely to be supported soon. These include file-level or directory-level snapshot, deduplication, online defragmentation, etc. It is even difficult to efficiently (without copy) support standard features such as hard links and modification of files or file attributes.

2.4 Block-Snapshot-Based Remote Image

Modern block stores [26, 28, 29, 38] usually have a concept of copy-on-write snapshot which is similar to layer in the container world. Cider [16] and Slacker [19] are attempts to make use of such similarity by mapping image layers to the snapshots of Ceph and VMstore [17], respectively.

Container image layer and block store snapshot, however, are not identical concepts. Snapshot is a point-in-time view of a disk. Its implementation tends to be specific to the block store. In many systems, snapshots belong to disks. When a disk is deleted, its snapshots are deleted as well. Although this is not absolutely necessary, many block stores behave this way by design. Layer, on the other hand, refers to the incremental change relative to a state which can be that of a different image. Layer emphasizes sharing among images, even those belonging to different users, and has a standard format to facilitate wide distribution.

2.5 Others

File System Changesets. Exo-clones [33] implement volume clones efficiently with file system changesets that can be exported. DADI images are conceptually exo-clones with block level deltas that are not tied to any specific file system.

P2P downloading. Several systems allow container hosts to download image layers in a P2P manner, significantly reducing the download time in large environments [20, 22, 24, 30, 37]. VMThunder [40] adopts a tree-structured P2P overlay network to deliver fine-grained data blocks on-demand for large VM clusters. We reuse this general idea in DADI's optional P2P subsystem with a refined design and a production-level implementation.

Trimmed images. In order to pull less data and start a container in less time, DockerSlim [6] uses a combination of static and dynamic analyses to generate smaller-sized container images in which only files needed by the core application are included. Cntr [35] improves this by allowing dynamic accesses to trimmed files in uncommon cases via a FUSE-based virtual files system.

Storage Configuration for Containers. The layering feature of container image introduces new complexities in configuring storage. [34] demonstrates the impact of Docker storage configuration on performance.

VM images. Standard VM image formats such as qcow2, vmdk, vhd, etc. are block-level image formats and are technically reusable for containers. The major drawback of these image formats is that they are not layered. It is possible to emulate layering by repeatedly applying QEMU's backing-file feature, but doing this incurs significant performance overhead for reads. As we shall see in Section 3.1, the translation tables for standard VM image formats are also much bigger than those needed for DADI.

3 DADI Image Service

DADI is designed to be a general solution that can become part of the container ecosystem. The core of DADI (Sections 3.1-3.4) is a remote image design that inherits the layering model of container image, and remains compatible with the Registry by conforming to the OCI-Artifacts [31] standard. DADI is independent of transfer protocols so it is possible to insert an optional P2P transfer module to cope with large-scale applications (Section 3.5). DADI is also independent of the underlying storage system so users can choose an appropriate storage system such as HDFS, NFS, CIFS, etc., to form a fully networked solution (Section 4.4). DADI uses a block-level interface which minimizes attack surface, a design point especially relevant for virtualized secure containers.

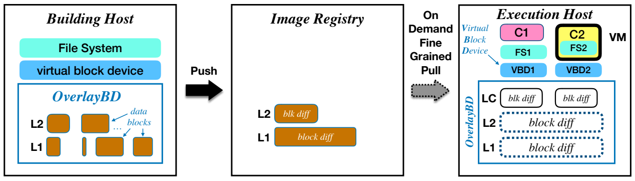

Figure 2: DADI Image. DADI image layer (L1, L2) consists of modified data blocks. DADI uses an overlay block device to provide each container (C1, C2) with a merged view of its layers.

3.1 DADI Image

As shown in Figure 2, DADI models an image as a virtual block device on which is laid a regular file system such as ext4. Note that there is no concept of file at the block level. The file system is a higher level of abstraction atop the DADI image. When a guest application reads a file, the request is first handled by the regular file system which translates the request into one or more reads of the virtual block device. The block read request is forwarded to a DADI module in user space, and then translated into one or more random reads of the layers.

DADI models an image as a virtual block device while retaining the layered feature. Each DADI layer is a collection of modified data blocks under the filesystem and corresponding to the files added, modified or deleted by the layer. DADI provides the container engine with merged views of the layers by an overlay block device (OverlayBD) module. We will use layer and changeset interchangeably in the rest of the paper for clearer statements. The block size (granularity) for reading and writing is 512 bytes in DADI, similar to real block devices. The rule for overlaying changesets is simple: for any block, the latest change takes effect. The blocks that are not changed (written) in any layer are treated as all-zero blocks.

The raw data written by the user, together with an index to the raw data, constitutes the layer blob. The DADI layer blob format further includes a header and a trailer. To reduce memory footprint and increase deployment density, we design an index based on variable-length segments, as illustrated in Figure 3. A segment tells where a change begins and ends in the image's logical block address (LBA) space, and also where the latest data is stored in the layer blob file's offset space. In this design, adjacent segments that are contiguous can be merged into a single larger segment to reduce the index size. The segment struct can record a change as small as 1 block which is the minimal write size for a block device. This avoids Copy-on-Write operations and helps to yield consistent write performance.

```
struct Segment {
  uint64_t offset:48;  // offset in image's LBA
  uint16_t length;     // length of the change
  uint64_t moffset:48; // mapped offset in layer blob
  uint16_t pos:12;     // position in the layer stack
  uint8_t flags:4;     // zeroed? etc.
  uint64_t end() {return offset + length;}
};
```

Figure 3: Definition of Segment. LBA is short for logical block address, offsets and lengths are in unit of blocks (512 bytes), size of the struct is 16 bytes.

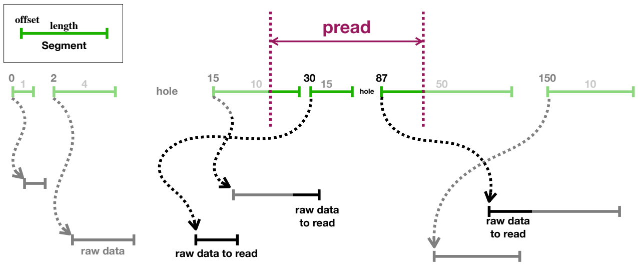

Figure 4: Index Lookup for Reading DADI Image. The lookup operation is a range query on a set of ordered non-overlapping variable-length segments, each of which points to the location of its raw data in the layer blob(s).

The index is an array of non-overlapping segments sorted by their offset. According to statistics from our production environment, the indices have fewer than 4.5K segments (see Section 5 for details) which corresponds to only 72KB of memory. In contrast, the qcow2 image format of QEMU has a fixed block size of 64KB by default, and an index based on radix-tree. QEMU allocates MBs of memory by default to cache the hottest part of its index.

To realize reading, DADI performs a range lookup in the index to find out where in the blob to read. The problem can be formally stated as given a set of disjoint segments in the LBA space, find all the segments (and "holes") within the range to read. This problem is depicted in Figure 4. For efficiency, the algorithm deals with variable-length segments directly without expanding them to fixed-sized blocks. As the index is ordered and read-only, we simply use binary search for efficient lookup, as shown in Algorithm 1. A B-tree could achieve higher efficiency but as the index contains only a few thousand entries in practice, we leave this optimization as a possible future work.

3.2 Merged View of Layers

When there are multiple layers, if the lookup procedure goes through the layers one by one, the time complexity is $O(n \cdot \log m)$ where n is the number of layers and m is the average number of segments in a layer. In other words, the cost increases linearly with n. We optimize this problem with a merged index that is pre-calculated when the indices are

```
Input: the range (offset, length) to look up
end ← offset + length;
i ← index.binary_search_first_not_less(offset);
if i < index.size() then
    delta ← offset - index[i].offset;
    if delta > 0 then // trim & yield 1st segment
        s ← index[i]; s.offset ← offset;
        s.moffset += delta; s.length -= delta;
        yield s; offset ← s.end(); i++;
    end
end
while i < index.size() and index[i].offset < end do
    len ← index[i].offset - offset;
    if len > 0 then // yield a hole
        yield Hole(offset, len);
        offset ← index[i].offset;
    end
    s ← index[i]; // yield next segment
    s.length ← min(s.length, end - offset);
    yield s; offset ← s.end(); i++;
end
if offset < end then // yield final hole
    yield Hole(offset, end - begin);
end
```

Algorithm 1: Index Lookup. Yields a collection of segments within the specified range (offset, length) with `i` initialized to the first element in the index that is not less than `offset`, and Hole being a special type of segment representing a range that has never been written.

```
Input: an array of indices[1..n];
       subscript i of the indices array for this recursion;
       the range to merge (offset, length)
for s in indices[i].lookup(offset, length) do
    if s is NOT a Hole then
        s.pos ← i;
        yield s;
    else if i > 0 then // ignore a real hole
        indices_merge(indices, i-1, s.offset, s.length);
    end
end
```

Algorithm 2: Index Merge by Recursion.

```
Input: an array of file objects blobs[0..n];
       a rage (offset, length) to pread
for s in merged_index.lookup(offset, length) do
    // s.pos == 0 for Hole segments
    // blobs[0] is a special virtual file object
    // that yields zeroed content when pread
    blobs[s.pos].pread(s.offset, s.length);
end
```

Algorithm 3: Read Based on Merged Index.

loaded, thus reducing the complexity to $O(\log M)$ where M is the number of segments in the merged index. The merging problem is illustrated in Figure 5.

To merge the indices, we put them in an array indexed from 1 to n where n is the number of layers, and in an order such that base layers come earlier. Algorithm 2 shows the recursive procedure to merge indices for a specified range. To merge them as whole, the algorithm is invoked for the entire range of the image. We make use of the `pos` field in the final merged index to indicate which layer a segment comes from. With the merged index, random read operation (pread) can be easily implemented as Algorithm 3, supposing that we have an array of file objects representing the ordered layers' blobs.

We analyzed 1,664 DADI image layers from 205 core applications in our production environment to extract the size of the merged indices. The statistics are summarized in Figure 6. They show that the indices have no more than 4.5K segments so the algorithm for merging indices is efficient enough to be run when an image is launched. Observe also that the number of segments is not correlated with the number of layers. This suggests that the performance of DADI OverlayBD does not degrade as the number of layers increases. Figure 7 plots the throughput of index queries on a single CPU core. Observe that at an index size of 4.5K segments, a single CPU core can perform more than 6 million index queries per second. In Section 5.4, we find that IOPS tops out at just under 120K for both LVM and DADI, suggesting that DADI spends no more than 1/50 of a CPU core performing index lookups.

3.3 Compression and Online Decompression

Standard compression file formats such as gz, bz2, xz, etc., do not support efficient random read operation. Files in these formats usually need to be decompressed from the very beginning until the specified part is reached. To support compression of the layers' blobs and enable remote image at the same time, DADI introduces a new compression file format called ZFile.

ZFile includes the source file compressed in a fixed-sized chunk-by-chunk manner and a compressed index. To read

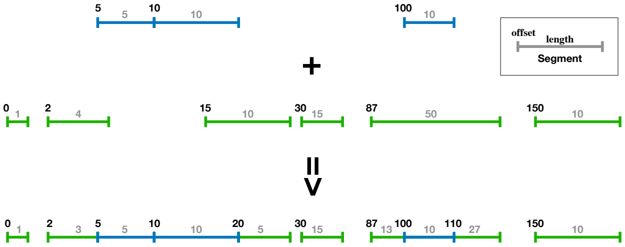

Figure 5: Index Merge.

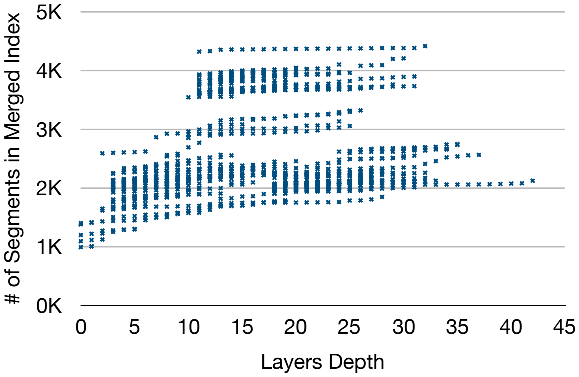

Figure 6: Index Size of Production Applications.

an offset into a ZFile, one looks up the index to find the offset and length of the corresponding compressed chunk(s), and decompresses only these chunks. ZFile supports various efficient compression algorithms including lz4, zstd, gzip, etc., and can additionally store a dictionary to assist some compression algorithms to achieve higher compression ratio and efficiency. Figure 8 illustrates the format of ZFile.

The index stored in ZFile is an array of 32-bit integers, each of which denotes the size of the corresponding compressed chunk. The index is compressed with the same compression algorithm as the data chunks. When loaded into memory, the index is decompressed and accumulated into an array of 64-bit integers denoting the offsets of the compressed chunks in the ZFile blob. After the conversion, index lookup becomes a simple array addressing at $offset/chunk\_size$.

Due to the fixed-size nature of chunks and the aligned nature of the underlying storage device, ZFile may read and decompress more data than requested by a user read. The decompression itself is an extra cost compared to the conventional I/O stack. In practice, however, ZFile improves user-perceived I/O performance even on servers with high-speed NVMe SSD. The advantage is even larger for slower storage (e.g. HDD or Registry). This is because, with the compression agorithm in use (lz4), the time saved reading the smaller amount of compressed data more than offsets the time spent decompressing the data. See Section 5.4 for detailed results.

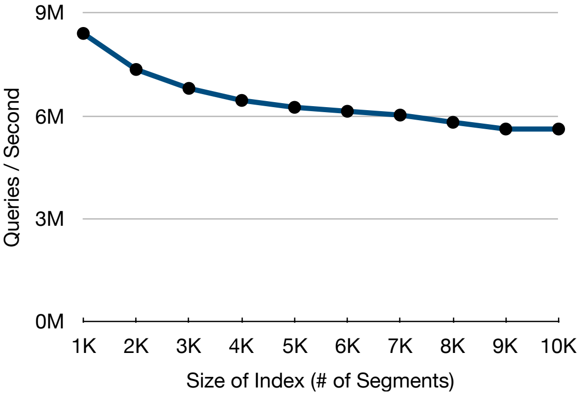

Figure 7: Index Performance on Single CPU Core.

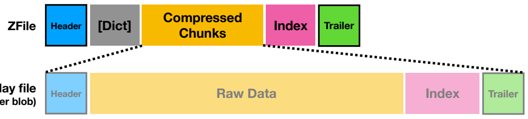

Figure 8: ZFile Format.

In order to support online decompression, a fast compression algorithm can be used at some expense to the compression ratio. We typically use lz4 in our deployment. Individually compressing chunks of the original files also impacts the compression ratio. As a result, DADI images are usually larger than the corresponding .tgz images but not by much.

We analyzed the blob sizes of 205 core applications in our production environment. Figure 9 shows the blob sizes in various formats relative to their .tar format sizes. In general, DADI uncompressed format (.dadi) produces larger blobs than .tar, due to the overhead of the image file system (ext4 in this case) but the overhead is usually less than 5% for layers that are larger than 10MB. Note that the compression ratio varies greatly among these images and some of them are not compressible. As discussed, ZFile blobs tend to be larger than their .tgz counterparts.

By adhering to the layered model of container image, DADI images are able to share layers. To further save space and network traffic, deduplication can be performed at the chunk level of DADI images, followed by compression of the unique chunks.

3.4 DADI Container Layer

Unlike other remote image systems (e.g. [18, 21]), DADI realizes a writable container layer. The writable layer is not only a convenient way to build new image layers, but also

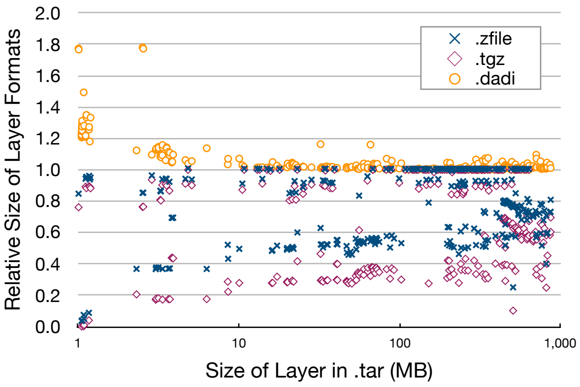

Figure 9: Relative Layer Blob Size.

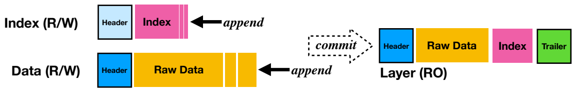

Figure 10: DADI's Writable Layer.

provides an option to eliminate the dependency on a union file system. We base the writable layer on a log-structured [32] design because this makes DADI viable on top of virtually all kinds of storage systems, including those that do not support random writes (e.g. HDFS). The log-structured writable layer is also technically a natural extension of the read-only layers.

As shown in Figure 10, the writable layer consists of one file for raw data and one for index. Both of these files are open-ended, and are ready to accept appends. As overwrites occur in the writable layer, these files will contain garbage data and index records. When there is too much garbage, DADI will spawn a background thread to collect the garbage by copying the live data to a new file, and then deleting the old file. When the writable layer is committed, DADI will copy the live data blocks and index records to a new file in layer format, sorting and possibly combining them according to their LBAs.

The index for the writable layer is maintained in memory as a red-black tree to efficiently support lookup, insertion and deletion. On a write, DADI adds a new record to the index of the writable layer. On a read, DADI first looks up the index of the writable layer. For each hole (a segment with no data written) within the range to read, DADI further looks up the merged index of the underlying read-only layers. DADI supports `TRIM` by adding to the writable layer an index record that is flagged to indicate that the range contains all-zero content.

3.5 P2P Data Transfer

Although remote image can greatly reduce the amount of image data that has to be transferred, there are situations where more improvement is necessary. In particular, there are several critical applications in our production environment that are deployed on thousands of servers, and that comprise layers as large as several GBs. The deployment of these applications places huge pressure on the the Registry and the network infrastructure.

To better handle such large applications, DADI caches recently used data blocks on the local disk(s) of each host. DADI also has the option to transfer data directly among the hosts in a peer-to-peer manner. Given that all the peers need roughly the same set of data and in roughly the same order during the startup time period, DADI adopts a tree-structured overlay topology to realize application-level multicast similar to VMThunder [40] instead of the rarest-first policy commonly used in P2P downloading tools [15, 20, 22].

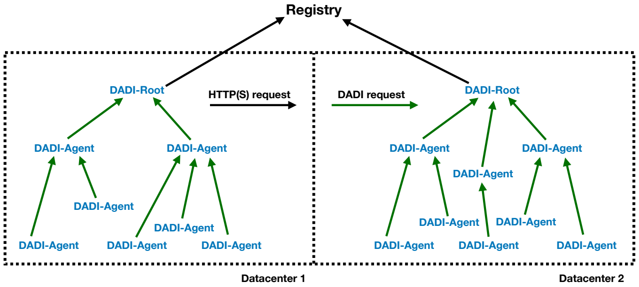

Figure 11: DADI's Tree-Structured P2P Data Transfer.

As shown in Figure 11, each container host runs a P2P module called DADI-Agent. In addition, there is a P2P module called DADI-Root in every data center that plays the role of root for topology trees. DADI-Root is responsible for fetching data blocks from the Registry to a local persistent cache, and also for managing the topology trees within its own datacenter. A separate tree is created and maintained for each layer blob.

Whenever an agent wants to read some data from a blob for the first time or when its parent node does not respond, it sends a request RPC to the root. The root may service the request by itself, or it may choose to rearrange the topology and redirect the requesting agent to a selected parent. The requesting agent is considered to join the tree as a child of the selected parent. Every node in a tree, including the root, serves at most a few direct children. If the requested data is not present in the parent's cache, the request flows upward until a parent has the data in its cache. The data received from the parent is added to the child's cache as it will probably be needed soon by other children or the node itself.

DADI-Root manages the topology. It knows how many children every node has. When a node needs to be inserted into the tree, the root simply walks down the tree in memory, always choosing a child with the fewest children. The walk stops at the first node with fewer direct children than a threshold. This node becomes the selected parent for the requesting agent. When a node finds that its parent has failed, it reverts to the root to arrange another parent for it. As the P2P transfer is designed to support the startup of containers and this startup process usually does not last long, DADI-Root expires topology information relatively quickly, by default after 20 minutes.

DADI-Root is actually a replicated service running on several servers for availability, and deployed separately for different clusters. An agent randomly chooses a root server in the same cluster when joining a transfer topology. It switches to another root server when it encounters a failure. The Registry tends to be shared by many clusters and possibly across a long distance so its performance may not always be high. In order to ensure that data blocks are likely to exist on the root when they are needed, we warm up the root servers' cache in

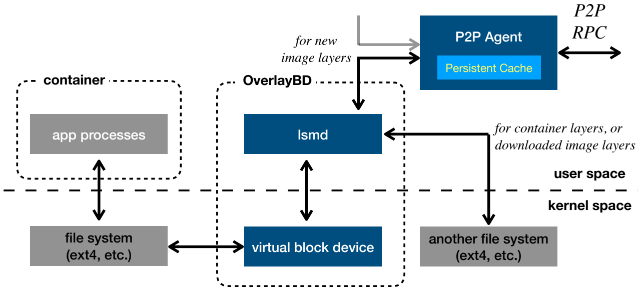

Figure 12: I/O Path for cgroups Runtime.

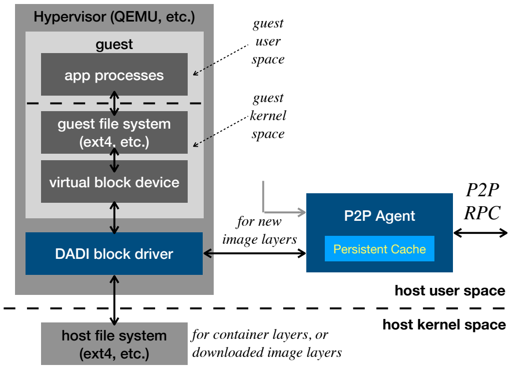

Figure 13: I/O Path for Virtualized Runtime (QEMU, etc).

our production environment whenever a new layer is built or converted.

To protect against potential data corruption, we create a separate checksum file for each and every layer blob as part of the image building or conversion process. The checksum file contains the CRC32 value for each fixed-sized block of the layer. As the checksum files are small, they are distributed whole to every involved node as part of the image pulling process. The data blocks are verified on arrival at each node.

4 Implementation and Deployment

This section discusses how DADI interfaces with applications and container engines, as well as how DADI can be deployed in different user scenarios.

4.1 Data Path

DADI connects with applications through a file system mounted on a virtual block device. DADI is agnostic to the choice of file system so users can select one that best fits their needs. By allowing the dependency on the file system to be explicitly captured at image creation time, DADI can help applications exploit the advanced features of file systems such as XFS [11], Btrfs [2], ZFS [12].

In the case of the cgroups runtime, we use an internal module called `vrbd` to provide the virtual block device. `vrbd` is similar to `nbd` but contains improvements that enable it to perform better and handle crashes of the user-space daemon. As shown in Figure 12, I/O requests go from applications to a regular file system such as ext4. From there they go to the virtual block device and then to a user-space daemon called `lsmd`. Reads of data blocks belonging to layers that have already been downloaded are directed to the local file system where the layers are stored. Other read operations are directed to DADI's P2P agent which maintains a persistent cache of recently used data blocks. Write and trim operations are handled by lsmd which writes the data and index files of the writable layer to the local file system.

We have also realized a QEMU driver for its block device backend to export an image to virtualized containers. As shown in Figure 13, the data path in this case is conceptually similar to that for the cgroups runtime except that the image file system and virtual block device are running in the guest context, and the block driver takes the place of lsmd. Integration with other hypervisors should be straightforward. It is also possible to pass the virtual block device from the host into the guest context. This approach works with virtually all hypervisors but incurs a slightly higher overhead. As the block device interface is narrower and simpler than a file system interface, it exposes a small attack surface to the untrusted guest container.

4.2 Container Engine Integration

DADI is integrated with Docker through a graph driver which is a Docker plugin to compose the root file system from layers. The layers form a graph (actually tree) topology hence the name graph driver. DADI is also integrated with containerd through a snapshotter which provides functions similar to those of the graph driver. We will use the term "driver" to refer to either of them in the rest of the paper.

We implemented the drivers to recognize existing and DADI image formats. When they encounter .tgz image, they invoke existing drivers. When they come across DADI image, they perform DADI-specific actions. In this way, the container engine can support both types of images at the same time so that the deployment of DADI to a host does not require the eviction of existing .tgz based containers or images from that host. This enables us to use a canary approach to systematically roll out DADI across our complex production environment.

DADI currently fakes the image pulling process with a small tarball file consisting of DADI-specific metadata. The tarball is very small so that the image pull completes quickly. We are preparing a proposal to the container community for extensions to the image format representation to enable lazy image pulling and make the engine aware of remote images.

4.3 Image Building

DADI supports image building by providing a log-structured writable layer. The log-structured design converts all writes into sequential writes so that the build process with DADI is usually faster than that for regular .tgz images (see Section 5 for details). As DADI uses faster compression algorithms, the commit operation is faster with DADI than it is for regular .tgz images. DADI also avoids pulling entire base images and this saves time when building images on dedicated image building servers where the base images are usually not already local.

In order to build a new layer, DADI first prepares the base image file system by bringing up a virtual block device and mounting the file system on it. When the layer is committed, DADI unmounts the file system and brings down the device. These actions are repeated for each layer produced in a new image, adding up to a lot of time. According to the specification of the image building script (dockerfile), each line of action will produce a new layer. It is not uncommon to see tens of lines of actions in a dockerfile in our environment so a single build job may result in an image with many new layers. This design was supposed to improve the speed of layer downloading by increasing parallelism, but it may become unnecessary with remote image.

We optimized the DADI image build process by bringing the device up and down only once. The intermediate down-and-ups are replaced with a customized operation called stack-and-commit. As its name suggests, stack-and-commit first stacks a new writable layer on top of existing layers, and then commits the original writable layer in the background. This optimization significantly increases image building speed, especially on high-end servers with plenty of resources.

To convert an existing .tgz image into the DADI format, DADI proceeds from the lowest layer of the image to its highest layer. For each layer, DADI creates a new writable layer and unpacks the corresponding .tgz blob into the layer while handling whiteouts, a special file name pattern that indicates deletion of an existing file. If users want to build a DADI image from a .tgz base image, the base image layers must first be converted into the DADI format using this process.

Some container engines implicitly create a special init layer named as xxxxx-init between the container layer and its images layers. This init layer contains some directories and files that must always exist in containers (e.g. /proc, /dev, /sys). During commit, DADI merges this init layer with the container layer so as to keep the integrity of the image file system.

4.4 Deployment Options

The P2P data transfer capability of DADI is optional and targeted at users with large applications. Other users may prefer to use DADI with the layer blobs stored in a high-performance shared storage system as a compromise between fetching the layer blobs from the Registry and storing the layer blobs on every host. Similar solutions have been proposed in the community (e.g. Teleport [9], Wharf [41]). DADI further enhances these solutions by not requiring the layers to be unpacked and supporting alternative storage systems such as HDFS.

For users who do not wish to set up shared storage, DADI provides them with the option to fetch layer blobs on-demand from the Registry and cache the data blocks on local disk(s). This approach greatly reduces cold startup latencies by avoiding the transfer of data blocks that are not needed. If there is a startup I/O trace available when launching a new container instance, DADI can make use of the trace to prefetch the data blocks needed by the starting container, yielding a near-warm startup latency. The trace can be simply collected with `blktrace`, and replayed with `fio`. See Section 5.2 for details.

Users may also choose to use DADI by downloading the layer blobs to local disk(s). DADI layers do not need to be unpacked, saving a time-consuming sequential process needed for .tgz layers. Thus pulling DADI images is much faster. The downloading can be optionally offloaded to P2P tools such as [20,22,24,30,37]. We use this approach as a backup path in case our on-demand P2P transfer encounters any unexpected error.

5 Evaluation

In this section, we evaluate the performance and scalability of DADI Image Service.

5.1 Methodology

We compare the container startup latency with DADI to that with the standard tarball image, Slacker, CRFS, LVM (dm or device mapper), and P2P image download. We also analyze the I/O performance as observed by an application inside the container.

Slacker uses Tintri VMstore as its underlying storage system. We do not have access to such a system so we use LVM together with NFS as an approximation of Slacker (denoted as pseudo-Slacker). At the time of this writing, CRFS has not yet achieved its goal of realizing an internal overlayfs so we rely on the kernel implementation of overlayfs for the comparisons.

We generally use NVMe SSDs as local storage. We also emulate a low-speed disk by limiting IOPS to 2,000 and throughput to 100 MB/s. These are the performance characteristics of the most popular type of virtual disks on public clouds so we refer to such a disk as “cloud disk” in the rest of the paper. We use ZFile by default for DADI unless explicitly noted. Before starting a test, we drop the kernel page cache in the host and guest (if applicable) as well as the persistent cache of DADI.

The physical servers we use are all equipped with dual-way multi-core Xeon CPUs and 10GbE or higher-speed NICs. The

VMs are hosted on our public cloud. Each VM is equipped with 4 CPU cores and 8 GBs of memory. The vNICs are capable of a burst bandwidth of 5 Gbps and sustained bandwidth of 1.5 Gbps.

5.2 Startup Latency

To evaluate container startup latency, we use the application image `WordPress` from DockerHub.com. WordPress is the most popular content management system powering about one third of the Web in 2019 [7]. The image consists of 21 layers in .tgz format with a total size of 165MB. When unpacked, the image size is 501MB. In DADI compressed format with lz4 compression, the image occupies 274MB. The tarball of DADI-specific metadata that is downloaded on image pull is only 9KB in size.

Cold start of a single instance. We test startup latencies of a single container instance running WordPress when the layer blobs are stored in the Registry (.tgz, DADI, CRFS) and on remote storage servers (DADI, pseudo-Slacker). All the servers are located in the same datacenter as the container host. The results, as summarized in Figure 14, show that container cold startup time is markedly reduced with DADI.

Warm start of a single instance. Once the layer blobs are stored or cached on local disk, the containers can be started and run without a remote data source. In this case, any difference in startup time can be attributed to the relative efficiency of the I/O paths. As indicated in Figure 15, DADI performs 15%~25% better than overlayfs and LVM on NVMe SSD, and more than 2 times better on cloud disk.

Cold startup with trace-based prefetching. We first make use of `blktrace` to record an I/O trace when starting a container. On another host, we use `fio` to replay only the read operations in the trace while starting a new container instance of the same image. We set fio to replay with a relatively large I/O depth of 32 so as to fetch data blocks before they are actually read by the application. Figure 16 shows the results. Observe that trace-based prefetching can reduce 95% of the difference between cold and warm startup times.

Batch cold startup. In practice, many applications are large and require multiple instances to be started at the same time. For this batch startup scenario, we compare only pseudo-Slacker and DADI because the .tgz image and CRFS are bottlenecked by the Registry. The results are presented in Figure 17. Note that the startup time with pseudo-Slacker begins at 1.5s for one instance and increases to 2.3s for 32 instances. On the other hand, the startup time with DADI remains largely constant at 0.7s as the number of instances increases.

Startup in our Production Environment. We selected typical deployment tasks for an application in our production environment and analyzed its timing data. As shown in Figure 18, pulling the DADI metadata tarball takes no more than 0.2s for nearly half of the hosts and around 1s for the rest of the hosts. This compares very favorably with pulling the equivalent .tgz image which takes more than 20s for most

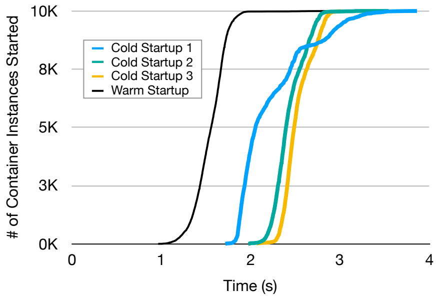

Figure 20: Startup Latency using DADI (Large-Scale Startup).

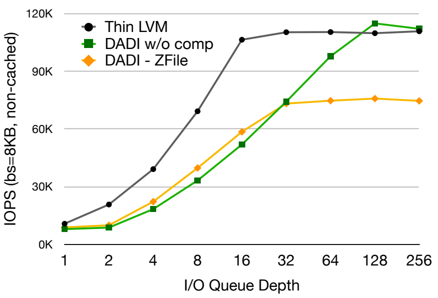

Figure 22: Uncached Random Read Performance.

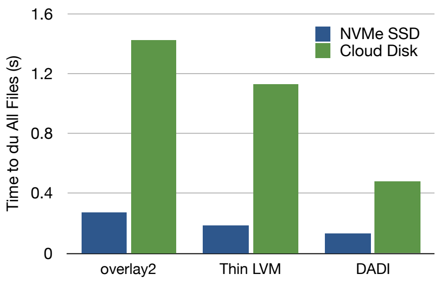

Figure 23: Time to `du` All Files.

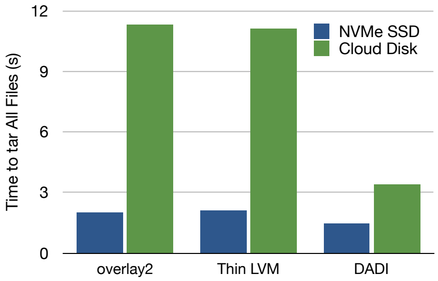

Figure 24: Time to `tar` All Files.

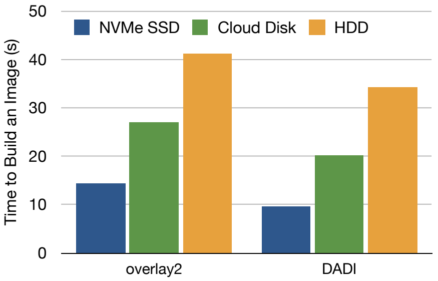

Figure 25: Time to Build Image.

of the hosts. Note that in this case, the .tgz image pull only needs to download the application layers as the much larger dependencies and OS layers already exist on the hosts. If all the layers have to be downloaded, the time needed will be even higher.

As shown in Figure 19, applications start faster using DADI remote image and P2P data transfer than with the .tgz image stored on local SSD. This result surprised us initially but it turned out to be a common occurrence for a couple of reasons. First, overlayBD performs better than OverlayFS (See Section 5.4). Second, with the tree-structured P2P data transfer, hosts effectively read from their parents' page cache, and this is faster than reading from their local disks.

5.3 Scalability

For the scalability analysis, we use a lightweight application called `Agility`. Agility is a Python application based on CentOS 7.6. Its image consists of 16 layers with a total size of 575MB in ZFile format and 894MB uncompressed. When Agility starts, it accesses a specified HTTP server which records the time stamps of all the accesses. We use Agility instead of WordPress for our scalability test because it provides a means to collect timings of a large number of container instances. Agility also consumes fewer resources, allowing us to create many more containers in our testbed.

Large-scale startup with DADI. We create 1,000 VMs on our public cloud platform and use them as hosts for containers. A large and increasing portion of our production environment is VM-based so this test reflects our real world situation. We start 10 containers running Agility on each host for a total of 10,000 containers. As shown in Figure 20, the cold start latency with DADI is within a second or two of that for warm start. The experimental environment is not dedicated and some noise is apparent in one of the runs (Cold Startup 1). Note that other than for ramp-up and long-tail effects, the time taken to start additional containers is relatively constant.

Hyper-scale startup with DADI. We deliberately construct a special P2P topology with tens of hosts and use it to project the behavior for a full tree with tens of thousands of hosts. The special topology models a single root-to-leaf path where each interior node has the maximum number of children. Each host again runs 10 instances of Agility. As shown in Figure 21, the startup time is largely flat as the number of containers increases to 100,000. Notice also that a binary tree for P2P is best when there are fewer than 20,000 participating hosts. A 3-ary or 4-ary tree works better beyond that scale.

5.4 I/O Performance

We perform micro benchmarks with `fio` to compare uncached random read performance. The results are summarized in Figure 22. At an I/O queue depth of 1, DADI offers comparable performance to LVM despite its user-space implementation. DADI's performance ramps up slower as the queue depth is increased but it catches up and tops LVM to achieve the highest IOPS at an I/O queue depth of 128 and without compression. This behavior suggests that DADI's index is more efficient than that of LVM, but there is room to optimize our queueing and batching implementation. Observe that DADI with compression performs 10%~20% better than without compression when the I/O queue depth is less than 32. This is because compression, by reducing the amount of data transferred, increases effective I/O throughput provided that the CPU is not bottlenecked. In our experimental setup, the CPU becomes bottlenecked for ZFile beyond a queue depth of 32.

We also test I/O performance with `du` and `tar` to scan the entire image from inside the container. These tests respectively emphasize small random read and large sequential read. The output of these commands are ignored by redirecting to `/dev/null`. As shown in Figure 23 and 24, DADI outperforms both overlayfs and LVM in all cases especially on the cloud disk. This is again primarily due to the effect of compression in reducing the amount of data transferred.

5.5 Image Building Speed

Image building speed is driven primarily by write performance and the time needed to setup an image. We evaluate image building performance with a typical dockerfile from our production environment. The dockerfile creates 15 new layers comprising 7,944 files with a total size of 545MB, and includes a few `chmod` operations that trigger copy-ups in overlayfs-backed images. As shown in Figure 25, the image is built 20%~40% faster on DADI than on overlayfs. Note that the time to commit or compress the image is not included in this measurement.

6 Discussion and Future Work

With overlayfs, containers that share layers are able to share the host page cache when they access the same files in those shared layers. Because DADI realizes each layered image as a separate virtual block device, when multiple containers access the same file in a shared layer, the accesses appear to the host to be for distinct pages. In other words, the host page cache is not shared, potentially reducing its efficiency.

One way to address this issue is to introduce a shared block pool for all the virtual block devices corresponding to the different containers on a host. The basic idea is to use the device mapper to map segments from the pool to the virtual block devices such that accesses by different containers to the same file in a shared layer appear to be for the same segment in the pool. The pool is backed by the page cache while the virtual block device and file system on top will need to support Direct Access (DAX) to avoid double caching. This solution can be further improved by performing block-level deduplication in the pool.

With the emergence of virtualized runtimes, container is becoming a new type of virtual machine and vice versa. The runtimes of container and VM may also begin to converge. By being based on the widely supported block device, DADI image is compatible with both containers and VMs, and is naturally a converged image service. Such a converged infrastructure will bring the convenience and efficiency of layered image to VM users on the cloud today. It will also provide users with increased flexibility and enable applications to evolve gradually from cloud-based to cloud-native.

A key part of realizing the potential of DADI is to standardize its image format and facilitate its adoption. We are working to contribute core parts of DADI to the container community.

7 Conclusions

We have designed and implemented DADI, a block-level remote image service for containers. DADI is based on the observation that incremental image can be realized with block-based layers where each layer corresponds to a set of file changes but is physically the set of changes at the block level underneath a given file system. Such a design allows the image service to be file system and platform agnostic, enabling applications to be elastically deployed in different environments. The relative simplicity of block-based layers further facilitates optimizations to increase agility. These include fine-grained on-demand data transfer of remote images, online decompression with efficient codecs, trace-based prefetching, peer-to-peer transfer to handle burst workload, easy integration with the container ecosystem. Our experience with DADI in the production environment of one of the world's largest ecommerce platforms show that DADI is very effective at increasing agility and elasticity in deploying applications.

Acknowledgments

This paper would not have been possible without the close collaboration of our storage, container, serverless, kernel and virtualization teams. We are especially grateful to Haobo Xu, Liang Han, Qianbo Huai and Jiwei Lu for delivering the initial version of the P2P Data Transfer capability. We are also grateful to our shepherd, Vasily Tarasov, and anonymous reviewers for helping us improve the paper.

Efficient Miss Ratio Curve Computation for Heterogeneous Content Popularity

Damiano Carra
University of Verona, Italy

Giovanni Neglia
Inria, Université Côte d'Azur, France

Abstract

The Miss Ratio Curve (MRC) represents a fundamental tool for cache performance profiling. Approximate methods based on sampling provide a low-complexity solution for MRC construction. Nevertheless, in this paper we show that, in case of content with a large variance in popularity, the approximate MRC may be highly sensitive to the set of sampled content. We study in detail the impact of content popularity heterogeneity on the accuracy of the approximate MRC. We observe that few, highly popular, items may cause large error at the head of the reconstructed MRC.

From these observations, we design a new approach for building an approximate MRC, where we combine an exact portion of the MRC with an approximate one built from samples. Results for different real-world traces show that our algorithm computes MRC with an error up to 10 times smaller than state-of-the-art methods based on sampling, with similar computational and space overhead.

1 Introduction

Caches have been widely used in different contexts to improve system performance, from CPU, to disk, to web. As the architectures become more complex, with multi-core CPUs, or clusters of machines, caches maintain a key role in providing fast access to the most used content. Being a shared resource, a cache may be misused by some aggressive processes or application, hurting the performance of other processes.

To provide a fair sharing, one may virtually divide the cache and assign dynamically different portions to specific applications or types of applications. For instance, Sundarrajan *et al.* [33] show that, in case of Web caches, video streaming, web browsing, and software updates have extremely different content access patterns and cache resource requirements. Similarly, when multiple VMs run on the same physical host, efficient sharing of storage resources, like a SSD used as cache, needs detailed VM profiling [21, 24, 28, 32]. Analogous observations have been made in different contexts, such as multiprocessor systems [10, 19] and distributed processing in datacenters [27, 35].

The most important performance metric for a cache is usually the *hit ratio*. For cache partitioning, it is necessary to quantify the hit ratio a given application would experience given the amount of available cache space. This relation is captured by the *Miss Ratio Curve* (MRC), which gives the miss ratio as a function of the cache size. The use of MRCs can be helpful also in contexts where caches can be provisioned *on demand* [7, 29] with a pay-as-you-go model, as it is in the case for cloud caches [1–3].

MRC can be computed analytically for many caching policies—sometimes exactly [14, 20], more often approximately [15, 16]—but only under idealized models for the request process. Real traffic usually exhibits complex patterns that diverge from these models.

A more common approach, dating back to Mattson's seminal work [25], is to compute the MRC directly from the trace of the specific workload. The MRC can be built with $\mathcal{O}(\log M)$ computational complexity per request, and $\mathcal{O}(M)$ memory [9, 13], where M is the number of distinct items that are requested. Since content popularity (and consequently the MRC) may vary over time, the usual approach is to select an interval of time over which the traffic request process may be considered stationary. Then, the requests observed during this interval are used to build a MRC, which drives the resource assignment for the next interval. In case of high traffic rate, if we need to continuously build many MRCs for different application types, computational complexity and memory requirements may represent a heavy burden [7, 33].

For this reason, by trading accuracy with computational complexity and memory, recent works propose to compute approximate MRCs with $\mathcal{O}(1)$ operations per request, and $\mathcal{O}(1)$ memory [17, 29, 36, 37]. Such low-complexity solutions are based on the common idea of sampling the trace.

Limitation of the prior work. Sampling has been applied widely in different domains. A potential pitfall of sampling is the introduction of biases. In building the approximate MRC, there could be two approaches: sampling the *requests* [4, 34], or sampling the *items* and observing the requests for those items [36, 37]. Request sampling introduces a bias [30, 39], which motivated the introduction of item sampling, also called *spatial sampling*. Nevertheless, if request rates vary greatly across items, spatial sampling can be biased too, a fact that was implicitly acknowledged by Waldspurger *et al.* [37]. To the best of our knowledge, we are the first to thoroughly address and explain such a bias in detail.

As an example, the left column of Figure 1 shows the exact and approximate MRCs using the LRU eviction policy, built from various samples, considering traces with different traffic characteristics. In particular, item request frequencies, usually referred to as *popularities*, are Zipf-distributed with two different values of the Zipf exponent (α)—experiments' details are provided in Section 3, but they are not essential to understand what follows. With higher values of α, the distribution becomes more skewed, and therefore popularities become highly heterogeneous. The approximate MRCs in the left column are obtained using SHARDS [37] with a constant sampling rate $R = 0.01$. The experiments show that SHARDS is able to obtain an accurate MRC when item popularity is not highly skewed. But, as heterogeneity increases, the error drastically increases. Waldspurger *et al.* [37] recognized this possible bias, and proposed the variant SHARDS$_{\text{adj}}$ that partially solves the problem. The curves in Figure 1, right column, show that SHARDS$_{\text{adj}}$ correctly estimates the tail of the MRC, but not its head, with large errors for high miss ratio values (above 30% in the bottom subfigure) that may even exceed 100% (top subfigure). Miss ratios above 70% are the norm for many caches, including HDD [37] and SSD ones [21, 24], and hierarchical web caches, where the higher level resides in RAM [5, 26]. Caches consist of fast, expensive storage, and they are inherently a scarce, shared resource. An accurate assignment requires the knowledge of the MRC for *any size*, even when the miss ratio is large.

Contributions. In this work we study the impact of heterogeneity on the accuracy of the approximate MRC. With the help of different sets of experiments, and a model of a representative scenario, we observe that highly popular item play a fundamental role, and we shed lights on the fact that the MRC is highly sensitive to the specific content sampled. Consequently, we design a new approach, where we combine exact MRC computation for small values of the cache capacity (which is mainly influenced by popular items) with approximate computation for larger values. We evaluate our scheme with both synthetic and real-world traces. Our results show that our method is able to reconstruct the MRC with an average error up to 10 times smaller than state of the art approaches, with the same complexity. We also consider a scenario where items have heterogeneous sizes, and show how our solution correctly addresses it.

Roadmap. The remaining of the paper is organized as follows. In Section 2 we provide the background information and discuss the related work. In Section 3 we study the impact of popular items on the accuracy of the spatial sampling approaches. Section 4 presents our solution, which is evaluated in Section 5. Section 6 provides additional considerations on the scheme we propose, and Section 7 concludes the paper.

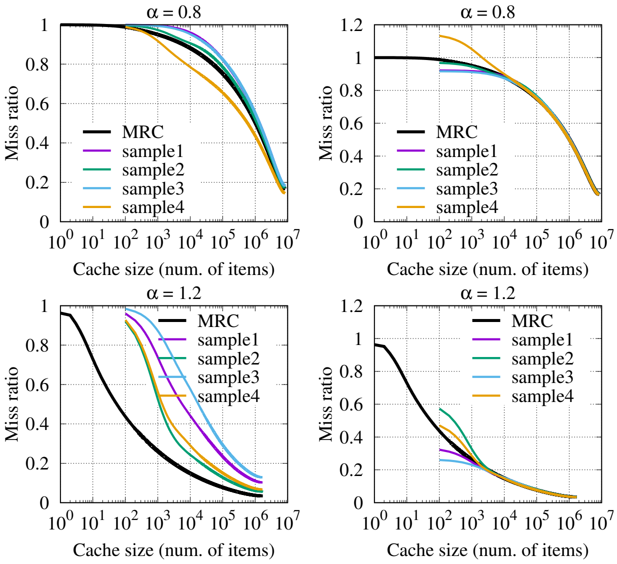

Figure 1: Approximate MRCs built from samples compared to the exact MRC for different values of the parameter α of the Zipf distribution used for item popularity ($R = 0.01$): SHARDS (left column) and SHARDS$_{\text{adj}}$ (right column).

2 Background and Related Work

The MRC can be computed with a single pass on the request trace if the eviction policy satisfies the inclusion property, *i.e.*, the set of items stored in the cache at a given time is a subset of the set of items that would be stored if the cache had a larger size [25]. Widely adopted policies such as LRU, LFU, and MRU satisfy such property, therefore MRCs are useful in many practical systems.

Methods with different computational and memory requirements have been proposed to build the MRC [6, 37]. We describe here a specific algorithm suitable when all items have the same size. The caching policies listed above all maintain an ordered list of the items in the cache, where, at any instant, the last item in the list is the current candidate to be evicted. The MRC algorithm goes through the trace, maintaining an ordered list $\mathcal{T}$ of references to the items mimicking how the corresponding caching policy would work if the cache size were infinite. Given a request for item j, if the item is not in the cache, we have a *cold miss*. If the item is in the cache, then the algorithm determines its current position (called the *reuse distance*) and updates an empirical histogram of reuse distances. Once the trace is analyzed, the histogram is normalized dividing each value by the total number of requests. By summing the histogram values up to a given capacity C, one obtains the corresponding hit ratio, whose one's complement is the miss ratio.

Exact MRC computation requires $\mathcal{O}(M)$ memory, where M is the number of distinct items in the trace, and has a computational complexity of $\mathcal{O}(\log M)$ per request due to the access to $\mathcal{T}$, which can be implemented with a tree data structure [40]. The approximate solutions based on sampling may adopt two approaches: request sampling and item sampling. The solutions based on request sampling—such as sampling every n requests [4], or sampling for small intervals of time [34]—are known to be biased [30, 39]. To overcome these issues, item sampling has been recently proposed for computing the reuse distance to characterize the use of storage memory [38] or program locality in single core [12] and multi-core architectures [30], and for building approximate MRC with low computational complexity [17, 36, 37].

In this work we consider the solution adopted by SHARDS [37]. SHARDS selects randomly a fraction R of the items, computes the MRC considering only the requests from these items, and then scales the cache capacity on the X-axis by a factor $1/R$. The item selection is done using a hash of the item identifier, id_j. Since sampling may exclude or include very popular items, the authors of SHARDS proposed an adjustment, called SHARDS$_{\text{adj}}$, in which the estimated miss ratios are scaled up by the ratio between the actual and the expected number of sampled references.

How to measure the Accuracy. In evaluating the approximate MRCs, accuracy is usually measured using the Mean Absolute Error (MAE): this is the average of the absolute differences between the exact and the approximate MRC for all cache sizes considered. Such a metric is easy to interpret, but it gives the same importance to all different values of cache size. The following simple example illustrates a potential problem. Figure 2 shows the exact and approximate MRC obtained with SHARDS for a publicly available trace which we name *ms-ex*—trace details in Section 5.3. In the figure on the left, the two curves look similar and indeed the MAE is only 0.025, *i.e.*, if we pick an arbitrary value of the cache size, on average the approximate MRC allow us to estimate the miss rate with an error of ±2.5%. The figure on the right contains the same information but using a log scale for the X-axis. It appears that the average error is not representative. In fact, the error for small cache sizes can be 5-6 times bigger.

In this paper we introduce a *new metric*—MAEQ, Mean Absolute Error per Quantile—that maintains the simplicity of MAE, but it takes into account how much the MRC varies in the different intervals. While the MAE provides the average error for a cache size sampled uniformly at random, the MAEQ provides the average error when a *miss ratio* is sampled uniformly at random. In particular, the metric is based on the concept of *quantiles*. We consider different uniformly spaced quantiles for the miss ratio and identify the corresponding cache size intervals. For instance, if we consider the quantiles at 0.8, 0.6, 0.4, and 0.2 in Figure 2, right, we identify the following intervals for cache sizes: The first interval goes from 0 to 50, the second one from 50 to 10^5, the third from 10^5 to $8 \cdot 10^5$, and the fourth one from $8 \cdot 10^5$ till the end. Note that no portion of the MRC falls below 0.2, so the last quantile is not considered. Once we have identified the ranges that correspond to the quantiles, we compute the MAE in each range, and then we average the MAE. More formally, $MAEQ = \sum_{i=1}^{Q^*} MAE_i/Q^*$, where the interval i is defined by the quantile, and Q^* is the number of quantile intervals considered. In practice, we consider quantiles with a step increment of 0.01: for each variation of 0.01 in the miss ratio, we compute the MAE, and then we take the average of the MAEs. If we compute the MAEQ for the above trace, we obtain 0.090, which provides a better idea of the accuracy of the approximate MRC, when we look at different miss ratio ranges.

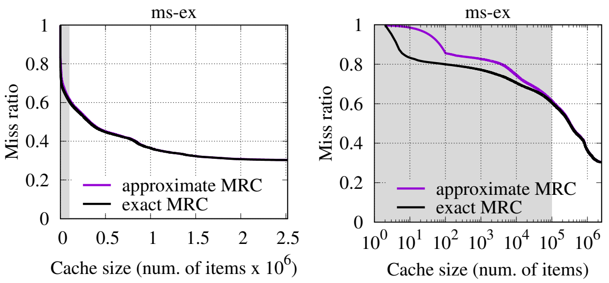

Figure 2: Error between approximate and exact MRCs (without and with log scale in the X-axis). The shaded area highlights the portion where the approximate and exact MRCs differ the most.

3 Evaluation of Spatial Sampling Approaches

3.1 Evaluation Methodology and Settings

In this section we evaluate the impact of content popularity heterogeneity on the accuracy of the approximate MRC. We consider the SHARDS and SHARDS$_{\text{adj}}$ approaches [37] with a fixed sampling rate, denoted by R, which varies from 0.1 to 0.001. In order to have highly controllable experiments, we first consider a set of traces generated according to the Independent Reference Model (IRM), in which the probability that the next request for item i is constant over time and independent from the previous requests. We call this probability the *popularity* of content i and denote it as p_i. In particular, we use the Zipf popularity distribution ($p_i \propto i^{-\alpha}$) with different values of the parameter α. We have tested different combinations of catalogue size and trace length; in what follows we report the representative results for the case with 50M requests for a set of 10M items and different values of the parameter α.

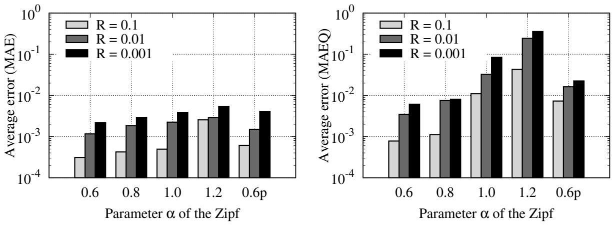

Figure 3: Accuracy for different values of the parameter α of the Zipf distribution used for item popularity, and for different sampling rates R: MAE (left) and MAEQ (right).

3.2 Results with the IRM Traces

Figure 1 shows the exact and approximate MRCs for different values of α (sampling rate $R = 0.01$). The results in left columns have been obtained using SHARDS, while the ones in the right column using SHARDS$_{\text{adj}}$. Note that, with spatial sampling, we are able to build the MRC at points that are multiples of $1/R$—this is why the approximated MRCs start at $1/R = 100$.

In case of SHARDS, as α increases, the error increases significantly. The problem is partially solved by SHARDS$_{\text{adj}}$, whose effect is to decrease the error in the tail of the MRC. This is obtained by rescaling the approximated MRC, but such a rescaling has an impact on the whole MRC, and it leads to significant errors for small cache values yielding miss ratios larger than 1. This detail was not discussed in the SHARDS work [37]. Our model in Section 3.3 explains these findings.

In Figure 3 we show SHARDS$_{\text{adj}}$ MAE and MAEQ values for different values of the sampling rate R and the Zipf parameter α—the case labeled as "0.6p" will be discussed later. Each value has been computed averaging five different samples. The MAE indicates an error smaller than 0.006, but, as we discussed above, such metric considers all cache sizes equally important. The MAEQ, instead, indicates an average error over the quantiles that, for $\alpha = 1.2$ and $R = 0.001$ may be as high as 0.35, which better describes the difference between the exact and the approximate MRC.

On the head of the MRC. The presence of a relatively small number of *highly popular items* determines the accuracy of MRCs. If we observe the empirical item popularity distribution in real-world traces—we will show some examples in Figure 9—we notice that there are often two groups of items: a small group with very popular items, and a large one with much less popular items.

Inspired by these real-world traces, we modify a Zipf distribution with $\alpha = 0.6$ by adding 20 popular items, whose popularity is randomly selected between 0.005 and 0.01. Popularities have been normalized to guarantee that their sum equals one. Figure 4, left, compares this new popularity distribution, labeled as "0.6p", with the Zipf distribution used in the previous section. Figure 4, center and right, shows approximate MRCs for a sampling rate $R = 0.01$ with SHARDS and SHARDS$_{\text{adj}}$, respectively. With the addition of a few popular items (20 out of 10M) the accuracy of the approximate MRC is significantly affected. The MAE and the MAEQ are shown in Figure 3, with the label "0.6p." This experiment confirms that, when sampling fails to capture the contribution of the popular items, the result may be heavily biased. On the other hand, less popular items have limited impact on the MRC and they may be sampled randomly.

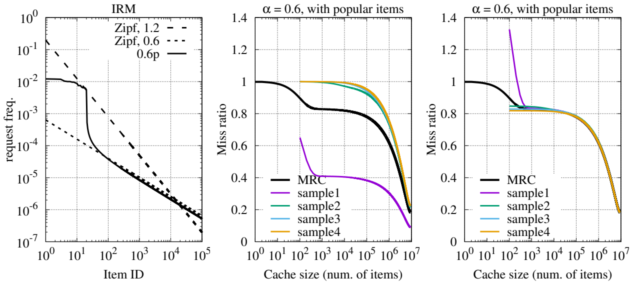

Figure 4: Distributions used for the experiments (left) and MRCs built from samples for the "0.6p" case ($R = 0.01$) through SHARDS (center) and SHARDS$_{\text{adj}}$ (right).

3.3 Understanding the role of popular items

We analyze a *simple scenario* for which we can derive an approximate model. Consider a finite set of items where there is a single very popular item (content c_1), with popularity p, and M items with approximately homogeneous popularity, *i.e.*, each item has a popularity of approximately $(1-p)/M$, and $p \gg (1-p)/M$. The request sequence is generated following the IRM model. Let r_n denote the n-th request. We consider the *reuse distance*, *i.e.*, the number of unique references between two references to the same item [40], and the *reuse time*, *i.e.*, the total number of references between two references to the same item [17].

For small cache sizes, the reuse distance can be approximated by the reuse time, *i.e.*, misses for content c_1 occur (almost) every time the reuse time for the content exceeds the cache size C.[1] The reuse distance is geometrically distributed with expected value $1/p$. Then, the miss probability for content c_1 starts decreasing significantly as the cache reaches size $1/p$, and decreases exponentially fast for bigger and bigger cache sizes. Once the cache size is 3 to 4 times larger than $1/p$, content c_1 is highly likely to be in the cache and the miss ratio is at most $1-p$. For larger cache sizes, the miss rate still decreases because of the contribution of the unpopular items. The decrease is now linear in the cache size. This reasoning can be made formal, *e.g.*, using a simple model based on the Che's approximation [11], and we obtain that the miss ratio

[1] This is an approximation because requests for other items contribute to move content c_1 closer to the tail only if they are misses. But, for small cache sizes, almost all requests for the M unpopular items generate misses.

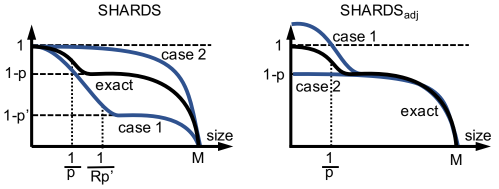

Figure 5: Simple scenario: exact MRC, along with two cases of approximate MRCs.

when the cache has capacity $C \in [0, M]$ is:

$$m(C) \approx pe^{-pC} + (1-p)\left(1 - \frac{C}{M}\right). \tag{1}$$

Figure 5 shows a sketch of what the miss ratio looks like using a logarithmic scale for the capacity axis—curve labeled "exact."

Now, assume we sample the items with sampling rate R. Either the set of sampled items contains the very popular content (with probability R), or it does not contain it (with probability $1-R$). In the following, we consider these two cases and show that the resulting MRCs differ significantly from the exact MRC.

Case 1: content c_1 is sampled. The sample contains requests for content c_1 and, on average, $M' = RM$ unpopular items. The fraction of requests for content c_1 is $p' = p/(p+(1-p)R) > p$. The exact MRC of the sampled trace is determined by (1) with M' and p' replacing respectively M and p. For the approximate MRC, we replace C with RC and we obtain:

$$m(C) \approx p'e^{-p'RC} + (1-p')\left(1 - \frac{C}{M}\right). \tag{2}$$

The curve labeled "case 1" in Figure 5, left, corresponds to (2). We observe a fast decrease of the miss ratio for cache sizes around $1/(p'R)$ from 1 to $1-p' < 1-p$. Then, the approximate MRC underestimates the miss ratio at least for large values of the cache size.

Case 2: content c_1 is not sampled. In this case there are on average $M' = RM$ equally popular items in the cache, then the miss ratio is

$$m(C) \approx 1 - \frac{C}{M}, \tag{3}$$

and is represented by the curve labeled "case 2" in Figure 5, left.

Adjustment proposed in SHARDS$_{\text{adj}}$. SHARDS$_{\text{adj}}$ rescales the estimated MRC by a factor $N_S/(RN)$, where N_S is the number of requests observed in the sample. For *Case 1*, we have $N_S = pN + RN(1-p)$, and we obtain

$$m_{\text{adj}}(C) \approx \frac{p}{R}e^{-p'RC} + (1-p)\left(1 - \frac{C}{M}\right). \tag{4}$$

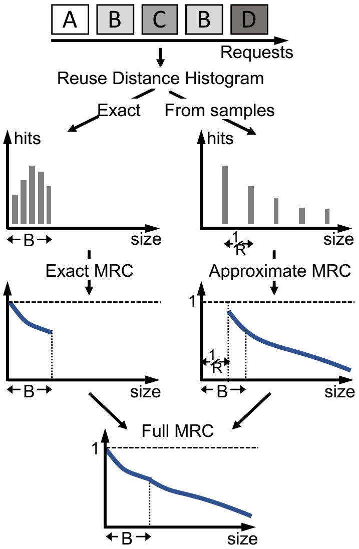

Figure 6: Approximate MRC building process.

We observe then how SHARDS$_{\text{adj}}$ removes the bias for large capacity values but amplifies it for small ones, leading to a miss ration greater than 1 in this example ($m_{\text{adj}}(0^+) \approx p/R + (1-p) > 1$). Similarly, for *Case 2*, we obtain

$$m_{\text{adj}}(C) \approx (1-p)\left(1 - \frac{C}{M}\right). \tag{5}$$

SHARDS$_{\text{adj}}$ correctly predicts the tail of the MRC, as for *Case 1*, but it now underestimates the head. Figure 5, right, shows the curves that corresponds to *Case 1* and *Case 2* when using SHARDS$_{\text{adj}}$.

4 Proposed solution

In the previous section we observed that popular and less popular items have different impacts on the MRC building process. These observations motivate our solution. We design a scheme, where we combine an exact MRC for small cache sizes (where the miss ratio depends mostly on the highly popular items), with an approximate MRC built from sampled items for large cache sizes. In particular, for the approximate MRC we use SHARDS$_{\text{adj}}$, because it predicts the MRC tail better. The approach is qualitatively illustrated in Figure 6. For the portion of the MRC built from samples, the general scheme can adopt either a *constant sampling rate* or an adaptive sampling rate to achieve *constant computational complexity*. We discuss these two schemes below.

Constant Sampling Rate Scheme. Algorithm 1 describes the solution we propose. We assume the use of the LRU eviction policy, but the scheme may be adapted easily to any policy that satisfies the inclusion property. The algorithm requires two parameters: B, which is the number of items for

Algorithm 1: Approximate MRC building process

```
input : $B$, number of positions for the exact MRC
input : $R_s$, sampling rate for the approximate MRC
input : request sequence
$\mathcal{T}_e \leftarrow$ countingBTree(); $V_e \leftarrow$ reuseVector();
$\mathcal{T}_s \leftarrow$ countingBTree(); $V_s \leftarrow$ reuseVector();
foreach request $r$ for item with id $j$ do
    if $(j \in \mathcal{T}_e)$ then
        $\text{pos}_j \leftarrow \text{remove}(j, \mathcal{T}_e)$;
        update $V_e$ at $\text{pos}_j$;
    add $j$ to $\mathcal{T}_e$;
    if $(size(\mathcal{T}_e) > B)$ then
        remove last item from $\mathcal{T}_e$;
    if $(hash(j) \bmod P < R_s P)$ then
        // sampled item
        if $j \in \mathcal{T}_s$ then
            $\text{pos}_j \leftarrow \text{remove}(j, \mathcal{T}_s)$;
            update $V_s$ at $\text{pos}_j$;
        add $j$ to $\mathcal{T}_s$;
MRC$[0..B] \leftarrow$ buildExactMRC$(V_e)$;
MRC$[B..\infty] \leftarrow$ buildApproxMRC$(V_s)$;
```

the exact MRC, and R_s, which is the sampling rate. Given a set of requests for an unknown catalogue of items, we maintain two tree data structures respectively to build the exact MRC ($\mathcal{T}_e$), and the approximate one ($\mathcal{T}_s$). $\mathcal{T}_e$ size equals B item references, while $\mathcal{T}_s$ depends on the number of items in the trace and the sampling rate. *Splay Trees* or *Counting BTrees* are possible candidates for such data structures, since they have logarithmic complexity for the insert/delete operations. Instead, for the lookup we maintain a hash table.

Once the trace is processed, we build the exact MRC ($m_e(C)$) and the approximate one ($m_s(C)$). We then connect by continuity the approximate MRC starting from B, and modulating exponentially any potential step discontinuity (equal to $m_e(B) - m_s(B)$), i.e.

$$m(C) = \begin{cases} m_e(C) & \text{if } C \leq B, \\ m_s(C) + (m_e(B) - m_s(B))e^{-\frac{C-B}{4B}} & \text{if } C > B. \end{cases}$$

Notice that, if we set $B = 0$, we obtain SHARDS$_{\text{adj}}$ scheme with constant sampling rate.

As for the parameters B and R_s, we provide a sensitivity analysis in Section 5, while we discuss the general guidelines for setting them in Section 6. Here we anticipate that in our experiments no particular tuning was required.

As for R_s, the considerations made by Waldspurger *et al.* [37] are valid also in our case. As for B, in our experiments we notice that, even for traces with millions of items, only few hundreds have very high popularity, and a value of B as low as 10^3 item references provides very accurate results. For the same trace, if we use $R_s = 0.01$, the memory necessary to hold the references to the sampled items is of the order of 10^4 item references, and $B = 10^3$ adds only a small fraction to that memory consumption.

The proposed scheme has a complexity $\mathcal{O}(\log R_s M)$, where M is the number of distinct items in the trace, which is due to accesses to $\mathcal{T}_s$. As for $\mathcal{T}_e$, since its size is constant (B item references), the cost for the data structure operations is $\mathcal{O}(1)$.

Constant Complexity Scheme. A fixed sampling rate has computational complexity and memory requirements that depend on the number of sampled items, which may grow as we consider longer and longer traces. Waldspurger *et al.* [37] propose an adaptive sampling method to maintain a $\mathcal{O}(1)$ complexity per requests. This can be achieved by fixing a priori the number $s_{\max}$ of items to sample, and then tracking the $s_{\max}$ items with smallest values of the hash function. As more requests are processed, the sampling rate implicitly converges to the minimum value required to maintain $s_{\max}$ references. Our mixed approach can be easily adapted in this direction, by fixing the size of $\mathcal{T}_s$.

5 Evaluation

5.1 Experimental Methodology

We compare our solution with the state-of-the-art approaches based on spatial sampling [37] [36], both when the sampling rate is fixed, and when the complexity is constant. If not otherwise stated, we consider the SHARDS$_{\text{adj}}$ variant

In case of fixed sampling rate, SHARDS$_{\text{adj}}$ adopts a sampling rate R. Given a trace with M distinct items, the scheme keeps track of RM items. For a fair comparison with our scheme, we adopt a sampling rate R_s that leads to keep track of the same number of item references, i.e., $B + R_s M = RM$. If not otherwise stated, we set $B = 1000$ and $R_s = R - B/M$. In most of our experiments, M is of the order of few millions, so with $R = 0.01$, R_s is slightly smaller than R. In Section 5.2 we will show the impact of B on the accuracy.

In case of constant complexity, SHARDS$_{\text{adj}}$ fixes the number of operations by maintaining a constant number of item references $s_{\max}$. This means that the scheme requires $2\log(s_{\max})$ operations per request (where the factor 2 is due to the additional data structure to track the $s_{\max}$ items with smallest hash). In our case, there is an additional cost of $\log B$ due to the exact portion of the MRC, so, to make a fair comparison, we set the size of $\mathcal{T}_s$ to a value of $s'_{\max}$ such that $\log B + 2\log(s'_{\max}) = 2\log(s_{\max})$, *i.e.*, $s'_{\max} = s_{\max}/\sqrt{B}$.

In the following sections, we will report simply R or $s_{\max}$ used for SHARDS$_{\text{adj}}$ [37]. The corresponding parameters of our scheme are computed as explained above.

5.2 IRM traces

We start testing our solution with the IRM traces described in Section 3. We focus on the two more problematic popularity

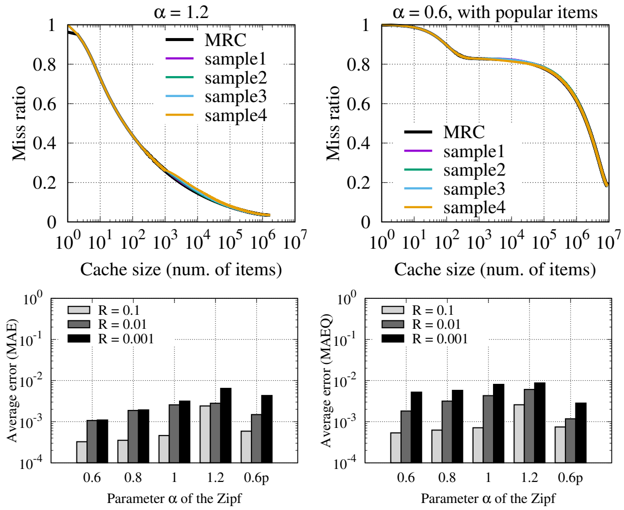

Figure 7: MRCs built from samples with our approach (top) and accuracy (MAE bottom left, MAEQ bottom right).

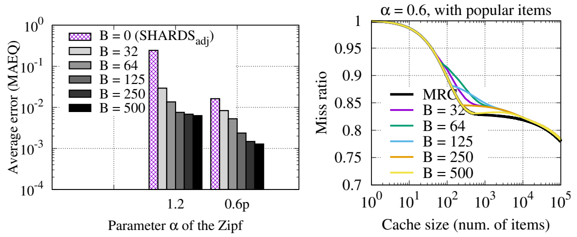

Figure 8: Accuracy for different values of B ($R = 0.01$), and the corresponding MRC ($\alpha = 0.6p$, zoom on the head of the MRC).

distributions: the Zipf one with $\alpha = 1.2$, and the Zipf one with $\alpha = 0.6$ modified by introducing 20 very popular items, labeled as "0.6p." Figure 7 shows the approximate MRC, along with the MAE and MAEQ. Our solution is able to build approximate MRCs using the same amount of memory as SHARDS$_{\text{adj}}$. The average error per quantile reaches at most 0.008 in case of an equivalent sampling rate as low as $R = 0.001$—the corresponding value of R_s is 0.0004 for $\alpha = 1.2$ and 0.0008 for the "0.6p" case. With SHARDS$_{\text{adj}}$, instead, the error with $R = 0.001$ was more than 40 times larger (0.35) for $\alpha = 1.2$ (Figure 3, right). For most of the settings, our solution also slightly improves the MAE, being equal only for $\alpha = 1.2$ and $R = 0.001$.

Impact of B. The proposed scheme has a parameter B, which is the maximum cache size considered for the exact MRC. Recall that, if $B = 0$, we obtain SHARDS$_{\text{adj}}$'s results. Figure 8, left, shows the impact of the accuracy for different values of B. We consider the default case with $R = 0.01$. Since the ratio B/M is less than 10^{-3}, then the equivalent R_s is approximately 0.01 too.

As we increase B, there is a significant error reduction. The reason can be seen looking at the approximate MRC, which is shown in Figure 8, right. Since we have a sampling rate $R_s \approx R = 0.01$, only one of the 100 most popular items, on average, is sampled, so the approximate MRC is very inaccurate in the range $[1, 100]$. As our algorithm uses the approximate sample-based MRC starting from $B + 1$, as long as B is smaller than 100 (*i.e.*, $1/R_s$), the error of the approximate MRC also affects the final MRC.

Table 1: Trace characteristics

name	year	# items	# req	reference
fiu	2008	6.1 M	14.3 M	[22]
ms-ex	2007	2.6 M	8.9 M	[18]
ms-dev	2007	6.3 M	18.2 M	[18]
systor	2016	12.7 M	34.3 M	[23]
CDN	2015	1.6 M	11.2 M	[8]

5.3 Real-world traces

We consider a set of publicly-available block I/O traces from SNIA IOTTA repository [31], along with traces from Akamai, a major CDN provider. Table 1 summarizes the characteristics of the traces. From the SNIA IOTTA repository, we have considered the most recent trace—labeled as *systor* [23]—along with older traces collected at FIU [22] and at Microsoft [18].

For experimental reproducibility, we report here the details of the traces. For the *fiu* traces [22], we consider the subtrace IODedup/Web. The *ms-ex* is the trace named "Microsoft Enterprise Traces, Exchange Server Traces" [18], which have been collected for Exchange server for a duration of 24-hours—we consider the first 3.5 hours. The *ms-dev* is the trace named "Microsoft Production Server Traces - Development Tools Release" [18]. The *systor* traces [23] collect requests for different block storage devices over 28 days: we consider one day (March, 9th) of the device called "LUN2." Finally, the *CDN* trace [8] contains multiple days of traffic, of which we consider portions of 6 hours—we tested different intervals finding similar qualitative results.

Request distribution. Figure 9 shows the empirical popularity distribution for two representative traces (*systor* and *CDN*), since the others are similar. The distributions show the presence of two distinct groups of items: a head with highly popular items, and a power-law tail—the figure shows the exponent α of the fitting power law distribution.

Approximate MRC with Constant Sampling Rate. Figure 10 shows the comparison between the exact MRC and the ones obtained with SHARDS$_{\text{adj}}$ (left column) and with our approach (right column) for some representative traces. In all cases we consider $R = 0.01$ and $B = 1000$. We have also computed the MAEQ (bottom subfigure).

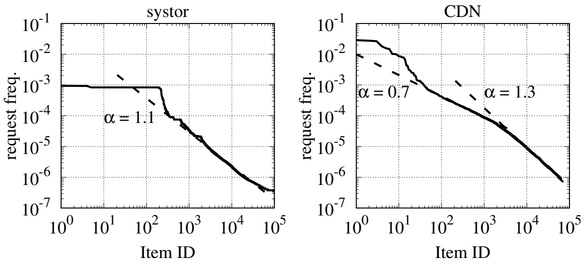

Figure 9: Item popularity distribution of the traces.

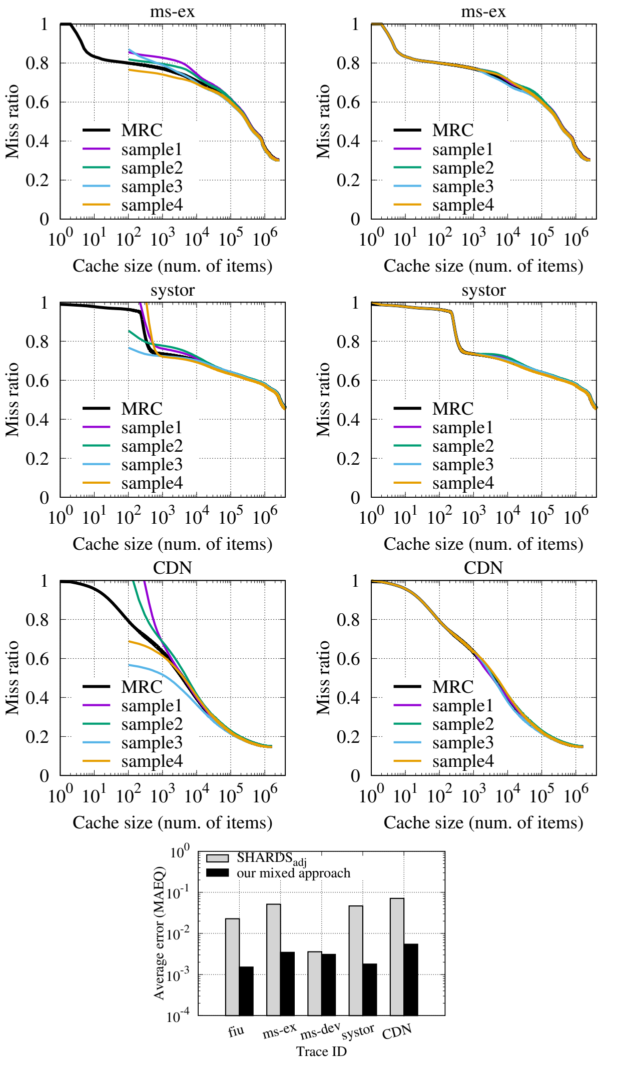

Figure 10: MRCs built from samples with $\text{SHARDS}_{\text{adj}}$ (left) and our approach (right). Bottom: MAEQ.

Except for the *ms-dev* trace, $\text{SHARDS}_{\text{adj}}$ fails to build an accurate MRC, with MAEQ in the range 0.05–0.10. With our approach, instead, the MAEQ is always below 0.01, and the accuracy can be appreciated visually comparing the approximate and exact MRCs. The *ms-dev* trace is representative of the case in which $\text{SHARDS}_{\text{adj}}$ provides good accuracy: our approach is able to provide equally accurate results.

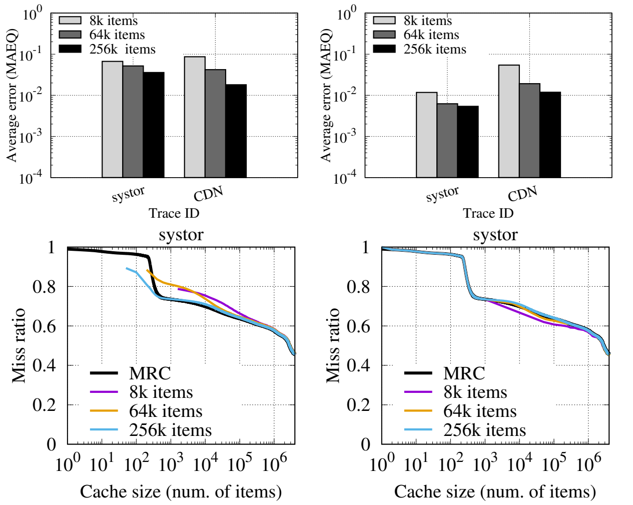

Figure 11: Top: Accuracy (MAEQ) for constant complexity with $\text{SHARDS}_{\text{adj}}$ (left) and our approach (right). Bottom: MRC of a representative trace, with $\text{SHARDS}_{\text{adj}}$ (left) and our approach (right).

Approximate MRC with Constant Complexity. We recall (Section 4) that a constant complexity per request is achieved by putting a cap on the number of sampled items s'_{max}, and then to the total memory used ($B + s'_{\text{max}}$). Figure 11 (top) shows the MAEQ with $\text{SHARDS}_{\text{adj}}$ and with our approach for different memory sizes—if not otherwise stated $B = 1000$. Figure 11 (bottom) shows the MRC. As the number of items increases, the head of the approximate MRC with $\text{SHARDS}_{\text{adj}}$ converges to the exact shape. With our approach, the MAEQ is smaller, because the first B positions are always correct.

Overheads. The experimental campaign has been specifically designed to compare our scheme and $\text{SHARDS}_{\text{adj}}$, and the memory used in both scenarios—constant sampling rate and constant complexity—as described in Section 5.1. We have evaluated the CPU usage using user and system time components as reported by `/usr/bin/time`. Our experiments confirm that $\text{SHARDS}_{\text{adj}}$ has a 75x speed up compared to the exact MRC computation [37]. Our scheme performs slightly worse with CPU usage on average 10%, and at most 20%, higher than $\text{SHARDS}_{\text{adj}}$. While the asymptotic computational complexity of the two schemes is the same, ours requires indeed a few more operations per request. Under $\text{SHARDS}_{\text{adj}}$, at each request, we need to compute the hash of the item identifier. With our scheme, in addition to this, we need to insert the item at the head of the tree data structure that keeps track of the first B positions (in case of a hit we first need to remove the item, but this does not happen at every request). The fact that CPU load only increases by 10% suggests that the overhead due to the additional insertion/deletion operations appears negligible in comparison to the hash computation cost. On a consumer laptop, our solution processed the traces in Table 1 (which span multiple hours) in less than 30s. It can the be used, not only offline on collected traces, but also online, as requests arrive. In the latter case, one may select a duration for the observation interval, e.g., one hour or less, and the MRC is computed at the end of the interval.

6 Discussion

Parameter configuration. In Section 5 we have presented a sensitivity analysis with respect to the parameter B, the sampling rate R_s (in case of constant sampling rate), and the maximum number of item references $B + s'_{\max}$ (in case of constant complexity). The choice of these parameters determines the amount of memory that will be used for the approximate MRC computation. Given the memory budget and using some simple characteristics of the trace, such as the number of items or the number of requests (which can also be estimated in an online setting), it is possible to estimate the maximum values for B and R_s.

We have already shown that, due to the specific way in which the final MRC is built, one should adopt a value $B \geq 1/R_s$ to avoid connecting the two MRCs at a point where the sampled one is very imprecise. Additional constraints, due to the specific context in which the MRCs are used, can drive the exact setting. For instance, if the cache needs to be split across different application types, their number and the total amount of storage available further limits B.

Extension to "non-stack" algorithms. The MRC construction technique in case of eviction policies that do not satisfy the inclusion property is different, *i.e.*, one needs to compute the miss ratios for different cache sizes in parallel, and then join the results. Waldspurger *et al.* [36] propose a general method where the miss ratio for cache size C is obtained simulating a cache with size RC with a request trace sampled with rate R. In their experiments they use the same scaling factor R for all the sizes, but our findings suggest that one wants to *differentiate* the sampling rate used, adopting a high (resp. low) sampling rate for small (resp. large) caches. The higher sampling rate for the small caches would be compensated by the smaller sampling rate used at large ones, so overall the memory requirement and the computational complexity could be maintained similar to the case with constant sampling rate.

Heterogeneous item size. Most of the work about MRC consider items with uniform sizes. In contrast, there are different scenarios, such as Web caches, where items have *heterogeneous sizes*. In this case, the MRC should inform the miss rate obtained for a given size of the cache in *bytes*, rather than in number of items. In order to build such a MRC, we need to modify the data structure used to keep track of the items in the cache as explained in Carra *et al.* [8].

Figure 12 (left) shows the exact and approximate MRC with SHARDS$_{\text{adj}}$ for the *CDN* trace. Notice that the X-axis now reports the cache size in MB. Figure 12 (right) shows the results with our approach. By combining the exact MRC with the one built from the samples, we are able to build a more accurate MRC using the same amount of memory as used by SHARDS$_{\text{adj}}$. The results are confirmed by the MAEQ, for which we obtain an average value of 0.007—almost one order of magnitude smaller than SHARDS$_{\text{adj}}$'s value (0.052).

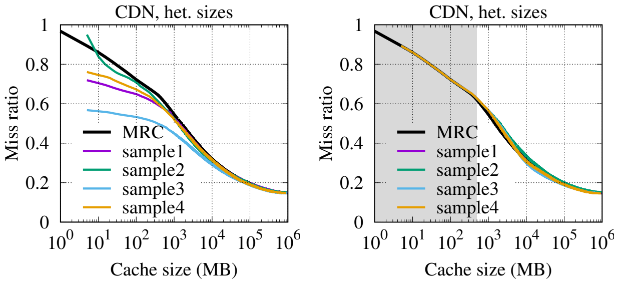

Figure 12: MRCs built from samples with SHARDS$_{\text{adj}}$ (left) and our approach (right—the shaded area corresponds to the portion of the exact MRC).

7 Conclusions

Sampling has been applied to calculate approximate MRCs with limited computational complexity. The use of such a technique requires a careful design in order to avoid the introduction of biases in the MRC construction. In this work, using a set of experiments and a model of a representative scenario, we studied the impact of popular items on the accuracy of the MRC, and we proposed a new approach that uses exact MRC calculation for small cache sizes while relying on sampling for large ones. The results using different real-world traces show that our solution is able to build approximate MRC with an error per quantile one order of magnitude smaller than state-of-the-art approaches, such as SHARDS$_{\text{adj}}$. As a future work, we plan to study how the parameters of our scheme should be set online depending on the characteristics of the request stream.

Acknowledgments

We would like to thank Pietro Michiardi for the initial discussions on this work, and for the computational resources kindly provided for part of the experiments. We thank the anonymous reviewers and our shepherd, Raju Rangaswami, for their constructive feedback. This work was partially supported by the Italian National Group for Scientific Computation (GNCS-INDAM) and by "Progetto di Eccellenza" of the Computer Science Dept., Univ. of Verona, Italy.

Can Applications Recover from `fsync` Failures?

Computer Sciences Department, University of Wisconsin – Madison

Abstract

We analyze how file systems and modern data-intensive applications react to fsync failures. First, we characterize how three Linux file systems (ext4, XFS, Btrfs) behave in the presence of failures. We find commonalities across file systems (pages are always marked clean, certain block writes always lead to unavailability), as well as differences (page content and failure reporting is varied). Next, we study how five widely used applications (PostgreSQL, LMDB, LevelDB, SQLite, Redis) handle fsync failures. Our findings show that although applications use many failure-handling strategies, none are sufficient: fsync failures can cause catastrophic outcomes such as data loss and corruption. Our findings have strong implications for the design of file systems and applications that intend to provide strong durability guarantees.

1 Introduction

Applications that care about data must care about how data is written to stable storage. Issuing a series of write system calls is insufficient. A write call only transfers data from application memory into the operating system; the OS usually writes this data to disk lazily, improving performance via batching, scheduling, and other techniques [25,44,52,53].

To update persistent data correctly in the presence of failures, the order and timing of flushes to stable storage must be controlled by the application. Such control is usually made available to applications in the form of calls to fsync [9,47], which forces unwritten ("dirty") data to disk before returning control to the application. Most update protocols, such as write-ahead logging or copy-on-write, rely on forcing data to disk in particular orders for correctness [30,31,35,38,46,56].

Unfortunately, recent work has shown that the behavior of fsync during failure events is ill-defined [55] and error prone. Some systems, for example, mark the relevant pages clean upon fsync failure, even though the dirty pages have not yet been written properly to disk. Simple application responses, such as retrying the failed fsync, will not work as expected, leading to potential data corruption or loss.

In this paper, we ask and answer two questions related to this critical problem. The first question (§3) relates to the file system itself: why does fsync sometimes fail, and what is the effect on file-system state after the failure event?

To answer this first question, we run carefully-crafted micro-workloads on important and popular Linux file systems (ext4 [43], XFS [54], Btrfs [50]) and inject targeted block failures in the I/O stream. We then use a combination of tools to examine the results. Our findings show commonalities across file systems as well as differences. For example, all three file systems mark pages clean after fsync fails, rendering techniques such as application-level retry ineffective. However, the content in said clean pages varies depending on the file system; ext4 and XFS contain the latest copy in memory while Btrfs reverts to the previous consistent state. Failure reporting is varied across file systems; for example, ext4 data mode does not report an fsync failure immediately in some cases, instead (oddly) failing the subsequent call. Failed updates to some structures (e.g., journal blocks) during fsync reliably lead to file-system unavailability. And finally, other potentially useful behaviors are missing; for example, none of the file systems alert the user to run a file-system checker after the failure.

The second question we ask is (§4): how do important data-intensive applications react to fsync failures? To answer this question, we build CuttleFS, a FUSE file system that can emulate different file system fsync failures. CuttleFS maintains its own page cache in user-space memory, separate from the kernel page cache, allowing application developers to perform durability tests against characteristics of different file systems, without interference from the underlying file system and kernel.

With this test infrastructure, we examine the behavior of five widely-used data-management applications: Redis [18], LMDB [15], LevelDB [12], SQLite [20] (in both RollBack [1] and WAL modes [21]), and PostgreSQL [15] (in default and DirectIO modes). Our findings, once again, contain both specifics per system, as well as general results true across some or all. Some applications (Redis) are surprisingly careless with fsync, not even checking its return code before returning success to the application-level update; the result is a database with old, corrupt, or missing keys. Other applications (LMDB) exhibit false-failure reporting, returning an error to users even though on-disk state is correct. Many applications (Redis, LMDB, LevelDB, SQLite) exhibit data corruptions; for example, SQLite fails to write data to its rollback journal and corrupts in-memory state by reading from said journal when a transaction needs to be rolled back. While corruptions can cause some applications to reject newly inserted records (Redis, LevelDB, SQLite), both new and old data can be lost on updates (PostgreSQL). Finally, applications (LevelDB, SQLite, PostgreSQL) sometimes seemingly work correctly as long as the relevant data remains in the file-system cache; when said data is purged from the cache (due to cache pressure or OS restart), however, the application then returns stale data (as retrieved from disk).

We also draw high-level conclusions that take both file-system and application behavior into account. We find that applications expect file systems on an OS platform (e.g., Linux) to behave similarly, and yet file systems exhibit nuanced and important differences. We also find that applications employ numerous different techniques for handling fsync failures, and yet none are (as of today) sufficient; even after the PostgreSQL fsync problem was reported [55], no application yet handles its failure perfectly. We also determine that application recovery techniques often rely upon the file-system page cache, which does not reflect the persistent state of the system and can lead to data loss or corruption; applications should ensure recovery protocols only use existing persistent (on-disk) state to recover. Finally, in comparing ext4 and XFS (journaling file systems) with Btrfs (copy-on-write file system), we find that the copy-on-write strategy seems to be more robust against corruptions, reverting to older states when needed.

The rest of this paper is organized as follows. First, we motivate why this study is necessary (§2), followed by a file-system study (§3). Next, we study how applications react to fsync failures (§4). We then discuss the implications of our findings (§5), discuss related work (§6), and conclude (§7).

2 Motivation

Applications that manage data must ensure that they can handle and recover from any fault that occurs in the storage stack. Recently, a PostgreSQL user encountered data corruption after a storage error and PostgreSQL played a part in that corruption [17]. Because of the importance and complexity of this error, we describe the situation in detail.

PostgreSQL is an RDBMS that stores tables in separate files and uses a write-ahead log *(wal)* to ensure data integrity [16]. On a transaction commit, the entry is written to the log and the user is notified of the success. To ensure that the log does not grow too large (as it increases startup time to replay all entries in the log), PostgreSQL periodically runs a checkpoint operation to flush all changes from the log to the different files on disk. After an fsync is called on each of the files, and PostgreSQL is notified that everything was persisted successfully, the log is truncated.

Of course, operations on persistent storage do not always complete successfully. Storage devices can exhibit many different types of partial and transient failures, such as latent sector errors [27, 41, 51], corruptions [26], and misdirected writes [42]. These device faults are propagated through the file system to applications in a variety of ways [40, 49], often causing system calls such as read, write, and fsync to fail with a simple return code.

When PostgreSQL was notified that fsync failed, it retried the failed fsync. Unfortunately, the semantics for what should happen when a failed fsync is retried are not well defined. While POSIX aims to standardize behavior, it only states that outstanding IO operations are not guaranteed to have been completed in the event of failures during fsync [14]. As we shall see, on many Linux file systems, data pages that fail to be written, are simply marked clean in the page cache when fsync is called and fails. As a result, when PostgreSQL retried the fsync a second time, there were no dirty pages for the file system to write, resulting in the second fsync succeeding without actually writing data to disk. PostgreSQL assumed that the second fsync persisted data and continued to truncate the write-ahead log, thereby losing data. PostgreSQL had been using fsync incorrectly for 20 years [55].

After identifying this intricate problem, developers changed PostgreSQL to respond to the fsync error by crashing and restarting without retrying the fsync. Thus, on restart, PostgreSQL rebuilds state by reading from the *wal* and retrying the entire checkpoint process. The hope and intention is that this crash and restart approach will not lose data. Many other applications like WiredTiger/MongoDB [24] and MySQL [3] followed suit in fixing their fsync retry logic.

This experience leads us to ask a number of questions. As application developers are not certain about the underlying file-system state on fsync failure, the first part of our study answers what happens when fsync fails. How do file systems behave after they report that an fsync has failed? Do different Linux file systems behave in the same way? What can application developers assume about the state of their data after an fsync fails? Thus, we perform an in-depth study into the fsync operation for multiple file systems.

The second part of our study looks at how data-intensive applications react to fsync failures. Does the PostgreSQL solution indeed work under all circumstances and on all file systems? How do other data-intensive applications react to fsync failures? For example, do they retry a failed fsync, avoid relying on the page cache, crash and restart, or employ a different failure-handling technique? Overall, how well do applications handle fsync failures across diverse file systems?

3 File System Study

Our first study explores how file systems behave after reporting that an fsync call has failed. After giving a brief background of caching in file systems, we describe our methodology and our findings for the three Linux file systems.

3.1 Background

File systems provide applications with open, read, and write system calls to interact with the underlying storage media. Since block devices such as hard disks and solid state drives are much slower than main memory [57], the operating system maintains a page cache of frequently used pages of files in kernel space in main memory.

When an application calls read, the kernel first checks if the data is in the page cache. If not, the file system retrieves the data from the underlying storage device and stores it in the page cache. When an application calls write, the kernel only *dirties* the page in memory while notifying the application that the write succeeded; there is now a mismatch between the data in memory and on the device and data can potentially be lost. For durability, the file system periodically synchronizes content between memory and disk by *flushing* dirty pages and marking them clean. Applications that require stronger durability guarantees can force the dirty pages to disk using the fsync system call.

Applications can choose to bypass the page cache altogether by opening files with *O_DIRECT* (DirectIO). For caching, applications must perform their own in user space. Calls to fsync are still required since data may be cached within the underlying storage media; an fsync issues a FLUSH command to the underlying device so it pushes data all the way to stable storage.

3.2 Methodology

To understand how file systems should behave after reporting an fsync failure, we begin with the available documentation. The fsync man pages [9] report that fsync may fail for many reasons: the underlying storage medium has insufficient space (*ENOSPC* or *EDQUOT*), the file descriptor is not valid (*EBADF*), or the file descriptor is bound to a file that does not support synchronization (*EINVAL*). Since these errors can be discovered by validating input and metadata before initiating write operations, we do not investigate them further.

We focus on errors that are encountered only after the file system starts synchronizing dirty pages to disk; in this case, fsync signals an *EIO* error. *EIO* errors are difficult to handle because the file system may have already begun an operation (or changed state) that it may or may not be able to revert.

To trigger *EIO* errors, we consider single, transient, write faults in line with the fail-partial failure model [48,49]. When the file system sends a write request to the storage device, we inject a fault for a single sector or block within the request. Specifically, we build a kernel module device-mapper target that intercepts block-device requests from the file system and fails a particular write request to a particular sector or block while letting all other requests succeed; this allows us to observe the impact on an unmodified file system.

3.2.1 Workloads

To exercise the fsync path, we create two simple workloads that are representative of common write patterns seen in data-intensive applications.

Single Block Update (w_{su}): open an existing file containing three pages (12KB) and modify the middle page. This workload resembles many applications that modify the contents of existing files: LMDB always modifies the first two metadata pages of its database file; PostgreSQL stores tables as files on disk and modifies them in-place. Specifically, w_{su} issues system calls in the following sequence: open, lseek(4K), write(4K), *fsync*, *fsync*, sleep(40), close. The first fsync forces the dirty page to disk. While one fsync is sufficient in the absence of failures, we are interested in the impact of fsync retries after a failure; therefore, w_{su} includes a second fsync. Finally, since ext4, XFS, and Btrfs write out metadata and checkpoint the journal periodically, w_{su} includes a sleep for 40 seconds.

Multi Block Append (w_{ma}): open a file in append mode and write a page followed by an fsync; writing and fsyncing is repeated after sleeping. This workload resembles many applications that periodically write to a log file: Redis writes every operation that modifies its in-memory data structures to an append only file; LevelDB, PostgreSQL, and SQLite write to a write-ahead-log and fsync the file after the write. w_{ma} repeats these operations after a delay to allow checkpointing to occur; this is realistic as clients do not always write continuously and checkpointing may occur in those gaps. Specifically, w_{ma} issues system calls in the following sequence: open (in append mode), write(4K), *fsync*, sleep(40), write(4K), *fsync*, sleep(40), close.

3.2.2 Experiment Overview

We run the workloads on three different file systems: ext4, XFS, and Btrfs, with default mkfs and mount options. We evaluate both ext4 with metadata ordered journaling (data=ordered) and full data journaling (data=journal). We use an Ubuntu OS with Linux kernel version 5.2.11.

For each file system and workload, we first trace the block write access pattern. We then repeat the workload multiple times, each time configuring the fault injector to fail the i^{th} write access to a given sector or block. We only fail a single block or sector within the block in each iteration. We use a combination of offline tools (debugfs and xfs_db) and documentation to map each block to its respective file system data structure. We use SystemTap [22] to examine the state of relevant buffer heads and pages associated with data or metadata in the file system.

3.2.3 Behavior Inference

We answer the following questions for each file system:

Basics of fsync Failures:

Q1 Which block (data, metadata, journal) failures lead to fsync failures?

Q2 Is metadata persisted if a data block fails?

Q3 Does the file system retry failed block writes?

Q4 Are failed data blocks marked clean or dirty in memory?

Q5 Does in-memory page content match what is on disk?

Failure Reporting:

Q6 Which future fsync will report a write failure?

Q7 Is a write failure logged in the syslog?

After Effects of fsync Failure:

Q8 Which block failures lead to file-system unavailability?

Q9 How does unavailability manifest? Does the file system shutdown, crash, or remount in read-only mode?

Q10 Does the file suffer from holes or block overwrite failures? If so, in which parts of a file can they occur?[1]

Recovery:

Q11 If there is any inconsistency introduced due to fsync failure, can fsck detect and fix it?

3.3 Findings

We now describe our findings for the three file systems we have characterized: ext4, XFS, and Btrfs. Our answers to our posed questions are summarized in Table 1.

3.3.1 Ext4

The ext4 file system is a commonly-used journaling file system on Linux. The two most common options when mounting this file system are *data=ordered* and *data=journal* which enable ext4 ordered mode and ext4 data mode, respectively. Ext4 ordered mode writes metadata to the journal whereas ext4 data mode writes both data and metadata to the journal.

Ext4 ordered mode: We give an overview of ext4 ordered mode by describing how it behaves for our two representative workloads when no failures occur.

Single Block Update (w_{su}). When no fault is injected and fsync is successful, ext4 ordered mode behaves as follows. During the write (Step 1), ext4 updates the page in the page cache with the new contents and marks the page dirty. On fsync, the page is written to a data block; after the data-block write completes successfully, the metadata (i.e., the inode with a new modification time) is written to the journal, and fsync returns 0 indicating success (Step 2). After the fsync, the dirty page is marked clean and contains the newly written data. On the second fsync, as there are no dirty pages, no block writes occur, and as there are no errors, fsync returns 0 (Step 3). During sleep, the metadata in the journal is checkpointed to its final in-place block location (Step 4). No writes or changes in page state occur during the close (Step 5).

If fsync fails (i.e., returns -1 with errno set to *EIO*), a variety of write problems could have occurred. For example, the data-block write could have failed; if this happens, ext4 does not write the metadata to the journal. However, the updated page is still marked clean and contains the newly written data from Step 1, causing a discrepancy with the contents on disk. Furthermore, even though the inode table was not written to the journal at the time of the data fault, the inode table containing the updated modification time is written to the journal on the second fsync in Step 3. Steps 4 and 5 are the same as above, and thus the inode table is checkpointed.

Thus, applications that read this data block while the page remains in the page cache (i.e., the page has not been evicted and the OS has not been rebooted) will see the new contents of the data; however, when the page is no longer in memory and must be read from disk, applications will see the old contents.

Alternatively, if fsync failed, it could be because a write to one of the journal blocks failed. In this case, ext4 aborts the journal transaction and remounts the file system in read-only mode, causing all future writes to fail.

Multi Block Append (w_{ma}). This next workload exercises additional cases in the fsync error path. If there are no errors and all fsyncs are successful, the multi-block append workload on ext4 behaves as follows. First, during write, ext4 creates a new page with the new contents and marks it dirty (Step 1). On fsync, the page is written to a newly allocated on-disk data block; after the data-block write completes successfully, the relevant metadata (i.e., both the inode table and the block bitmap) are written to the journal, and fsync returns success (Step 2). As in w_{su}, the page is marked clean and contains the newly written data. During sleep, the metadata is checkpointed to disk (Step 3); specifically, the inode contains the new modification time and a link to the newly allocated block, and the block bitmap now indicates that the newly allocated block is in use. The pattern is repeated for the second write (Step 4), fsync (Step 5), and sleep (Step 6). As in w_{su}, there are no write requests or changes in page state during close (Step 7).

An fsync failure could again indicate numerous problems. First, a write to a data block could have failed in Step 2. If this is the case, the fsync fails and the page is marked clean; as in w_{su}, the page contains the newly written data, differing from the on-disk block that contains the original block contents. The inode table and block bitmap are written to disk in Step 3; thus, even though the data itself has not been written, the inode is modified to reference this block and the corresponding bit is set in the block bitmap. When the workload writes another 4KB of data in Step 4, this write continues oblivious of the previous fault and Steps 5, 6, and 7 proceed as usual.

Thus, with a data-block failure, the on-disk file contains a non-overwritten block where it was supposed to contain the data from Step 1. A similar possibility is that the write to a data block in Step 5 fails; in this case, the file has a non-overwritten block at the end instead of somewhere in the middle. Again, an application that reads any of these failed data blocks while they remain in the page cache will see the newly appended contents; however, when any of those pages are no longer in memory and must be read from disk, applications will read the original block contents.

An fsync failure could also indicate that a write to a journal-block failed. In this case, as in w_{su}, the fsync returns an error and the following write fails since ext4 has been remounted in read-only mode.

Because this workload contains an fsync after the metadata has been checkpointed in Step 3, it also illustrates the impact of faults when checkpointing the inode table and block bitmap. We find that despite the fact that a write has failed and

[1] In file-system terminology, a hole is a region in a file for which there is no block allocated. If a block is allocated but not overwritten with the new data, we consider the file to have a *non-overwritten block* and suffer from *block overwrite failure*.

		fsync Failure Basics					Error Reporting		After Effects			Recovery
		Which block failure causes fsync failure?	Is metadata persisted on data block failure?	Which block failures are retried?	Is the page dirty or clean after failure?	Does the in-memory content match disk?	Which fsync reports the failure?	Is the failure logged to syslog?	Which block failure causes unavailability?	What type of unavailability?	Holes or block overwrite failures? If yes where do they occur?	Can fsck help detect holes or block overwrite failures?
		Q1	Q2	Q3	Q4	Q5	Q6	Q7	Q8	Q9	Q10	Q11
ext4	ordered	data,jrnl	yes [A]		clean [B]	no [B]	immediate	yes	jrnl	remount-ro	NOB, anywhere [A]	no
	data	data,jrnl	yes [A]		clean [B]	no [B]	next [C]	yes	jrnl	remount-ro	NOB, anywhere [A]	no
XFS		data,jrnl	yes [A]	meta	clean [B]	no [B]	immediate	yes	jrnl,meta	shutdown	NOB, within [A]	no
Btrfs		data,jrnl	no		clean	yes	immediate	yes	jrnl,meta	remount-ro	HOLE, within [D]	yes

[A] Non-overwritten blocks (Q10) occur because metadata is persisted despite data-block failure (Q2).

[B] Marking a dirty page clean (Q4) even though the content does not match the disk (Q5) is problematic.

[C] Delayed reporting (Q6) of fsync failures may confuse application error-handling logic.

[D] Continuing to write to a file after an fsync failure is similar to writing to an offset greater than file size, causing a hole in the skipped portion (Q10).

Table 1: **Behavior of Various File Systems when fsync Fails.** *The table summarizes the behavior of the three file systems: ext4, XFS, and Btrfs according to the questions posed in Section 3.2.3. The questions are divided into four categories mentioned at the top. For questions that require identifying a block type, we use the following abbreviations: Data Block (data), Journal Block (jrnl), Metadata Block (meta). In Q9, Remount-**ro** denotes remounting in read-only mode. In Q10, "anywhere" and "within" describe the locations of the holes or non-overwritten blocks (NOB); "within" does not include the end of the file. Entries with a superscript denote a problem.*

the file system will now be in an inconsistent state, the following fsync does not return an error. However, the metadata error is logged to syslog.

We note that for none of these fsync failures does ext4 ordered mode recommend running the file system checker; furthermore, running the checker does not identify or repair any of the preceding problems. Finally, future calls to fsync never retry previous data writes that may have failed. These results for ext4 ordered mode are all summarized in Table 1.

The ext4 file system also offers functionality to abort the journal if an error occurs in a file data buffer (mount option data_err=abort) and remount the file system in read-only mode on an error (mount option errors=remount-ro). However, we observe that the results are identical with and without the mount options. [2]

Ext4 Data Mode: Ext4 data mode differs from ordered mode in that data blocks are first written to the journal and then later checkpointed to their final in-place block locations.

As shown in Table 1, the behavior of fsync in ext4 data mode is similar to that in ext4 ordered mode for most cases: for example, on a write error, pages may be marked clean even if they were not written out to disk, the file system is remounted in read-only mode on journal failures, meta-data failures are not reported by fsync, and files can end up with non-overwritten blocks in the middle or end.

However, the behavior of ext4 data mode differs in one important scenario. Because data blocks are first written to the journal and later to their actual block locations during checkpointing, the first fsync after a write may succeed even if a data block will not be successfully written to its permanent in-place location. As a result, a data-block fault causes the second fsync to fail instead of the first; in other words, the error reporting by fsync is delayed due to a *failed intention* [36].

3.3.2 XFS

XFS is a journaling file system that uses B-trees. Instead of performing physical journaling like ext4, XFS journals logical entries for changes in metadata.

As shown in Table 1, from the perspective of error reporting and fsync behavior, XFS is similar to that of ext4 ordered mode. Specifically, failing to write data blocks leads to fsync failure and the faulty data pages are marked clean even though they contain new data that has not been propagated to disk; as a result, applications that read this faulty data will see the new data only until the page has been evicted from the page cache. Similarly, failing to write a journal block will cause fsync failure, while failing to write a metadata block will not. XFS remains available for reads and writes after data-block faults.

XFS handles fsync failures in a few ways that are different than ext4 ordered mode. First, on a journal-block fault, XFS shuts down the file system entirely instead of merely remounting in read-only mode; thus, all subsequent read and write operations fail. Second, XFS retries metadata writes when it encounters a fault during checkpointing; the retry limit is determined by a value in /sys/fs/xfs/*/error/metadata/*/max_retries, but is infinite by default. If the retry limit is exceeded, XFS again shuts down the file system.

The multi-block append workload illustrates how XFS handles metadata when writes to related data blocks fail. If the write to the first data block fails, XFS writes no metadata to the journal and fails the fsync immediately. When later data blocks are successfully appended to this file, the metadata is updated which creates a non-overwritten block in the file corresponding to the first write. If instead, a write to a

[2] We verified our observations by reproducing them using standard Linux tools and have filed a bug report for the same [2].

data block contained in the last journal transaction fails, the on-disk metadata is not updated to reflect any of these last writes (i.e., the size of the file is not increased if any related blocks fail in the last transaction). [3] Thus, while in ext4 a failed write always causes a non-overwritten block, in XFS, non-overwritten blocks cannot exist at the end of a file. However, for either file system, if the failed blocks remain in the page cache, applications can read those blocks regardless of whether they are in the middle or the end of a file.

3.3.3 Btrfs

Btrfs is a copy-on-write file system that avoids writing to the same block twice except for the superblock which contains root-node information. At a high level, some of the actions in Btrfs are similar to those in a journaling file system: instead of writing to a journal, Btrfs writes to a log tree to record changes when an `fsync` is performed; instead of checkpointing to fixed in-place locations, Btrfs writes to new locations and updates the roots in its superblock. However, since Btrfs is based on copy-on-write, it has a number of interesting differences in how it handles `fsync` failures compared to ext4 and XFS, as shown in Table 1.

Like ext4 ordered mode and XFS, Btrfs fails `fsync` when it encounters data-block faults. However, unlike ext4 and XFS, Btrfs effectively reverts the contents of the data block (and any related metadata) back to its old state (and marks the page clean). Thus, if an application reads the data after this failure, it will never see the failed operation as a temporary state. As in the other file systems, Btrfs remains available after this data-block fault.

Similar to faults to the journal in the other file systems, in Btrfs, faults to the log-tree result in a failed `fsync` and a remount in read-only mode. Unlike ext4 and XFS, faults in the metadata blocks during checkpointing result in a remount in read-only mode (but `fsync` still does not return an error).

The multi-block append workload illustrates interesting behavior in Btrfs block allocation. If the first append fails, the state of the file system, including the B-tree that tracks all free blocks, is reverted. However, the next append will continue to write at the (incorrectly) updated offset stored in the file descriptor, creating a hole in the file. Since the state of the B-tree was reverted, the deterministic block allocator will choose to allocate the same block again for the next append operation. Thus, if the fault to that particular block was transient, the next `write` and `fsync` will succeed and there will simply be a one block hole in the file. If the fault to that particular block occurs multiple times, future writes will continue to fail; as a result, Btrfs may cause more holes within a file than ext4 and XFS. However, unlike ext4 and XFS, the file does not have block overwrite failures.

3.3.4 File System Summary

We now present a set of observations for the file systems based on the questions from Section §3.2.3.

File System Behavior to `fsync` Failures. On all the three file systems, only data and journal-block failures lead to `fsync` failures (Q1). Metadata-block failures do not result in `fsync` failures as metadata blocks are written to the journal during an `fsync`. However, during a checkpoint, any metadata failure on XFS and Btrfs lead to unavailability (Q8) while ext4 logs the error and continues.[4]

On both modes of ext4 and XFS, metadata is persisted even after the file system encounters a data-block failure (Q2); timestamps are always updated in both the file systems. Additionally, ext4 appends a new block to the file and updates the file size while XFS does so only when followed by a future successful `fsync`. As a result, we find non-overwritten blocks in both the middle and end of files for ext4, but in only the middle for XFS (Q10). Btrfs does not persist metadata after a data-block failure. However, because the process file-descriptor offset is incremented, future `writes` and `fsyncs` cause a hole in the middle of the file (Q10).

Among the three, XFS is the only file system that retries metadata-block writes. However, none of them retry data or journal-block writes (Q3).

All the file systems mark the page clean even after `fsync` fails (Q4). In both modes of ext4 and XFS, the page contains the latest write while Btrfs reverts the in-memory state to be consistent with what is on disk (Q5).

We note that even though all the file systems mark the page clean, this is not due to any behavior inherited from the VFS layer. Each file system registers its own handlers to write pages to disk (`ext4_writepages`, `xfs_vm_writepages`, and `btrfs_writepages`). However, each of these handlers call `clear_page_dirty_for_io` before submitting the bio request and do not set the dirty bit in case of failure in order to avoid memory leaks[5], replicating the problem independently.

Failure Reporting. While all file systems report data-block failures by failing `fsync`, ext4 ordered mode, XFS, and Btrfs fail the immediate `fsync`. As ext4 data mode puts data in the journal, the first `fsync` succeeds and the next `fsync` fails. (Q6). All block write failures, irrespective of block type are logged in the syslog (Q7).

After Effects. Journal block failures always lead to file-system unavailability. On XFS and Btrfs, metadata-block failures do so as well (Q8). While ext4 and Btrfs remount in read-only mode, XFS shuts down the file system (Q9). Holes and non-overwritten blocks (Q10) have been covered previously as part of Q2.

Recovery. None of the file systems alert the user to run a

[3] To be precise, the mtime and ctime of the file are updated, but not the size of the file. Additional experiments removed for space confirm this behavior.

[4] Ext4's error handling behavior for metadata has unintended side-effects but we omit the results as the rest of the paper focuses on data-block failures.

[5] Ext4 focuses on the common case of users removing USB sticks while still in use. Dirty pages that can never be written to the removed USB stick have to be marked clean to unmount the file system and reclaim memory [23].

file-system checker. However, the Btrfs checker is capable of detecting holes in files (Q11).

4 Application Study

We now focus on how applications are affected by `fsync` failures. In this section, we first describe our fault model with CuttleFS, followed by a description of the workloads, execution environment, and the errors we look for. Then, we present our findings for five widely used applications: Redis (v5.0.7), LMDB (v0.9.24), LevelDB (v1.22), SQLite (v3.30.1), and PostgreSQL (v12.0).

4.1 CuttleFS

We limit our study to how applications are affected by data-block failures as journal-block failures lead to unavailability and metadata-block failures do not result in `fsync` failures (§3.3). Our fault model is simple: when an application writes data, we inject a single fault to a data block or a sector within it.

We build CuttleFS[6] - a FUSE [39] file system to emulate the different file-system reactions to failures defined by our fault model. Instead of using the kernel's page cache, CuttleFS maintains its own page cache in user-space memory. Write operations modify user-space pages and mark them dirty while read operations serve data from these pages. When an application issues an `fsync` system call, CuttleFS synchronizes data with the underlying file system.

CuttleFS has two modes of operation: trace mode and fault mode. In trace mode, CuttleFS tracks writes and identifies which blocks are eventually written to disk. This is different from just tracing a `write` system call as an application may write to a specific portion of a file multiple times before it is actually flushed to disk.

In fail mode, CuttleFS can be configured to fail the ith write to a sector or block associated with a particular file. On `fsync` failure, as CuttleFS uses in-memory buffers, it can be directed to mark a page clean or dirty, keep the latest content, or revert the file to the previous state. Error reporting behavior can be configured to report failures immediately or on the next `fsync` call. In short, CuttleFS can react to `fsync` failures in any of the ways mentioned in Table 1 (Q4,5,6). Additionally, CuttleFS accepts commands to evict all or specific clean pages.

We configure CuttleFS to emulate the failure reactions of the file systems studied in Section 3.3. For example, in order to emulate ext4 ordered mode and XFS (as they both have similar failure reactions), we configure CuttleFS to mark the page clean, keep the latest content, and report the error immediately. Henceforth, when presenting our findings and referring to characteristics emulated by CuttleFS, we use CuttleFS$_{\text{ext4o,xfs}}$ for the above configuration. When the page is marked clean, has the latest content, but the error is reported on the next `fsync`, we use CuttleFS$_{\text{ext4d}}$. When the page is marked clean, the content matches what is on disk, and the error is reported immediately, we refer to it as CuttleFS$_{\text{btrfs}}$.

4.2 Workloads and Execution Environment

We run CuttleFS in trace mode and identify which blocks are written to by an application. For each application, we choose a simple workload that inserts a single key-value pair, a commonly used operation in many applications. We perform experiments both with an existing key (update) as well as a new key (insert). The keys can be of size 2B or 1KB.[7] The values can be of size 2B or 12KB. We run experiments for all four combinations. The large keys allow for the possibility of failing a single sector within the key and large values for pages within a value. Since SQLite and PostgreSQL are relational database management systems, we create a single table with two columns: keys and values.

Using the trace, we generate multiple failure sequences for each of the identified blocks and sectors within them. We then repeat the experiment multiple times with CuttleFS in fault mode, each time with a different failure sequence and file-system reaction. In order to observe the effects after a fault, we dump all key-value pairs before and after the workload.

We look for the following types of errors when performing the experiments:

- **OldValue (OV):** The system returns the new value for a while but then reverts to an old value, or the system conveys a successful response but returns the old value later on.
- **FalseFailure (FF):** The system informs the user that the operation failed but returns the new value in the future.
- **KeyCorruptions (KC)** and **ValueCorruptions (VC):** Corrupted keys or values are obliviously returned.
- **KeyNotFound (KNF):** The system informs the user that it has successfully inserted a key but it cannot be found later on, or the system fails to update a key to a new value but the old key-value pair disappears as well.

We also identify the factors within the execution environment that cause all these errors to be manifested. If an application maintains its own in-memory data structures, some errors may occur only when an application restarts and rebuilds in-memory state from the file system. Alternatively, the manifestation of these errors may depend on state changes external to the application, such as a single page eviction or a full page cache flush. We encode these different scenarios as:

- **App=KeepGoing:** The application continues without restarting.
- **App=Restart:** The application restarts either after a crash or a graceful shutdown. This forces the application to rebuild in-memory state from disk.

[6] Cuttlefish are sometimes referred to as the "chameleons of the sea" because of their ability to rapidly alter their skin color within a second. CuttleFS can change characteristics much faster.

[7] As LMDB limits key sizes to 511B, we use key sizes of 2B and 511B for LMDB experiments.

	A=KeepGoing	A=Restart
BC=Keep	\	/
BC=Evict	∣	−

Applications		ext4o,xfs = { clean differs immediate					ext4d = { clean differs next `fsync`					btrfs = { clean matches immediate				
		OV	**FF**	**KC**	**VC**	**KNF**	**OV**	**FF**	**KC**	**VC**	**KNF**	**OV**	**FF**	**KC**	**VC**	**KNF**
Redis		−		−	−	−	−		−	−	−	⌿				⌿
LMDB			−				+			+

SQLite	Rollback		+		+			+		−	−		✳			
	WAL		/							−	−					
PostgreSQL	Default		⌿				−				−					
	Direct I/O						−				−					

Table 2: **Findings for Applications on `fsync` Failure.** *The table lists the different types of errors that manifest for applications when `fsync` fails due to a data-block write fault. The errors (OV, FF, KC, VC, KNF) are described in §4.2. We group columns depending on how a file system reacts to an `fsync` failure according to our findings in §3.3 for Q4, Q5, and Q6. For example, both ext4 ordered and XFS (ext4o,xfs) mark a page **clean**, the page **differs** in in-memory and on-disk content, and the `fsync` failure is reported **immediately**. For each application, we describe when the error manifests, in terms of combinations of the four different execution environment factors (§4.2) whose symbols are provided at the top left corner. For example, OldValue manifests in Redis in the first group (ext4-ordered, XFS) only on (A)App=Restart,(BC)BufferCache=Evict. However, in the last group (Btrfs), the error manifests both on App=Restart,BufferCache=Evict as well as App=Restart,BufferCache=Keep, depicted as a combination of the two symbols.*

- **BufferCache=Keep:** No evictions take place.
- **BufferCache=Evict:** One or more clean pages are evicted.

Note that BufferCache=Evict can manifest by clearing the entire page cache, restarting the file system, or just evicting clean pages due to memory pressure. A full system restart would be the combination of App=Restart and BufferCache=Evict, which causes a loss of both clean and dirty pages in memory while also forcing the application to restart and rebuild state from disk.

Configuring CuttleFS to fail a certain block and react according to one of the file-system reactions while the application runs only addresses App=KeepGoing and BufferCache=Keep. The remaining three scenarios are addressed as follows. To simulate App=Restart and BufferCache=Keep, we restart the application and dump all key-value pairs, ensuring that no page in CuttleFS is evicted. To address the remaining two scenarios, we instruct CuttleFS to evict clean pages for both App=KeepGoing and App=Restart.

4.3 Findings

We configured all five applications to run in the form that offers most durability and discuss what they are in their respective sections. Table 2 summarizes the per-application results across different failure characteristics.

Note that these results are only for the simple workload that inserts a single key-value pair. A complex workload may exhibit more errors or mask the ones we observe.

Redis: Redis is an in-memory data-structure store, used as a database, cache, and message broker. By default, it periodically snapshots in-memory state to disk. However, for better durability guarantees, it provides options for writing every operation that modifies the store to an append-only file *(aof)* [19] and how often to `fsync` the *aof*. In the event of a crash or restart, Redis rebuilds in-memory state by reading the contents of the *aof*.

We configure Redis to `fsync` the file for every operation, providing strong durability. Thus, whenever Redis receives a request like an insert operation that modifies state, it writes the request to the *aof* and calls `fsync`. However, Redis trusts the file system to successfully persist the data and does not check the `fsync` return code. Regardless of whether `fsync` fails or not, Redis returns a successful response to the client.

As Redis returns a successful response to the client irrespective of `fsync` failure, FalseFailures do not occur. Since Redis reads from disk only when rebuilding in-memory state, errors may occur only during App=Restart.

On CuttleFS$_{\text{ext4o,xfs}}$ and CuttleFS$_{\text{ext4d}}$, Redis exhibits OldValue, KeyCorruption, ValueCorruption, and KeyNotFound errors. However, as seen in Table 2, these errors occur only on BufferCache=Evict and App=Restart. On BufferCache=Keep, the page contains the latest write which allows Redis to rebuild the latest state. However, when the page is evicted, future reads will force a read from disk, causing Redis to read whatever is on that block. OldValue and KeyNotFound errors manifest when a fault corrupts the *aof* format. When Redis restarts, it either ignores these entries when scanning the *aof*, or recommends running the *aof checker* which truncates the file to the last non-corrupted entry. A KeyCorruption and ValueCorruption manifest when the fault is within the key or value portion of the entry.

On CuttleFS$_{\text{btrfs}}$, Redis exhibits OldValue and KeyNotFound errors. These errors occur on App=Restart, regardless of buffer-cache state. When Redis restarts, the entries are missing from the *aof* as the file was reverted, and thus, the insert or update operation is not applied.

LMDB: Lightning Memory-Mapped Database (LMDB) is an embedded key-value store which uses B+Tree data structures whose nodes reside in a single file. The first two pages of the file are metadata pages, each of which contain a transaction ID and the location of the root node. Readers always use the metadata page with the latest transaction ID while writers make changes and update the older metadata page.

LMDB uses a copy-on-write bottom-up strategy [13] for committing write transactions. All new nodes from leaf to root are written to unused or new pages in the file, followed by an `fsync`. An `fsync` failure terminates the operation without updating the metadata page and notifies the user. If `fsync` succeeds, LMDB proceeds to update the old metadata page with the new root location and transaction ID, followed by another `fsync`.[8] If `fsync` fails, LMDB writes an old transaction ID to the metadata page in memory, preventing future readers from reading it.

On CuttleFS$_{\text{ext4o,xfs}}$, LMDB exhibits FalseFailures. When LMDB writes the metadata page, it only cares about the transaction ID and new root location, both of which are contained in a single sector. Thus, even though the sector is persisted to disk, failures in the seven other sectors of the metadata page can cause an `fsync` failure. As mentioned earlier, LMDB writes an old transaction ID (say ID1) to the metadata page in memory and reports a failure to the user. However, on BufferCache=Evict and App=Restart (such as a machine crash and restart), ID1 is lost as it was only written to memory and not persisted. Thus, readers read from the latest transaction ID which is the previously failed transaction.

LMDB does not exhibit FalseFailures in CuttleFS$_{\text{ext4d}}$ as the immediate successful `fsync` results in a success to the client. Instead, ValueCorruptions and OldValue errors occur on BufferCache=Evict, regardless of whether the application restarts or not. ValueCorruptions occur when a block containing a part of the value experiences a fault. As LMDB *mmaps*() the file and reads directly from the page cache, BufferCache=Evict such as a page eviction leads to reading the value of the faulted block from disk. OldVersion errors occur when the metadata page experiences a fault. The file system responds with a successful `fsync` initially (as data is successfully stored in the ext4 journal). For a short time, the metadata page has the latest transaction ID. However, when the page is evicted, the metadata page reverts to the old transaction ID on disk, resulting in readers reading the old value. KeyCorruptions do not occur as the maximum allowed key size is 511B.

As CuttleFS$_{\text{btrfs}}$ reports errors immediately, it does not face the problems seen in CuttleFS$_{\text{ext4d}}$. FalseFailures do not occur as the file is reverted to its previous consistent state. We observe this same pattern in many of the applications and omit them from the rest of the discussion unless relevant.

LevelDB: LevelDB is a widely used key-value store based on LSM trees. It stores data internally using MemTables and SSTables [33]. Additionally, LevelDB writes operations to a log file before updating the MemTable. When a MemTable reaches a certain size, it becomes immutable and is written to a new file as an SSTable. SSTables are always created and never modified in place. On a restart, if a log file exists, LevelDB creates an SSTable from its contents.

We configure LevelDB to `fsync` the log after every write, for stronger durability guarantees. If `fsync` fails, the MemTable is not updated and the user is notified about the failure. If `fsync` fails during SSTable creation, the operation is cancelled and the SSTable is left unused.

On CuttleFS$_{\text{ext4o,xfs}}$, as seen in Table 2, LevelDB exhibits FalseFailures only on App=Restart with BufferCache=Keep. When LevelDB is notified of `fsync` failure to the log file, the user is notified of the failure. However, on restart, since the log entry is in the page cache, LevelDB includes it while creating an SSTable from the log file. Read operations from this point forward return the new value, reflecting FalseFailures. FalseFailures do not occur on BufferCache=Evict as LevelDB is able to detect invalid entries through CRC checksums [33]. Faults in the SSTable are detected immediately and do not cause any errors as the newly generated SSTable is not used by LevelDB in case of a failure.

On CuttleFS$_{\text{ext4d}}$, LevelDB exhibits KeyNotFound and OldVersion errors when faults occur in the log file. When inserting a key-value pair, `fsync` returns successfully, allowing future read operations to return the new value. However, on BufferCache=Evict and App=Restart, LevelDB rejects the corrupted log entry and returns the old value for future read operations. Depending on whether we insert a new or existing key, we observe KeyNotFound or OldVersion errors when the log entry is rejected. Additionally, LevelDB exhibits KeyCorruption, ValueCorruption, and KeyNotFound errors for faults that occur in the SSTables. Ext4 data mode may only place the data in the journal and return a successful `fsync`. Later, during checkpointing, the SSTable is corrupted due to the fault. These errors manifest only on BufferCache=Evict, either while the application is running or on restart, depending on when the SSTable is read from disk.

SQLite: SQLite is an embedded RDBMS that uses BTree data structures. A separate BTree is used for each table and index but all BTrees are stored in a single file on disk, called the "main database file" *(maindb)*. During a transaction, SQLite stores additional information in a second file called the "rollback journal" *(rj)* or the "write-ahead log" *(wal)* depending on which mode it is operating in. In the event of a crash or restart, SQLite uses these files to ensure that committed or rolled-back transactions are reflected in the *maindb*. Once a transaction completes, these files are deleted. We perform experiments for both modes.

SQLite RollBack: In rollback journal mode, before SQLite modifies its user-space buffers, it writes the original contents to the *rj*. On commit, the *rj* is `fsyncd`. If it succeeds, SQLite writes a header to the *rj* and `fsyncs` again (2 `fsyncs` on the *rj*). If a fault occurs at this point, only the state in the user-space buffers need to be reverted. If not, SQLite proceeds to write to the *maindb* so that it reflects the state of the user-space buffers. *maindb* is then `fsyncd`. If the `fsync`

[8] To be precise, LMDB does not do a write followed by an `fsync` for metadata page updates. Instead, it uses a file descriptor that is opened in O_SYNC mode. On a write, only the metadata page is flushed to disk. On failure, it uses a normal file descriptor.

fails, SQLite needs to rewrite the old contents to the *maindb* from the *rj* and revert the state in its user-space buffers. After reverting the contents, the *rj* is deleted.

On CuttleFS$_{\text{ext4o,xfs}}$, SQLite Rollback exhibits FalseFailures and ValueCorruptions on BufferCache=Evict, regardless of whether the application restarts or not. When faults occur in the *rj*, SQLite chooses to revert in-memory state using the *rj* itself as it contains just enough information for a rollback of the user-space buffers. This approach works well as long as the latest contents are in the page cache. However, on BufferCache=Evict, when SQLite reads the *rj* to rollback in-memory state, the *rj* does not contain the latest write. As a result, SQLite's user-space buffers can still have the new contents (FalseFailure) or a corrupted value, depending on where the fault occurs.

SQLite Rollback exhibits FalseFailures in CuttleFS$_{\text{ext4d}}$ for the same reasons mentioned above as the `fsync` failure is caught on the second `fsync` to the *rj*. Additionally, due to the late error reporting in CuttleFS$_{\text{ext4d}}$, SQLite Rollback exhibits ValueCorruption and KeyNotFound errors when faults occur in the *maindb*. SQLite sees a successful `fsync` after writing data to the *maindb* and proceeds to delete the *rj*. However, on App=Restart and BufferCache=Evict, the above mentioned errors manifest depending on where the fault occurs.

On CuttleFS$_{\text{btrfs}}$, SQLite Rollback exhibits FalseFailures for the same reasons mentioned above. However, they occur irrespective of whether buffer-cache state changes due to the fact that the contents in the *rj* are reverted. As there is no data in the *rj* to recover from, SQLite leaves the user-space buffers untouched. ValueCorruptions cannot occur as no attempt is made to revert the in-memory content.

SQLite WAL: Unlike SQLite Rollback, changes are written to a write-ahead log *(wal)* on a transaction commit. SQLite calls `fsync` on the *wal* and proceeds to change in-memory state. If `fsync` fails, SQLite immediately returns a failure to the user. If SQLite has to restart, it rebuilds state from the *maindb* first and then changes state according to the entries in the *wal*. To ensure that the *wal* does not grow too large, SQLite periodically runs a Checkpoint Operation to modify *maindb* with the contents from the *wal*.

On CuttleFS$_{\text{ext4o,xfs}}$, as seen in Table 2, SQLite WAL exhibits FalseFailures only on App=Restart with BufferCache=Keep, for reasons similar to LevelDB. It reads valid log entries from the page cache even though they might be invalid due to faults on disk.

On CuttleFS$_{\text{ext4d}}$, SQLite WAL exhibits ValueCorruption and KeyNotFound Errors when there are faults in the *maindb* during a Checkpoint Operation for the same reasons mentioned in SQLite Rollback.

PostgreSQL: PostgreSQL is an object-relational database system that maintains one file per database table. On startup, it reads the on-disk tables and populates user-space buffers. Similar to SQLite WAL, PostgreSQL reads entries from the write-ahead log *(wal)* and modifies user-space buffers accordingly. Similar to SQLite WAL, PostgreSQL runs a checkpoint operation, ensuring that the *wal* does not grow too large. We evaluate two configurations of PostgreSQL: the default configuration and a DirectIO configuration.

PostgreSQL Default: In the default mode, PostgreSQL treats the *wal* like any other file, using the page cache for reads and writes. PostgreSQL notifies the user of a successful *commit* operation only after an `fsync` on the *wal* succeeds. During a checkpoint, PostgreSQL writes data from its user-space buffers into the table and calls `fsync`. If the `fsync` fails, PostgreSQL, aware of the problems with `fsync` [8], chooses to crash. Doing so avoids truncating the *wal* and ensures that checkpointing can be retried later.

On CuttleFS$_{\text{ext4o,xfs}}$, PostgreSQL exhibits FalseFailures for reasons similar to LevelDB. While App=Restart is necessary to read the entry from the log, BufferCache=Evict is not. Further, the application restart cannot be avoided as PostgreSQL intentionally crashes on an `fsync` failure. On BufferCache=Keep, PostgreSQL reads a valid log entry in the page cache. On BufferCache=Evict, depending on which block experiences the fault, PostgreSQL either accepts or rejects the log entry. FalseFailures manifest when PostgreSQL accepts the log entry. However, if the file system were to also crash and restart, the page cache would match the on-disk state, causing PostgreSQL to reject the log entry. Unfortunately, ext4 currently does not behave as expected with mount options `data_err=abort` and `errors=remount-ro` (§3.3.1).

Due to the late error reporting in CuttleFS$_{\text{ext4d}}$, as seen in Table 2, PostgreSQL exhibits OldVersion and KeyNotFound Errors when faults occur in the database table files. As PostgreSQL maintains user-space buffers, these errors manifest only on BufferCache=Evict with App=Restart. During a checkpoint operation, PostgreSQL writes the user-space buffers to the table. As the fault is not yet reported, the operation succeeds and the *wal* is truncated. If the page corresponding to the fault is evicted and PostgreSQL restarts, it will rebuild its user-space buffers using an incorrect on-disk table file. The errors are exhibited depending on where the fault occurs. While KeyNotFound errors occur in other applications when a new key is inserted, PostgreSQL *loses existing keys on updates* as it modifies the table file in-place.

PostgreSQL DIO: In the DirectIO mode, PostgreSQL bypasses the page cache and writes to the *wal* using DirectIO. The sequence of operations during a transaction commit and a checkpoint are exactly the same as the default mode.

FalseFailures do not occur as the page cache is bypassed. However, OldVersion and KeyNotFound errors still occur in CuttleFS$_{\text{ext4d}}$ for the same reasons mentioned above as writes to the database table files do not use DirectIO.

5 Discussion

We now present a set of observations and lessons for handling `fsync` failures across file systems and applications.

#1: Existing file systems do not handle fsync failures uniformly. In an effort to hide cross-platform differences, POSIX is intentionally vague on how failures are handled. Thus, different file systems behave differently after an `fsync` failure (as seen in Table 1), leading to non-deterministic outcomes for applications that treat all file systems equally. *We believe that the POSIX specification for `fsync` needs to be clarified and the expected failure behavior described in more detail.*

#2: Copy-on-Write file systems such as Btrfs handle fsync failures better than existing journaling file systems like ext4 and XFS. Btrfs uses new or unused blocks when writing data to disk; the entire file system moves from one state to another on success and no in-between states are permitted. Such a strategy defends against corruptions when only some blocks contain newly written data. *File systems that use copy-on-write may be more generally robust to `fsync` failures than journaling file systems.*

#3: Ext4 data mode provides a false sense of durability. Application developers sometimes choose to use a data journaling file system despite its lower performance because they believe data mode is more durable [11]. Ext4 data mode does ensure data and metadata are in a "consistent state", but only from the perspective of the file system. As seen in Table 2, application-level inconsistencies are still possible. Furthermore, applications cannot determine whether an error received from `fsync` pertains to the most recent operation or an operation sometime in the past. *When failed intentions are a possibility, applications need a stronger contract with the file system, notifying them of relevant context such as data in the journal and which blocks were not successfully written.*

#4: Existing file-system fault-injection tests are devoid of workloads that continue to run post failure. While all file systems perform fault-injection tests, they are mainly to ensure that the file system is consistent after encountering a failure. Such tests involve shutting down the file system soon after a fault and checking if the file system recovers correctly when restarted. *We believe that file-system developers should also test workloads that continue to run post failure, and see if the effects are as intended.* Such effects should then be documented. File-system developers can also quickly test the effect on certain characteristics by running those workloads on CuttleFS before changing the actual file system.

#5: Application developers write OS-specific code, but are not aware of all OS-differences. The FreeBSD VFS layer chooses to re-dirty pages when there is a failure (except when the device is removed) [6] while Linux hands over the failure handling responsibility to the individual file systems below the VFS layer (§3.3.4). *We hope that the Linux file-system maintainers will adopt a similar approach in an effort to handle `fsync` failures uniformly across file systems.* Note that it is also important to think about when to classify whether a device has been removed. For example, while storage devices connected over a network aren't really as permanent as local hard disks, they are more permanent than removable USB sticks. Temporary disconnects over a network need not be perceived as device removal and re-attachment; pages associated with such a device can be re-dirtied on write failure.

#6: Application developers do not target specific file systems. We observe that data-intensive applications configure their durability and error-handling strategies according to the OS they are running on, but treat all file systems on a specific operating system equally. Thus, as seen in Table 2, a single application can manifest different errors depending on the file system. *If the POSIX standard is not refined, applications may wish to handle `fsync` failures on different file systems differently.* Alternatively, applications may choose to code against *failure handling characteristics* as opposed to specific file systems, but this requires file systems to expose some interface to query characteristics such as "Post Failure Page State/Content" and "Immediate/Delayed Error Reporting".

#7: Applications employ a variety of strategies when fsync fails, but none are sufficient. As seen in Section 4.3, Redis chooses to trust the file system and does not even check `fsync` return codes, LMDB, LevelDB, and SQLite revert in-memory state and report the error to the application while PostgreSQL chooses to crash. We have seen that none of the applications retry `fsync` on failure; application developers appear to be aware that pages are marked clean on `fsync` failure and another `fsync` will not flush additional data to disk. Despite the fact that applications take great care to handle a range of errors from the storage stack (e.g., LevelDB writes CRC Checksums to detect invalid log entries and SQLite updates the header of the rollback journal only after the data is persisted to it), data durability cannot be guaranteed as long as `fsync` errors are not handled correctly. *While no one strategy is always effective, the approach currently taken by PostgreSQL to use direct IO may best handle `fsync` failures.* If file systems do choose to report failure handling characteristics in a standard format, applications may be able to employ better strategies. For example, applications can choose to keep track of dirtied pages and re-dirty them by reading and writing back a single byte if they know that the page content is not reverted on failure (ext4, XFS). On Btrfs, one would have to keep track of the page as well as its content. For applications that access multiple files, it is important to note that the files can exist on different file systems.

#8: Applications run recovery logic that accesses incorrect data in the page cache. Applications that depend on the page cache for faster recovery are susceptible to FalseFailures. As seen in LevelDB, SQLite, and PostgreSQL, when the *wal* incurs an `fsync` failure, the applications fail the operation and notify the user; In these cases, while the on-disk state may be corrupt, the entry in the page cache is valid; thus, an application that recovers state from the *wal* might read partially valid entries from the page cache and incorrectly update on-disk state. *Applications should read the on-disk content of files when performing recovery.*

#9: Application recovery logic is not tested with low level block faults. Applications test recovery logic and possibilities of data loss by either mocking system call return codes or emulating crash-restart scenarios, limiting interaction with the underlying file system. As a result, failure handling logic by the file system is not exercised. *Applications should test recovery logic using low-level block injectors that force underlying file-system error handling.* Alternatively, they could use a fault injector like CuttleFS that mimics different file-system error-handling characteristics.

6 Related Work

In this section, we discuss how our work builds upon and differs from past studies in key ways. We include works that study file systems through fault injection, error handling in file systems, and the impact of file-system faults on applications.

Our study on how file systems react to failures is related to work done by Prabhakaran et al. with IRON file systems [49] and a more recent study conducted by Jaffer et al. [40]. Other works study specific file systems such as NTFS [28] and ZFS [58]. All these studies inject failures beneath the file system and analyze if and how file systems detect and recover from them. These studies use system-call workloads (e.g., writes and reads) that make the file system interact with the underlying device.

While prior studies do exercise some portions of the `fsync` path through single system-call operations, they do not exercise the checkpoint path. More importantly, in contrast to these past efforts, our work focuses specifically on the *in-memory* state of a file system and the effects of *future operations* on a file system that has encountered a write fault. Specifically, in our work, we choose workloads that continue after a fault has been introduced. Such workloads help in understanding the after-effects of failures during `fsync` such as masking of errors by future operations, fixing the fault, or exacerbating it.

Mohan et al. [45] use bounded black-box crash testing to exhaustively generate workloads and discover many crash-consistency bugs by simulating power failures at different persistence points. Our work focuses on transient failures that may not necessarily cause a file system to crash and the effect on applications even though a file system may be consistent. Additionally, we inject faults in the middle of an `fsync` as opposed to after a successful `fsync` (persistence point).

Gunawi et al. describe the problem of failed intentions [36] in journaling file systems and suggest chained transactions to handle such faults during checkpointing. Another work develops a static-analysis technique named Error Detection and Propagation [37] and conclude that file systems neglect many write errors. Even though the Linux kernel has improved its block-layer error handling [10], file systems may still neglect write errors. Our results are purely based on injecting errors in bio requests that the file system can detect.

Vondra describes how certain assumptions about `fsync` behavior led to data loss in PostgreSQL [55]. The data loss behavior was reproduced using a device mapper with the dm-error target which inspired us to build our own fault injector (dm-loki [4]) atop the device mapper, similar to dm-inject [40]. Additionally, the FSQA suite (xfstests) [7] emulates write errors using the dm-flakey target [5]. While dm-flakey is useful for fault-injection testing, faults are injected based on current time; the device is available for x seconds and then exhibits unreliable behavior for y seconds (x and y being configurable). Furthermore, any change in configuration requires suspending the device. To increase determinism and avoid relying on time, dm-loki injects faults based on access patterns (e.g., fail the 2nd and 4th write to block 20) and is capable of accepting configuration changes without device suspension.

Recent work has shifted the focus to study the effects of file-system faults in distributed storage systems [34] and high-performance parallel systems [29]. Similarly, our work focuses on understanding how file systems and applications running on top of them behave in the presence of failures.

7 Conclusions

We show that file systems behave differently on `fsync` failure. Application developers can only assume that the underlying file system experienced a fault and that data may have either been persisted partially, completely, or not at all. We show that applications assuming more than the above are susceptible to data loss and corruptions. The widely perceived crash-restart fix in the face of `fsync` failures does not always work; applications recover incorrectly due to on-disk and in-memory mismatches.

However, we believe that applications can provide stronger guarantees if file systems are more uniform in their failure handling and error reporting strategies. Applications that care about durability should include sector- or block-level fault-injection tests to effectively test recovery code paths. Alternatively, such applications can choose to use CuttleFS to inject faults and mimic file system failure reactions.

We have open sourced CuttleFS at `https://github.com/WiscADSL/cuttlefs` along with the device-mapper kernel module and experiments to reproduce the results in this paper.

Abstract

The rise of containers has led to a broad proliferation of container images. The associated storage performance and capacity requirements place high pressure on the infrastructure of container registries that store and serve images. Exploiting the high file redundancy in real-world container images is a promising approach to drastically reduce the demanding storage requirements of the growing registries. However, existing deduplication techniques significantly degrade the performance of registries because of the high layer restore overhead.

We propose DupHunter, a new Docker registry architecture, which not only natively deduplicates layers for space savings but also reduces layer restore overhead. DupHunter supports several configurable *deduplication modes*, which provide different levels of storage efficiency, durability, and performance, to support a range of uses. To mitigate the negative impact of deduplication on the image download times, DupHunter introduces a *two-tier storage hierarchy* with a novel layer prefetch/preconstruct cache algorithm based on user access patterns. Under real workloads, in the *highest data reduction mode*, DupHunter reduces storage space by up to 6.9× compared to the current implementations. In the *highest performance mode*, DupHunter can reduce the `GET` layer latency up to 2.8× compared to the state of the art.

1 Introduction

Containerization frameworks such as Docker [2] have seen a remarkable adoption in modern cloud environments. This is due to their lower overhead compared to virtual machines [7,38], a rich ecosystem that eases application development, deployment, and management [17], and the growing popularity of microservices [69]. By now, all major cloud platforms endorse containers as a core deployment technology [10,28,31,47]. For example, Datadog reports that in 2018, about 21% of its customers' monitored hosts ran Docker and that this trend continues to grow by about 5% annually [19].

Container images are at the core of containerized applications. An application's container image includes the executable of the application along with a complete set of its dependencies—other executables, libraries, and configuration and data files required by the application. Images are structured in *layers*. When building an image with Docker, each executed command, such as `apt install`, creates a new layer on top of the previous one [4], which contains the files that the command has modified or added. Docker leverages union file systems [64] to efficiently merge layers into a single file system tree when starting a container. Containers can share identical layers across different images.

To store and distribute container images, Docker relies on image *registries* (e.g., Docker Hub [3]). Docker clients can push images to or pull them from the registries as needed. On the registry side, each layer is stored as a compressed tarball and identified by a content-based address. The Docker registry supports various storage backends for saving and retrieving layers. For example, a typical large-scale setup stores each layer as an object in an object store [32,51].

As the container market continues to expand, Docker registries have to manage a growing number of images and layers. Some conservative estimates show that in spring 2019, Docker Hub alone stored at least 2 million *public* images totaling roughly 1 PB in size [59,72]. We believe that this is just the tip of the iceberg and the number of *private* images is significantly higher. Other popular public registries [9, 27, 35, 46], as well as on-premises registry deployments in large organizations, experience a similar surge in the number of images. As a result, organizations spend an increasing amount of their storage and networking infrastructure on operating image registries.

The storage demand for container images is worsened by the large amount of duplicate data in images. As Docker images must be self-contained by definition, different images frequently include the same, common dependencies (e.g., libraries). As a result, different images are prone to contain a high number of duplicate files as shared components exist in more than one image.

To reduce this redundancy, Docker employs layer sharing. However, this is insufficient as layers are coarse and rarely identical because they are built by developers independently and without coordination. Indeed, a recent analysis of the Docker Hub image dataset showed that about 97% of files across layers are duplicates [72]. Registry storage backends exacerbate the redundancy further due to the replication they perform to improve image durability and availability [12].

Deduplication is an effective method to reduce capacity demands of intrinsically redundant datasets [52]. However, applying deduplication to a Docker registry is challenging due to two main reasons: 1) layers are stored in the registry as **compressed** tarballs that do not deduplicate well [44]; and 2) decompressing layers first and storing individual files incurs high reconstruction overhead and slows down image pulls. The slowdowns during image pulls are especially harmful because they contribute directly to the startup times of containers. Our experiments show that, on average, naive deduplication increases layer pull latencies by up to 98× compared to a registry without deduplication.

In this paper, we propose DupHunter, the first Docker registry that natively supports deduplication. DupHunter is designed to increase storage efficiency via layer deduplication while reducing the corresponding layer restoring overhead. It utilizes domain-specific knowledge about the stored data and the storage system to reduce the impact of layer deduplication on performance. For this purpose, DupHunter offers five key contributions:

1. DupHunter exploits existing replication to improve performance. It keeps a specified number of layer replicas as-is, without decompressing and deduplicating them. Accesses to these replicas do not experience layer restoring overhead. Any additional layer replicas needed to guarantee the desired availability are decompressed and deduplicated.
2. DupHunter deduplicates rarely accessed layers more aggressively than popular ones to speed up accesses to popular layers and achieve higher storage savings.
3. DupHunter monitors user access patterns and proactively restores layers *before* layer download requests arrive. This allows it to avoid reconstruction latency during pulls.
4. DupHunter groups files from a single layer in *slices* and evenly distributes the slices across the cluster, to parallelize and speed up layer reconstruction.
5. We use DupHunter to provide the first comprehensive analysis of the impact of different deduplication levels (file and block) and redundancy policies (replication and erasure coding) on registry performance and space savings.

We evaluate DupHunter on a 6-node cluster using real-world workloads and layers. In the *highest performance mode*, DupHunter outperforms the state-of-the-art Docker registry, Bolt [41], by reducing layer pull latencies by up to 2.8×. In the *highest deduplication mode*, DupHunter reduces storage consumption by up to 6.9×. DupHunter also supports other deduplication modes that support various trade-offs in performance and space savings.

2 Background and Related Work

We first provide the background on the Docker registry and then discuss existing deduplication works.

2.1 Docker Registry

The main purpose of a Docker registry is to store and distribute container images to Docker clients. A registry provides a REST API for Docker clients to *push* images to and *pull* images from the registry [20, 21]. Docker registries group images into *repositories*, each containing versions (*tags*) of the same image, identified as `<repo-name:tag>`. For each tagged image in a repository, the Docker registry stores a *manifest*, i.e., a JSON file that contains the runtime configuration for a container image (e.g., environment variables) and the list of layers that make up the image. A layer is stored as a compressed archival file and identified using a digest (SHA-256) computed over the uncompressed contents of the layer. When pulling an image, a Docker client first downloads the manifest and then the referenced layers (that are not already present on the client). When pushing an image, a Docker client first uploads the layers (if not already present in the registry) and then the manifest.

The current Docker registry software is a single-node application with a RESTful API. The registry delegates storage to a backend storage system through corresponding storage drivers. The backend storage can range from local file systems to distributed object storage systems such as Swift [51] or others [1, 5, 32, 51]. To scale the registry, organizations typically deploy a load balancer or proxy in front of several independent registry instances [11]. In this case, client requests are forwarded to the destination registries through a proxy, then served by the registries' backend storage system. To reduce the communication overhead between the proxy, registry, and backend storage system, Bolt [41] proposes to use a consistent hashing function instead of a proxy, distribute requests to registries, and utilize the local file system on each registry node to store data instead of using a remote distributed object storage system. Multiple layer replicas are stored on Bolt registries for high availability and reliability. DupHunter is implemented based on the architecture of Bolt registry for high scalability.

Registry performance is critical to Docker clients. In particular, the layer `pulling` performance (i.e., `GET` layer performance) impacts container startup times significantly [30]. A number of works have studied various dimensions of registry performance for a Docker image dataset [11, 14, 30, 60, 64, 71, 72]. However, such works do not provide deduplication for the registry. A community proposal exists to add file-level deduplication to container images [8], but as of now lacks even a detailed design, let alone performance analysis. Skourtis et al. [59] propose restructuring layers to optimize for various dimensions, including registry storage utilization. Their approach does not remove all duplicates, whereas DupHunter leaves images unchanged and can eliminate all duplicates in the registry. Finally, a lot of works aim to reduce the size of a single container image [22,29,54,65], and are complementary to DupHunter.

2.2 Deduplication

Data deduplication has received considerable attention, particularly for virtual machine images [33, 36, 61, 73]. Many deduplication studies focus on primary and backup data deduplication [23–25,39,40,42,48,58,63,68,74] and show the effectiveness of file- and block-level deduplication [45, 62]. To further reduce storage space, integrating block-level deduplication with compression has been proposed [66]. In addition to local deduplication schemes, a global deduplication method [49] has also been proposed to improve the deduplication ratio and provide high scalability for distributed storage systems.

Data restoring latency is an important factor for storage systems with deduplication support. Efficient chunk caching algorithms and forward assembly are proposed to accelerate data restore performance [15]. At first glance, one could apply existing deduplication techniques to solve the issue of high data redundancy among container images. However, as we demonstrate in detail in §3.2, such a naive approach leads to slow reconstruction of layers on image pulls, which severely degrades container startup times. DupHunter is specifically designed for Docker registries, which allows it to leverage image and workload information to reduce deduplication and layer restore overhead.

3 Motivating Observations

The need and feasibility of DupHunter is based on three key observations: 1) container images have a lot of redundancy; 2) existing scalable deduplication technologies significantly increase image pull latencies; and 3) image access patterns can be predicted reliably.

3.1 Redundancy in Container Images

Container image layers exhibit a large degree of redundancy in terms of duplicate files. Although Docker supports the sharing of layers among different images to remove some redundant data in the Docker registry, this is not sufficient to effectively eliminate duplicates. According to the deduplication analysis of the Docker Hub dataset [72], 97% of files have more than one file duplicate, resulting in a deduplication ratio of 2× in terms of capacity. We believe that the deduplication ratio is much higher when private repositories are taken into account.

Table 1: Dedup. ratio vs. increase in GET layer latency.

Technology	Dedup ratio, compressed layers	Dedup ratio, uncompressed layers	GET latency increase wrt. uncompressed layers
Jdupes	1	2.1	36 ×
VDO	1	4	60 ×
Btrfs	1	2.3	51 ×
ZFS	1	2.3	50 ×
Ceph	1	3.1	98 ×

The duplicate files are executables, object code, libraries, and source code, and are likely imported by different image developers using package installers or version control systems such as `apt`, `pip`, or `git` to install similar dependencies. However, as layers often share many but not all files, this redundancy cannot be eliminated by Docker's current layer sharing approach.

R-way replication for reliability further fuels the high storage demands of Docker registries. Hence, satisfying demand by adding more disks and scaling out storage systems quickly becomes expensive.

3.2 Drawbacks of Existing Technologies

A naive approach to eliminating duplicates in container images could be to apply an existing deduplication technique. To experimentally demonstrate that such a strategy has significant shortcomings, we try four popular local deduplication technologies, `VDO` [67], `Btrfs` [13], `ZFS` [70], `Jdupes` [34], in a single-node setup and on one distributed solution, `Ceph` [16], on a 3-node cluster. The deduplication block sizes are set to 4KB for both `VDO` and `Ceph`, and 128KB for both `Btrfs` [13] and `ZFS` [70] by default. Table 1 presents the deduplication ratio and pull latency overhead for each technology in two cases: 1) when layers are stored compressed (as-is); and 2) when layers are uncompressed and unpacked into their individual files. Note that the deduplication ratios are calculated against the case when all layers are compressed (the details of the dataset and testbed are presented in §6).

Deduplication ratios. Putting the original compressed layer tarballs in any of the deduplication systems results, unsuprisingly, in a deduplication ratio of 1. This is because even a single byte change in any file in a tarball scrambles the content of the compressed tarball entirely [18, 44]. Hence, to expose the redundancy to the deduplication systems, we decompress every layer before storing it.

After decompression, all deduplication schemes yield significant deduplication ratios. `Jdupes`, `Btrfs`, and `ZFS` reduce the dataset to about half and achieve deduplication ratios of 2.1, 2.3, and 2.3, respectively. `Ceph` has a higher

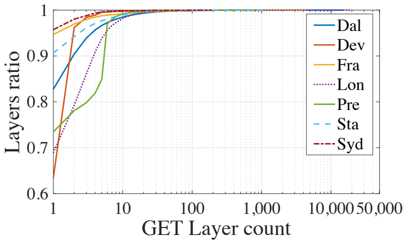

Figure 1: CDF of `GET` layer request count.

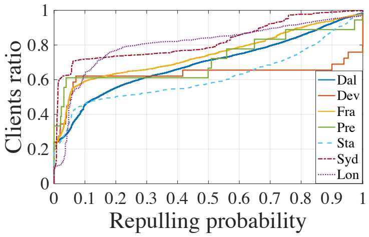

Figure 2: CDF of client repulling probability.

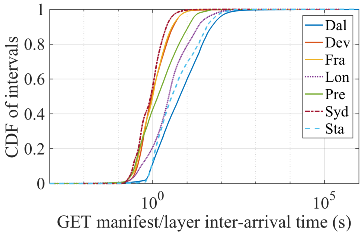

Figure 3: CDF of `GET` manifest/layer inter-arrival time.

deduplication ratio since it uses a smaller deduplication block size, while `VDO` shows the highest deduplication ratio as it also compresses deduplicated data.

It is important to note that for an enterprise-scale registry, a large number of storage servers need to be deployed and single-node deduplication systems (`Jdupes`, `Btrfs`, `ZFS`, and `VDO`) can only deduplicate data within a single node. Therefore, in a multi-node setup, such solutions can never achieve optimal *global* deduplication, i.e., duplication across nodes.

Pull latencies. To analyze layer pull latencies, we implement a layer restoring process for each technology. Restoring includes fetching files, creating a layer tarball, and compressing it. We measure the average `GET` layer latency and calculate the restore overhead compared to `GET` requests without layer deduplication.

As shown in Table 1, the restoration overhead is high. The file-level deduplication scheme `Jdupes` increases the `GET` layer latency by 36×. This is caused by the expensive restoring process. `Btrfs`, `ZFS`, and `VDO` show an increase of more than 50×, as they are block-level deduplication systems, and hence they also add file restoring overhead. The overhead for `Ceph` is the highest because restoration is distributed and incurs network communication.

In summary, our analysis shows that while existing technologies can provide storage space savings for container images (after decompression), they incur high cost during image pulls due to slow layer reconstruction. At the same time, pull latency constitutes the major portion of container startup times even without deduplication. According to [30], pulling images accounts for 76% of container startup times. This means that, for example, for Btrfs the increase of layer GET latency by 51× would prolong container startup times by 38×. Hence, deduplication has a major negative impact on the startup times of containerized applications.

3.3 Predictable User Access Patterns

A promising approach to mitigate layer restoring overhead is predicting which layers will be accessed and preconstruct them. In DupHunter, we can exploit the fact that when a Docker client pulls an image from the registry, it first retrieves the image manifest, which includes references to the image layers.

User pulling patterns. Typically, if a layer is already stored locally, then the client will not fetch this layer again. However, higher-level container orchestrators allow users to configure different policies for starting new containers. For example, Kubernetes allows policies such as `IfNotPresent`, i.e., only get the layer if it has not been pulled already, or `AlwaysGet`, i.e., always retrieve the layer, even if it is already present locally. These different behaviors need to be considered when predicting whether a layer will be pulled by a user or not.

We use the IBM Cloud registry workload [11] to analyze the likelihood for a user to *repull* an already present layer. The traces span ∼80 days for 7 registry clusters: Dallas, Frankfurt, London, Sydney, Development, Prestaging, and Staging. Figure 1 shows the CDF of layer `GET` counts by the same clients. The analysis shows that the majority of layers are only fetched once by the same clients. For example, 97% of layers from `Syd` are only fetched once by the same clients. However, there are clients that pull the same layers repeatedly. E.g., a client from London fetched the same layer 19,300 times.

Figure 2 shows the corresponding client repull probability, calculated as the number of repulled layers divided by the number of total `GET` layer requests issued by the same client. We see that 50% of the clients have a repull probability of less than 0.2 across all registries. We also observe that the slope of the CDFs is steep at both lower and higher probabilities, but becomes flat in the middle. This suggests that, by observing access patterns, we are able to classify clients into two categories, always-pull clients and pull-once clients, and predict, whether they will pull a layer or not by keeping track of user access history.

Layer preconstruction. We analyze the inter-arrival time between a `GET` manifest request and the subsequent `GET` layer request. As shown in Figure 3, the majority of intervals are greater than 1 second. For example, 80% of intervals from London are greater than 1 second, and 60% of the intervals from Sydney are greater than 5 seconds.

There are several reasons for this long gap. First, when

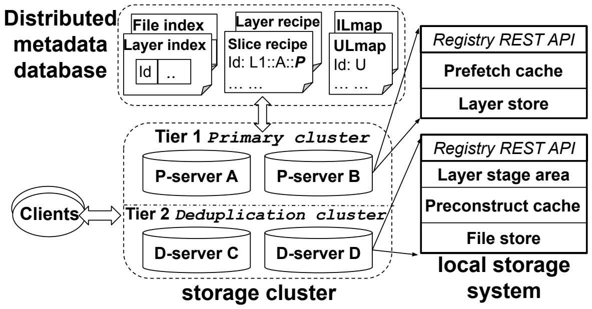

Figure 4: DupHunter architecture.

fetching an image from a registry, the Docker client fetches a fixed number of layers in parallel (three by default) starting from the lowest layer. In the case where an image contains more than three layers, the upper layers have to wait until the lower layers are downloaded, which delays the `GET` layer request for these layers. Second, network delay between clients and registry often accounts for a large portion of the `GET` latency in cloud environments.

As we show in §6, layer preconstruction can significantly reduce layer restoring overhead. In the case of a shorter duration between a `GET` manifest request and its subsequent `GET` layer requests, layer preconstruction can still be beneficial because the layer construction starts prior to the arrival of the `GET` request.

4 DupHunter Design

In this section, we first provide an overview of DupHunter (§4.1). We then describe in detail how it deduplicates (§4.2) and restores (§4.3) layers, and how it further improves performance via predictive cache management (§4.4). Finally, we discuss the integration of sub-file deduplication and erasure coding with DupHunter (§4.5).

4.1 Overview

Figure 4 shows the architecture of DupHunter. DupHunter consists of two main components: 1) a cluster of *storage servers*, each exposing the registry REST API; and 2) a distributed *metadata database*. When uploading or downloading layers, Docker clients communicate with any DupHunter server using the registry API. Each server in the cluster contains an API service and a backend storage system. The backend storage systems store layers and perform deduplication, keeping the deduplication metadata in the database. DupHunter uses three techniques to reduce deduplication and restoring overhead: 1) replica deduplication modes; 2) parallel layer reconstruction; and 3) proactive layer prefetching/preconstruction.

Replica deduplication modes. For higher fault tolerance and availability, existing registry setups replicate layers. DupHunter also performs layer replication, but additionally deduplicates files inside the replicas.

A *basic deduplication mode* n (B-mode n) defines that DupHunter should only keep n layer replicas intact and deduplicate the remaining $R-n$ layer replicas, where R is the layer replication level. At one extreme, B-mode R means that no replicas should be deduplicated, and hence provides the best performance but no data reduction. At the other end, B-mode 0 deduplicates all layer replicas, i.e., it provides the highest deduplication ratio but adds restoration overhead for `GET` requests. The remaining in-between B-modes allow to trade off performance for data reduction.

For heavily skewed workloads, DupHunter also provides a *selective deduplication mode* (S-mode). The S-mode utilizes the skewness in layer popularity, observed in [11], to decide how many replicas should be deduplicated for each layer. As there are hot layers that are pulled frequently, S-mode sets the number of intact replicas proportional to their popularity. This means that hot layers have more intact replicas, and hence can be served faster, while cold layers are deduplicated more aggressively.

Deduplication in DupHunter, for the example of B-mode 1, works as follows: DupHunter first creates 3 layer replicas across 3 servers. It keeps a single layer replica as the *primary layer replica* on one server. Deduplication is then carried out in one of the other servers storing a replica, i.e., the layer replica is decompressed and any duplicate files are discarded while unique files are kept. The unique files are replicated and saved on different servers for fault tolerance. Once deduplication is complete, the remaining two layer replicas are removed. Any subsequent `GET` layer requests are sent to the primary replica server first since it stores the complete layer replica. If that server crashes, one of the other servers is used to rebuild the layer and serve the `GET` request.

To support different deduplication modes, DupHunter stores a mix of both layer tarballs and individual files. This makes data placement decision more complex with respect to fault tolerance because individual files and their corresponding layer tarballs need to be placed on different servers. As more tarballs and files are stored in the cluster, the placement problem gets more challenging.

To avoid accidentally co-locating layer tarballs and unique files, which are present in the tarball, and simplify the placement problem, DupHunter divides storage servers into two groups (Figure 4): a *primary cluster* consisting of *P-servers* and a *deduplication cluster* consisting of *D-servers*. P-servers are responsible for storing full layer tarball replicas and replicas of the manifest, while D-servers deduplicate, store, and replicate the unique files from the layer tarballs. The split allows DupHunter to treat layers and individual files separately and prevent co-location during placement.

P- and D-servers form a 2-tier storage hierarchy. In the default case, the primary cluster serves all incoming `GET` requests. If a request cannot be served from the primary cluster (e.g., due to a node failure, or DupHunter operating in B-mode 0 or S-mode), it will be forwarded to the deduplication cluster and the requested layer will be reconstructed.

Parallel layer reconstruction. DupHunter speeds up layer reconstruction through parallelism. As shown in Figure 4, each D-server's local storage is divided into three parts: the layer stage area, preconstruction cache, and file store. The layer stage area temporarily stores newly added layer replicas. After deduplicating a replica, the resulting unique files are stored in a content addressable file store and replicated to the peer servers to provide redundancy. Once all file replicas have been stored, the layer replica is deleted from the layer stage area.

DupHunter distributes the layer's unique files onto several servers (see §4.2). All files on a single server belonging to the same layer are called a *slice*. A slice has a corresponding *slice recipe*, which defines the files that are part of this slice, and a *layer recipe* defines the slices needed to reconstruct the layer. This information is stored in DupHunter's metadata database. This allows D-servers to rebuild layer slices in parallel and thereby improve reconstruction performance. DupHunter maintains layer and file fingerprint indices in the metadata database.

Predictive cache prefetch and preconstruction. To improve the layer access latency, DupHunter employs a cache layer in both the primary and the deduplication clusters, respectively. Each P-server has an in-memory *user-behavior based prefetch cache* to reduce disk I/Os. When a `GET` manifest request is received from a user, DupHunter predicts which layers in the image will actually need to be `pulled` and prefetches them in the cache. Additionally, to reduce layer restoring overhead, each D-server maintains an on-disk *user-behavior based preconstruct cache*. As with the prefetch cache, when a `GET` manifest request is received, DupHunter predicts which layers in the image will be `pulled`, preconstructs the layers, and loads them in the preconstruct cache. To accurately predict which layers to prefetch, DupHunter maintains two maps: *ILmap* and *ULmap*. ILmap stores the mapping between images and layers while ULmap keeps track of a user's access history, i.e., which layers the user has pulled and how many times (see §4.4).

4.2 Deduplicating Layers

As in the traditional Docker registry, DupHunter maintains a *layer index*. After receiving a `PUT` layer request, DupHunter first checks the layer fingerprint in the *layer index* to ensure an identical layer is not already stored. If not, DupHunter, replicates the layer r times across the P-servers and submits the remaining $R - r$ layer replicas to the D-servers. Those replicas are temporarily stored in the layer stage areas of the D-servers. Once the replicas have been stored successfully, DupHunter notifies the client of the request completion.

File-level deduplication. Once in the staging area, one of the D-servers decompresses the layer and starts the deduplication process. First, it extracts file entries from the tar archive. Each file entry is represented as a *file header* and the associated *file content* [26]. The file header contains metadata such as file name, path, size, mode, and owner information. DupHunter records every file header in slice recipes (described below) to be able to correctly restore the complete layer archive later.

To deduplicate a file, DupHunter computes a file Id by hashing the file content and checks if the Id is already present in the file index. If present, the file content is discarded. Otherwise, the file content is assigned to a D-server and stored in its file store, and the file Id is recorded in the file index. The file index maps different file Ids to their physical replicas stored on different D-servers.

Layer partitioning. DupHunter picks D-servers for files to improve reconstruction times. For that, it is important that different layer slices are similarly sized and evenly distributed across D-servers. To achieve this, DupHunter employs a greedy packing algorithm. Consider first the simpler case in which each file only has a single replica. DupHunter first computes the total size of the layer's existing shared files on each D-server (this might be 0 if a D-server does not store any shared files for the layer). Next, it assigns the largest new unique file to the smallest partition until all the unique files are assigned. Note that during layer partitioning, DupHunter does not migrate existing shared files to reduce I/O overhead.

In the case where a file has more than one replica, DupHunter performs the above-described partitioning *per replica*. That means that it first assigns the primary replicas of the new unique files to D-servers according to the location of the primary replicas of the existing shared files. It then does the same for the secondary replicas and so on. DupHunter also ensures that two replicas of the same file are never placed on the same node.

Unique file replication. Next, DupHunter replicates and distributes the unique file replicas across D-servers based on the layer partitioning. The headers and content pointers of all files in the deduplicated layer that are assigned to a specific D-server are included in that D-server's *slice recipe* for that layer. After file replication, DupHunter adds the new slice recipes to the metadata database.

DupHunter also creates a *layer recipe* for the uploaded layer and stores it in the metadata database. The layer recipe records all the D-servers that store slices for that layer and which can act as *restoring workers*. When a layer needs to be reconstructed, one worker is selected as the *restoring master*, responsible for gathering all slices

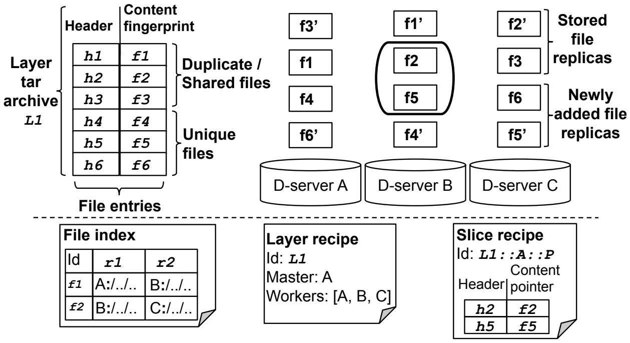

Figure 5: Layer dedup., replication, and partitioning.

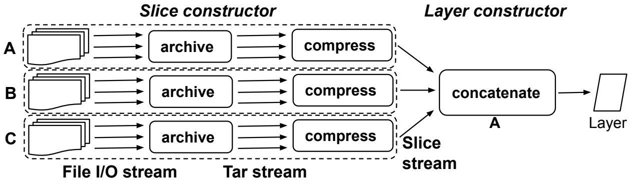

Figure 6: Parallel streaming layer construction.

and rebuilding the layer (see §4.3).

Figure 5 shows an example deduplication process. The example assumes B-mode 1 with 3-way replication, i.e., each unique file has two replicas distributed on two different D-servers. The files $f1$, $f2$, and $f3$ are already stored in DupHunter, and $f1'$, $f2'$, and $f3'$ are their corresponding replicas. Layer $L1$ is being pushed and contains files $f1$–$f6$. $f1$, $f2$, and $f3$ are *shared files* between $L1$ and other layers, and hence are discarded during file-level deduplication. The unique files $f4$, $f5$ and $f6$ are added to the system and replicated to D-servers A, B, and C.

After replication, server B contains $f2$, $f5$, $f1'$, and $f4'$. Together $f2$ and $f5$ form the *primary slice* of $L1$, denoted as $L1 :: B :: P$. This slice Id contains the layer Id the slices belongs to ($L1$), the node, which stores the slice (B) and the backup level (P for primary). The two backup file replicas $f1'$ and $f4'$ on B form the *backup slice* $L1 :: B :: B$. During layer restoring, $L1$ can be restored by using any combination of primary and backup slices to achieve maximum parallelism.

4.3 Restoring Layers

The restoring process works in two phases: slice reconstruction and layer reconstruction. Considering the example in Figure 5, restoring works as follows:

According to $L1$'s layer recipe, the restoring workers are D-servers A, B, and C. The node with the largest slice is picked as the restoring master, also called *layer constructor* (A in the example). Since A is the restoring master it sends `GET slice` requests for the primary slices to B and C. If a primary slice is missing, the master locates its corresponding backup slice and sends a `GET slice` request to the corresponding D-server.

After a `GET slice` request has been received, B's and C's *slice constructors* start rebuilding their primary slices and send them to A as shown in Figure 6. Meanwhile, A instructs its local slice constructor to restore its primary slice for $L1$. To construct a layer slice, a slice constructor first gets the associated slice recipe from the metadata database. The recipe is keyed by a combination of layer Id, host address and requested backup level, e.g., $L1 :: A :: P$. Based on the recipe, the slice constructor creates a slice tar file by concatenating each file header and the corresponding file contents; it then compresses the slice and passes it to the master. The master concatenates all the compressed slices into a single compressed layer tarball and sends it back to the client.

The layer restoration performance is critical to keep `pull` latencies low. Hence, DupHunter parallelizes slice reconstruction on a single node and avoids generating intermediate files on disk to reduce disk I/O.

4.4 Caching and Preconstructing Layers

DupHunter maintains a cache layer in both the primary and deduplication clusters to speedup `pull` requests. The primary cluster cache (in-memory prefetch cache) is to avoid disk I/O during layer retrievals while the deduplication cluster on-disk cache stores preconstructed layers, which are likely to be accessed in the future. Both caches are filled based on the user access patterns seen in §3.

Request prediction. To accurately predict layers that will be accessed in the future, DupHunter keeps track of image metadata and user access patterns in two data structures: *ILmap* and *ULmap*. ILmap maps an image to its containing *layer set*. ULmap stores for each user the layers the user has accessed and the corresponding pull count. A user is uniquely identified by extracting the sender IP address from the request. If DupHunter has not seen an IP address before, it assumes that the request comes from a new host, which does not store any layers yet.

When a `GET manifest` request r is received, DupHunter first calculates a set of image layers that have not been pulled by the user *r.addr* by calculating the difference S_Δ between the image's layer set and the user's accessed layer set:

$$S_\Delta = ILmap[r.img] - ULmap[r.addr].$$

The layers in S_Δ are expected to be accessed soon.

Recall from §3.3 that some users *always* pull layers, no matter if the layers have been previously pulled. To detect such users, DupHunter maintains a *repull probability* γ for each user. For a `GET manifest` request r by a user

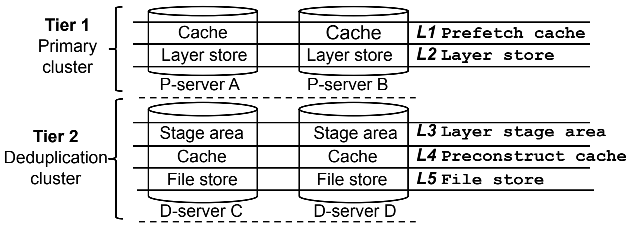

Figure 7: Tiered storage architecture.

$r.addr$, γ is computed as

$$\gamma[r.addr] = \sum_{l \in RL} l.pullCount \Big/ \sum_{l \in L} l.pullCount$$

where RL is the set of layers that the user has repulled before (i.e., with a pull count > 1) and L is the set of all layers the user has ever pulled. DupHunter updates the pull counts every time it receives a `GET layer` request.

DupHunter compares the clients' repull probability to a predefined threshold ε. If $\gamma[r.addr] > \varepsilon$, then DupHunter classifies the user as a repull user and computes the subset, $S_\cap$, of layers from the requested image that have already been pulled by the user:

$$S_\cap = ILmap[r.img] \cap ULmap[r.addr].$$

It then fetches the layers in $S_\cap$ into the cache.

Cache handling in tiered storage. The introduction of the two caches results in a 5-level 2-tier storage architecture of DupHunter as shown in Figure 7. Requests are passed through the tiers from top to bottom. Upon a `GET` layer request, DupHunter first determines the P-server(s) which is (are) responsible for the layer and searches the prefetch cache(s). If the layer is present, the request will be served from the cache. Otherwise, the request will be served from the layer store.

If a `GET layer` request cannot be served from the primary cluster due to a failure of the corresponding P-server(s), the request will be forwarded to the deduplication cluster. In that case, DupHunter will first lookup the layer recipe. If the recipe is not found, it means that the layer has not been fully deduplicated yet and DupHunter will serve the layer from one of the layer stage areas of the responsible D-servers. If the layer recipe is present, DupHunter will contact the restoring master to check, whether the layer is in its preconstruct cache. Otherwise, it will instruct the restoring master to rebuild the layer.

Both the prefetch and the preconstruct caches are write-through caches. When a layer is evicted, it is simply discarded since the layers are read-only. We use an Adaptive Replacement Cache (ARC) replacement policy [43], which keeps track of both the frequently and recently used layers and adapts to changing access patterns.

4.5 Discussion

The goal of DupHunter is to provide flexible deduplication modes to meet different space-saving and performance requirements and mitigate layer restore overhead. The above design of DupHunter mainly focuses on file-level deduplication and assumes layer replication.

To achieve a higher deduplication ratio, DupHunter can integrate with block-level deduplication. After removing redundant files, D-servers can further perform block-level deduplication only on unique files by using systems such as `VDO` [67] and `Ceph` [49]. However, higher deduplication ratios come with higher layer restoring overhead as the restoring latency for block-level deduplication is higher than that of file level as we show in §6. This is because to restore a layer, its associated files need to be first restored, which incurs extra overhead. Furthermore, when integrating with a global block-level deduplication scheme, the layer restoring overhead will be higher due to network communication. In this case, it is beneficial to maintain a number of layer replicas on P-servers to maintain a good performance.

While DupHunter exploits existing replication schemes, it is not limited to those. If the registry is using erasure coding for reliability, DupHunter can integrate with the erasure coding algorithm to improve space efficiency. Specifically, after removing redundant files from layers, DupHunter can store unique files as erasure-coded chunks. While DupHunter can not make use of existing replicas to improve pull performance in this case, its preconstruct cache remains beneficial to mitigate high restoring overheads as shown in §6.

A known side effect when performing deduplication is that the loss of a chunk has a bigger impact on fault tolerance as the chunk is referenced by several objects [57]. To provide adequate fault tolerance, DupHunter maintains at least three copies of a layer (either as full layer replicas or unique files that can rebuild the layer) in the cluster.

5 Implementation

We implemented DupHunter[1] in Go by adding $\sim 2,000$ lines of code to Bolt [41]. Note that Bolt is based on the reference Docker registry [20] for high availability and scalability (see Bolt details in §2.1.)

DupHunter can use any POSIX file system to store its data and uses Redis [6] for metadata, i.e., slice and layer recipes, file and layer indices, and ULmap and ILmap. We chose Redis because it provides high lookup and update performance and it is widely used in production systems. Another benefit of Redis is that it comes with a Go client library, which makes it easy to integrate with the Docker

[1] DupHunter's code is available at https://github.com/nnzhaocs/DupHunter.

Registry. We enable *append-only file* in Redis to log all changes for durability purposes. Moreover, we configure Redis to save snapshots every few minutes for additional reliability. To improve availability and scalability, we use 3-way replication. In our setup, Redis is deployed on all nodes of the cluster (P-servers and D-servers) so that a dedicated metadata database cluster is not needed. However, it is also possible to setup DupHunter with a dedicated metadata database cluster.

To ensure that the metadata is in a consistent state, DupHunter uses Redis' atomicity so that no file duplicates are stored in the cluster. For the file and layer indices and the slice and layer recipes, each key can be set to hold its value only if the key does not yet exist in Redis (i.e, using `SETNX` [55]). When a key already holds a value, a file duplicate or layer duplicate is identified and is removed from the registry cluster.

Additionally, DupHunter maintains a synchronization map to ensure that multiple layer restoring processes do not attempt to restore the same layer simultaneously. If a layer is currently being restored, subsequent `GET` layer requests to this layer wait until the layer is restored. Other layers, however, can be constructed in parallel.

Both the metadata database and layer store used by DupHunter are scalable and can handle large image datasets. DupHunter's metadata overhead is about 0.6% in practice, e.g., for a real-world layer dataset of 18 GB, DupHunter stores less than 100 MB of metadata in Redis.

6 Evaluation

We answer two questions in the evaluation: how do deduplication modes impact the performance–redundancy trade-off, and how effective are DupHunter's caches.

6.1 Evaluation Setup

Testbed. Our testbed consists of a 16-node cluster, where each node is equipped with 8 cores, 16 GB RAM, a 500 GB SSD, and a 10 Gbps NIC.

Dataset. We downloaded 0.93 TB of popular Docker images (i.e., images with a pull count greater than 100) with 36,000 compressed layers, totalling 2 TB after decompression. Such dataset size allowed us to quickly evaluate DupHunter's different modes without losing the generality of results. The file-level deduplication ratio of the decompressed dataset is 2.1.

Workload generation. To evaluate how DupHunter performs with production registry workloads, we use the IBM Cloud Registry traces [11] that come from four production registry clusters (`Dal`, `Fra`, `Lon`, and `Syd`) and span approximately 80 days. We use Docker registry trace player [11] to replay the first 15,000 requests from each workload as shown in Table 2. We modify the player to match requested layers in the IBM trace with real layers downloaded from Docker Hub based on the layer size[2]. Consequently, each layer request pulls or pushes a real layer. For manifest requests, we generate random well-formed, manifest files.

In addition, our workload generator uses a proxy emulator to decide the server for each request. The proxy emulator uses consistent hashing [37] to distribute layers and manifests. It maintains a ring of registry servers and calculates a destination registry server for each `push` layer or manifest request by hashing its digest. For `pull` manifest requests, the proxy emulator maintains two consistent hashing rings, one for the P-servers, and another for the D-servers. By default, the proxy first queries the P-servers but if the requested P-server is not available, it pulls from the D-servers.

Schemes. We evaluate DupHunter's deduplication ratio and performance using different deduplication and redundancy schemes. The base case considers 3-way layer replication and file-level deduplication. In that case, DupHunter provides five deduplication modes: B-mode 0, 1, 2, 3, and S-mode. Note that B-mode 0 deduplicates all layer replicas (denoted as global file-level deduplication with replication or *GF-R*) while B-mode 3 does not deduplicate any layer replicas.

To evaluate how DupHunter works with block-level deduplication, we integrate B-mode 0 with `VDO`. For each D-server, all unique files are stored on a local `VDO` device. Hence, in that mode DupHunter provides global file-level deduplication and local block-level deduplication (*GF+LB-R*).

We also evaluate DupHunter with an erasure coding policy instead of replication. We combine B-mode 0 with `Ceph` such that each D-server stores unique files on a `Ceph` erasure coding pool with global block-level deduplication enabled. We denote this scheme as *GB-EC*. We compare each scheme to Bolt [41] with 3-way replication as our baseline (*No-dedup*).

6.2 Deduplication Ratio vs. Performance

We first evaluate DupHunter's performance/deduplication ratio trade-off for all of the above described deduplication schemes. For the replication scenarios, we use 3-way replication and for GB-EC, we use a (6,2) Reed Solomon code [53, 56]. Both replication and erasure cod-

[2] The original player generates random or zeroed data for layers.

Table 3: Dedup. ratio vs. GET layer latency.

Mode	Dedup. ratio	Performance improvement (P-servers)
B-mode 1	1.5	1.6×
S-mode	1.3	2×
B-mode 2	1.2	2.6×
B-mode 3	1	2.8×
B-mode 0	Dedup ratio	Performance degradation (D-servers)
	GF-R (Global file-level [3 replicas])	
	2.1	-1.03 ×
	GF+LB-R (Global file- and local block-level [3 replicas])	
	3.0	-2.87×
	GB-EC (Global block-level [Erasure coding])	
	6.9	-6.37×

ing policies can sustain the loss of two nodes. We use 300 clients spread across 10 nodes and measure the average GET layer latency across the four production workloads. Table 3 shows the results normalized to the baseline.

We see that all four performance modes of DupHunter (B-mode 1, 2, and 3, and S-mode) have better GET layer performance compared to No-dedup. B-mode 1 and 3 reduce the GET layer latency by 1.6× and 2.8×, respectively. This is because the prefetch cache hit ratio on P-servers is 0.98 and a high cache hit ratio significantly reduces disk accesses. B-mode 3 has the highest GET layer performance but does not provide any space savings since each layer in B-mode 3 has three full replicas. B-mode 1 and 2 maintain only one and two layer replicas for each layer, respectively. Hence, B-mode 1 has a lower performance improvement (i.e., 1.6×) than B-mode 2 (i.e., 2.6×), but has a higher deduplication ratio of 1.5×. S-mode lies between B-mode 1 and 2 in terms of the deduplication ratio and performance. This is because, in S-mode, popular layers have three layer replicas while cold layers only have a single replica.

Compared to the above four modes, B-mode 0 has the highest deduplication ratio because *all* layer replicas are deduplicated. Consequently, B-mode 0 adds overhead to GET layer requests compared to the baseline performance. As shown in Table 3, if file-level deduplication and 3-way replication are used, the deduplication ratio of B-mode 0 is 2.1 while the GET layer performance is 1.03× slower.

If block-level deduplication and block-level compression are used (GF+LB-R), the deduplication ratio increases to 3.0 while the GET layer performance decreases to 2.87×. This is because of the additional overhead added by restoring the layer's files prior to restoring the actual layer. Compared to replication, erasure coding naturally reduces storage space. The deduplication ratio with erasure coding and block-level deduplication is the highest (i.e., 6.9). However, the GET layer performance decreases by 6.37× because to restore a layer, its containing files, which are split into data chunks and spread across different nodes, must first be restored.

Overall, DupHunter, even in B-mode 0, significantly decreases the layer restoring overhead compared to the naive approaches shown in Table 1 in §3.2. For example, DupHunter B-mode 0 with VDO (the GF+LB-R scheme) has a GET layer latency only 2.87× slower than the baseline compared to a the VDO-only scheme which is 60× slower compared to the baseline.

6.3 Cache Effectiveness

Next, we analyze DupHunter's caching behavior. We first study the prefetch cache and then the preconstruct cache.

6.3.1 Prefetch cache

To understand how the prefetch cache improves the P-servers' performance, we first show its hit ratio compared to two popular cache algorithms: LRU [50] and ARC [43]. Moreover, we compare DupHunter's prefetch cache with another prefetch algorithm, which makes predictions based on PUT requests [11] (denotes as ARC+P-PUT). Both of these algorithms are implemented on ARC since ARC outperforms LRU. DupHunter's prefetch algorithm, based on user behavior (UB), is denoted as ARC+P-UB. We vary the cache sizes from 5% to 15% of each workload's unique dataset size. Figure 8 shows the results for the four production workloads (Dal, Syd, Lon, and Fra).

For a cache size of 5%, the hit ratios of LRU are only 0.59, 0.58, 0.27, and 0.10, respectively. ARC hit ratios are higher compared to LRU (e.g., 1.6× Lon) because after a user pulls a layer, the user is not likely to repull this layer in the future as it is locally available. Compared to LRU, ARC maintains two lists, an LRU list and an LFU list, and adaptively balances them to increase the hit ratio.

ARC+P-PUT improves the ARC hit ratio by 1.9× for Lon. However, ARC+P-PUT only slightly improves the hit ratio for the other workloads. This is because ARC+P-PUT acts like a write cache which temporally holds recently uploaded layers and waits for the clients that have not yet pulled these layers to issue GET requests. This is not practical because the layer reuse time (i.e., interval between a PUT layer request and its subsequent GET layer request) is long. For example, the reuse time is 0.5 hr for Dal on average based on our observation. Moreover, ARC+P-PUT ignores the fact that some clients always repull layers. DupHunter's ARC+P-UB achieves the highest hit ratio. For example, ARC+P-UB's hit ratio for Dal is 0.89, resulting in a 4.2× improvement compared to ARC+P-PUT.

As shown in Figure 8, the hit ratio increases as the cache size increases. For example, when cache size increases from 5% to 15%, the hit ratio for ARC under workload Lon increases from 0.44 to 0.6. ARC+P-UB achieves the highest hit ratio of 0.96 for a cache size of 15% under workload Lon. Overall, this shows that by exploiting user behavior ARC+P-UB can achieve high hit ratios, even for smaller cache sizes.

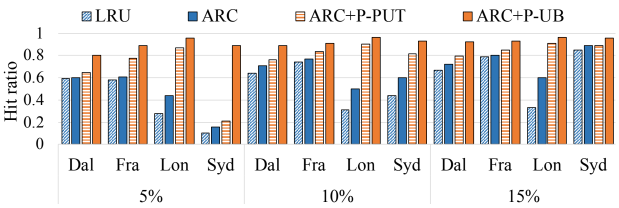

Figure 8: Cache hit ratio on P-servers with different cache algorithms.

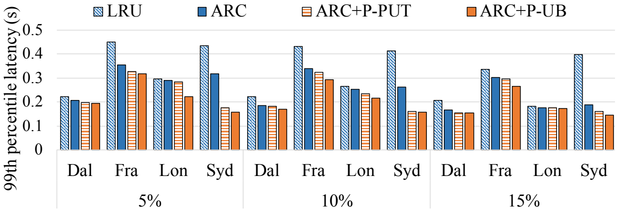

Figure 9: 99^{th} percentile GET layer latency of P-servers.

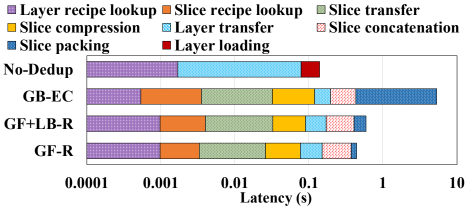

Figure 10: Layer restoring latency breakdown (X-axis is log-scale).

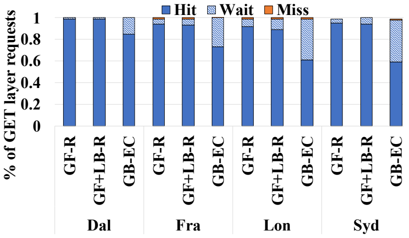

Figure 11: Preconstruct cache hit ratio.

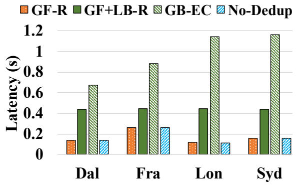

Figure 12: Performance of D-servers.

Figure 9 shows the 99^{th} percentile of GET request latencies for P-servers with different cache algorithms. The GET layer latency decreases with higher hit ratios. For example, when the cache size increases from 5% to 15%, the 99^{th} percentile latencies decrease from 0.19 s to 0.15 s for DupHunter's ARC+P-UB under workload Dal and the cache hit ratio increases from 0.8 to 0.92. Moreover, when the cache size is only 5%, ARC+P-UB significantly outperforms the other 3 caching algorithms. For example, ARC+P-UB reduces latency by 1.4 × compared to LRU for workload Fra. Overall, ARC+P-UB can largely improve GET layer performance for P-servers with a small cache size.

6.3.2 Preconstruct cache

For the preconstruct cache to be effective, layer restoring must be fast enough to complete within the time window between the GET manifest and GET layer request.

Layer restoring performance. To understand the layer restoring overhead, we disable the preconstruct cache and measure the average GET layer latency when a layer needs to be restored on D-servers. We evaluate GB-EC, GB+LB-R, and GF-R and compare it to No-dedup.

We break down the average reconstruction latency into its individual steps. The steps in layer reconstruction include looking up the layer recipe, fetching and concatenating slices, and transferring the layer. Fetching and concatenating slices in itself involves slice recipe lookup, slice packing, slice compression, and slice transfer. No-dedup contains three steps: layer metadata lookup, layer loading from disk to memory, and layer transfer.

As shown in Figure 10, GF-R has the lowest layer restoring overhead compared to GF+LB-R and GB-EC. It takes 0.44 s to rebuild a layer tarball for GF-R. Compared to the No-Dedup scheme, the GET layer latency of GF-R increases by 3.1×. Half of the GET layer latency is spent on slice concatenation. This is because slice concatenation involves writing each slice into a compressed tar archive, which is done sequentially. Slice packing and compression are faster, 0.07 s and 0.05 s, respectively, because slices are smaller and evenly distributed on different D-servers.

For the GF+LB-R scheme, it takes 0.55 s to rebuild a layer. Compared to GF-R, adding local block-level deduplication increases the overall overhead by up to 1.4× due to more expensive slice packing. It takes 0.18 s to pack a slice into an archive, 2.7× higher than GF-R's slice packing latency as reading files from the local VDO device requires an additional file restoring process.

The GB-EC scheme has the highest layer restoring overhead. The bottleneck is again slice packing which takes 5 s. This is because each file is split into four data chunks, distributed on different D-servers, and deduplicated. To pack a slice, each involved file needs to be reconstructed from different D-servers and then written to a slice archive, which incurs considerable overhead.

Preconstruct cache impact. To understand how the preconstruct cache improves D-servers' GET layer performance, we first show its hit ratio on D-servers with three deduplication schemes (GF-R, GF+LB-R, and GF-EC). The cache size is set to 10% of the unique dataset.

Figure 11 shows the preconstruct cache hit ratio breakdown. **Hit** means the requested layer is present in the cache while **Wait** means the requested layer is in the

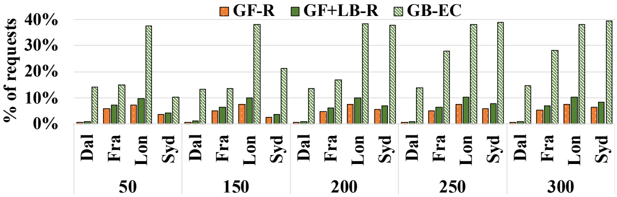

Figure 13: Request wait ratio with different number of clients.

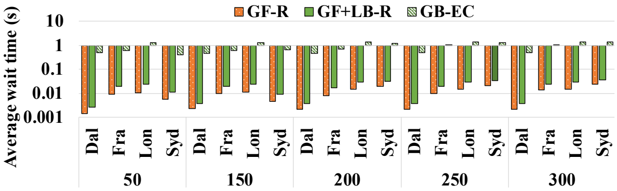

Figure 14: Average wait time with different number of clients (Y-axis is log-scale).

process of preconstruction and the request needs to wait until the construction process finishes. **Miss** means the requested layer is neither present in the cache nor in the process of preconstruction. As shown in the figure, GF-R has the highest hit ratio, e.g., 0.98 for the `Dal` workload. Correspondingly, GF-R also has the lowest wait and miss ratios because it has the lowest restoring latency and a majority of the layers can be preconstructed on time.

Note that the miss ratio of the preconstruct cache is slightly lower than that of the perfetch cache across all traces. This is because we use an in-memory buffer to hold the layer archives that are in the process of construction to avoid disk I/O. After preconstruction is done, the layers are flushed to the on-disk preconstruct cache. In this case, many requests can be served directly from the buffer and consequently, layer preconstruction does not immediately trigger cache eviction like layer prefetching. The preconstruct cache eviction is delayed til the layer preconstruction finishes.

GF+LB-R shows a slightly higher wait ratio than GF-R. Eg., the wait ratios for GF-R and GF+LB-R are 0.04 and 0.06, respectively under workload `Syd`. This is because the layer restoring latency of GF+LB-R is slightly higher than GF-R. GB-EC's wait ratio is the highest. Under workload `Syd`, 39% of `GET` layer requests are waiting for GB-EC as layers cannot be preconstructed on time.

Figure 12 shows the corresponding average `GET` layer latencies of D-servers compared to No-dedup. GF-R and GF+LB-R increase the latency by 1.04× and 3.1×, respectively, while GB-EC adds a 5× increase. This is due to GB-EC's high wait ratios.

Scalability. To analyze the scalability of the preconstruct cache under higher load, we increase the number of concurrent clients sending `GET` layer requests, and measure the request wait ratio (Figure 13) and the average wait time (Figure 14).

Under workload `Fra` and `Syd`, the wait ratio for GB-EC increases dramatically with the number of concurrent clients. For example, the wait ratio increases from 15% to 28% as the number of concurrent clients increases from 50 to 300. This is because the layer restore latency for GB-EC is higher and with more concurrent client requests, more requested layers cannot be preconstructed on time. Under workload `Lon` and `Dal`, the wait ratio for GB-EC remains stable. This is because the client requests are highly skewed. A small number of clients issue the majority of `GET` layer requests. Correspondingly, GB-EC also has the highest wait time. Under workload `Fra` and `Syd`, the average wait time increases from 0.6 s to 1.1 s and 0.4 s to 1.4 s respectively as the number of clients increases from 50 to 300 for GB-EC.

Although some layers cannot be preconstructed before the `GET` layer requests arrive, the preconstruct cache can still reduce the overhead because layer construction starts prior to the arrival of the `GET` requests. This is shown by the fact that the wait times are significantly lower than the layer construction times. For GF-R and GF+LB-R, the average wait times are only 0.001 s and 0.003 s, respectively under workload `Dal`. When the number of concurrent clients increases, the average wait time of GF-R and GF+LB-R remains low. This means that the majority of layers can be preconstructed on time for both GF-R and GF+LB-R, and the layers that cannot be preconstructed on time do not incur high overhead.

7 Conclusion

We presented DupHunter, a new Docker registry architecture that provides flexible and high performance deduplication for container images and reduces storage utilization. DupHunter supports multiple configurable deduplication modes to meet different space saving and performance requirements. Additionally, it parallelizes layer reconstruction locally and across the cluster to further mitigate overheads. Moreover, by exploiting knowledge of the application domain, DupHunter introduces a two-tier storage hierarchy with a novel layer prefetch/preconstruct cache algorithm based on user access patterns. DupHunter's prefetch cache can improve `GET` latencies by up to 2.8× while the preconstruct cache can reduce the restore overhead by up to 20.9× compared to the state of the art.

Abstract

We propose an Online-Model based Scheme for Cache Allocation for shared cache servers among cloud block storage devices. *OSCA* can find a near-optimal configuration scheme at very low complexity improving the overall efficiency of the cache server. *OSCA* employs three techniques. First, it deploys a novel cache model to obtain a miss ratio curve (MRC) for each storage node in the cloud infrastructure block storage system. Our model uses a low overhead method to obtain data reuse distances from the ratio of re-access traffic to the total traffic within a time window. It then translates the obtained reuse distance distribution into miss ratio curves. Second, knowing the cache requirements of storage nodes, it defines the total hit traffic metric as the optimization target. Third, it searches for a near optimal configuration using a dynamic programming method and performs cache reassignment based on the solution. Experimental results with real-world workloads show that our model achieves a Mean Absolute Error (MAE) comparable to existing state-of-the-art techniques, but we can do without the overheads of trace collection and processing. Due to the improvement of hit ratio, *OSCA* reduces IO traffic to the back-end storage server by 13.2% relative to an equal-allocation-to-all-instances policy with the same amount of cache memory.

1 Introduction

With widespread deployment of the cloud computing paradigm, the number of cloud tenants have significantly increased during the past years. To satisfy the rigorous performance and availability requirements of different tenants, cloud block storage (CBS) systems have been widely deployed by cloud providers (e.g., AWS, Google Cloud, Dropbox, Tencent, etc.). As revealed in previous studies [4, 13, 18, 40], cloud infrastructures typically employ cache servers, consisting of multiple cache instances competing for the same pool of resources. Judiciously designed cache policies play an important role in ensuring the stated service level objectives (SLO).

The currently used even-allocation policy called EAP or equal cache partitioning [41] determines the cache requirements in advance according to the respective subscribed SLOs and then provisions cache resources for each cache instance. However, this static configuration method is often suboptimal for the cloud environment and induces resource wastage, because the cloud I/O workloads are commonly highly-skewed [3, 16, 20].

In this paper, we aim to address the management of cache resources shared by multiple instances of a cloud block storage system. We propose an Online-Model Scheme for dynamic Cache Allocation (OSCA) with miss ration curves (MRC). *OSCA* does not require to separately obtain traces to construct MRCs. *OSCA* searches for a near-optimal configuration scheme at a very low complexity and thus improves the overall effectiveness of cache service. Specifically, the core idea of *OSCA* is three-fold. First, *OSCA* develops an online cache model based on re-access ratio (Section 3.2) to obtain the cache requirements of different storage nodes with low complexity. Second, *OSCA* uses the total hit traffic as the metric to gauge cache efficiency as the optimization target. Third, *OSCA* searches for an optimal configuration using dynamic programming method. Our approach is complementary to the most recent on-line scheme SHARDS [34]. It can achieve a suitable trade-off between computation complexity and space overhead (Section 2.3).

As the key contribution, we propose a Re-Access Ratio based Cache Model (*RAR-CM*) to construct the MRC and calculate the space requirements of each cache instance. Compared with previous models, *RAR-CM* does not need to collect and process traces, which can be expensive in many scenarios. Instead, we shift the cost of processing I/O traces to that of tracking the unique data blocks in a workload (i.e., the working set), and this proves advantageous when the number of unique blocks can be efficiently processed in memory. We experimentally demonstrate the efficacy of *OSCA* using an in-house CBS simulator with I/O traces collected from a CBS production system. We are in the process of releasing those traces to the SNIA IOTTA repository [27].

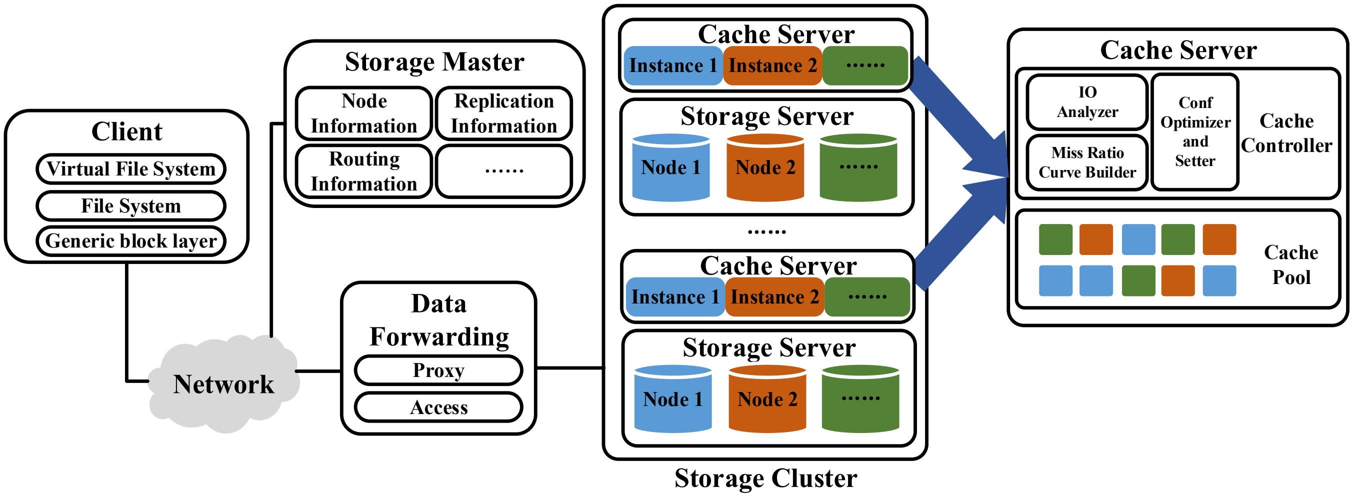

Figure 1: The architectural view of a cloud block storage system (CBS), which includes a client cloud disk layer, Data Forwarding layer, and Storage Cluster containing multiple storage servers each of which is paired with a cache server. The cache server is divided into multiple cache instances respectively responsible for the nodes (i.e., disks) in the corresponding storage server.

The rest of this paper is structured as follows. In Section 2, we introduce the background and motivation of this study and take a detailed look at existing cache modeling methods. In Section 3, we elaborate on the details of our *OSCA* cache management policy. In Section 4, we present our experimental method and the results. In Section 5, we discuss the related work and conclude in Section 6.

2 Background and Motivation

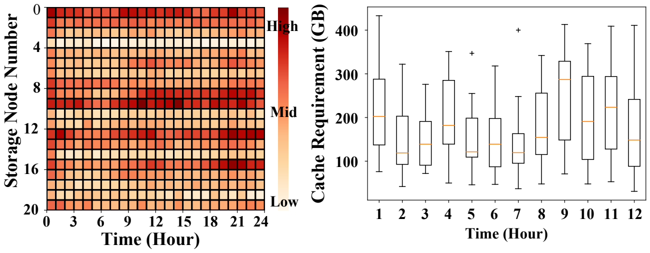
2.1 Cloud Block Storage

To provide tenants with a general, reliable, elastic and scalable block-level storage service, cloud block storage (CBS) has been developed and deployed extensively by the majority of cloud providers. CBS is made up of client layer, data forwarding layer, and storage server layer. The client layer presents tenants with the view of elastic and isolated logic cloud disks allocated according to the tenants' configuration and mounted to the client virtual machines. The data forwarding layer maps and forwards I/O requests from the client-end to the storage server-end. The storage server layer is responsible for providing physical data storage space and it typically employs replication to ensure data reliability and availability. More specifically, a CBS contains multiple components, the client, the storage master, the proxy and access server, and the storage server (as shown in Fig. 1). These components are interconnected through fast fiber-optic networks. The client provides the function of cloud disk virtualization and presents the view of cloud disks to tenants. The storage master (also called the metadata server) assumes the management of node information, replication information, and data routing information. The proxy server is responsible for external and internal storage protocol conversion. In our work, the I/O trace collection tasks are conducted on the proxy server. The access server is responsible for I/O routing that determines which storage node should an access be assigned to based on the MD5 digest calculated from the information of the record. It uses consistent hashing to map each MD5 digest to a positive integer denoting storage node. The storage server consists of multiple failure domains to reduce the probability of correlated failures. Storage servers allocate physical space from conventional hard disk drives, whose performance alone often cannot meet the requirements of cloud applications dominated by random accesses. Therefore, a CBS system typically employs a cache server (comprised of SSDs [18], NVMs [11], or other emerging storage technologies [20]) to improve performance.

As indicated in Fig. 1, the cache server includes a cache controller and a cache pool. To ensure scalability, there are often multiple cache instances, each associated with one storage node, at the cache server. The user-perceived cloud disk is a collection of logical blocks commonly spread across several physical node disks. A single physical disk is thus shared by multiple virtual disks. As a result, the accesses to a physical disk are mixed patterns. A cache instance is deployed to perform caching for each physical disk and our task is to partition the cache resource among all the cache instances.

2.2 Cache Allocation Scheme

The cache allocation scheme, which is responsible for cache resource assignment, largely influences the efficiency of the cache server. Even-allocation policy (EAP), where each block storage instance receives the same pre-determined amount of cache, is typically used in real production systems for its simplicity. The EAP first analyzes the total cache space requirements in advance according to the defined service-level objectives, and then uniformly allocates cache resources for each cache instance. In essence, it is a static allocation policy and suffers from cache underutilization if over-provisioned and performance degradation if under-provisioned, especially in the cloud environment featuring highly-skewed workloads with unpredictable and irregular dynamics [3, 16, 20]. As shown in Fig. 2 (a), we randomly selected 20 storage nodes and present their IO traffic lasting a period of 24 hours. The figure confirms that the traffic is unevenly distributed to the storage nodes in the realistic CBS production system. Presented from a different perspective, Fig. 2 (b) shows the distribution of cache requirements of those 20 storage nodes during the first 12 hours in order to reach for a level of 95% hit ratio. Again, it shows each storage node has different cache requirements at different times.



(a) (b)

Figure 2: Fig. (a) presents the frequency of accesses over storage nodes in a typical 24 hour period observed in our traces. The color indicates the intensity of accesses, measured by requests per seconds arriving at each storage node in one-hour time window. The darker the red color in the figure, the more intensive the I/O traffic is. Fig. (b) shows the distribution of cache requirements of those 20 storage nodes during the first 12 hours in order to reach for a level of 95% hit ratio. The orange horizontal line in each box denotes the median cache requirement of the 20 storage nodes, while the bottom and top side of the box represent the quartiles and the lines that extend out of the box (whiskers) represent data outside the upper and lower quartiles.

To improve this policy via ensuring more appropriate cache allocations, there have been proposed two broad categories of solutions. The first category is intuition-based policies such as TCM [19], REF [42], which are **qualitative methods** based on intuition or experience. These policies often provide a feasible solution to the combined optimization problem at an acceptable computation and space cost. For example, according to memory access characteristics, TCM categorizes threads as either latency-sensitive or bandwidth-sensitive and correspondingly prioritizes the latency-sensitive threads over the bandwidth-sensitive threads as far as cache allocation concerns. Such coarse grained qualitative methods are heavily dependent on prior reliable experiences or workload regularities. Therefore, their efficacy is not guaranteed for cloud workloads which are diverse and constantly changing.

The other category is model-based policies, which are **quantitative methods** enabled by cache models typically described by Miss Rate Curves (MRCs), which plot the ratio of cache misses to total references, as a function of cache size [14, 29, 33, 34]. Compared with intuition-based policies, model-based policies are based on cache models containing information about dynamic space requirements of each cache instance and thus are to result in a near-optimal solution. The biggest challenge with quantitative methods lies in constructing accurate miss rate curves at practically acceptable computational and space complexity in an online manner. Most cache models rely on offline analysis due to the enormous computation complexity and space overhead, limiting their practical applicability. A host of research efforts have been conducted to cost-effectively construct miss rate curves with the goal to enable realistic online MRC profiling [4, 29, 31, 33, 34]. Especially, the most recent proposed Spatially Hashed Approximate Reuse Distance Sampling (SHARDS) [34] is an on-line cache model which takes constant space overhead and significantly reduced computational complexity, yet still generating highly accurate MRCs. (Section 2.3 presents more details about SHARDS).

2.3 Existing Cache Modeling Methods

The biggest obstacle to apply an optimal policy to a real system is the huge computational complexity and storage overhead involved to construct accurate cache models which are used to obtain the space requirement of each cache instance. Existing commonly-used cache modeling methods can be divided into two categories, the cache modeling based on locality quantization method and simulation method.

Locality quantization method analyzes the locality characteristics (e.g., Footprint [39], Reuse Distance [34], Average Eviction Time [14], etc.) of workloads and then translates these characteristics into miss ratio curves [7]. The miss ratio curve indicates the miss ratio corresponding to different cache sizes, which can be leveraged to quantitatively determine the cache requirements of different storage nodes. The most commonly used locality characteristic is the Reuse Distance Distribution (as shown in Fig. 3). The reuse distance is the amount of unique data blocks between two consecutive accesses to the same data block. For example, suppose a reference sequence is A-B-C-D-B-D-A, the reuse distance of data block A is 3 because the unique data set between two successive accesses to A is {B, C, D}. The reuse distance is workload-specific and its distribution might change over time.

The distribution of reuse distance has a great influence on the cache hit ratio. More specifically, a data block hits the cache only when its reuse distance is smaller than its eviction distance which is defined as the amount of unique

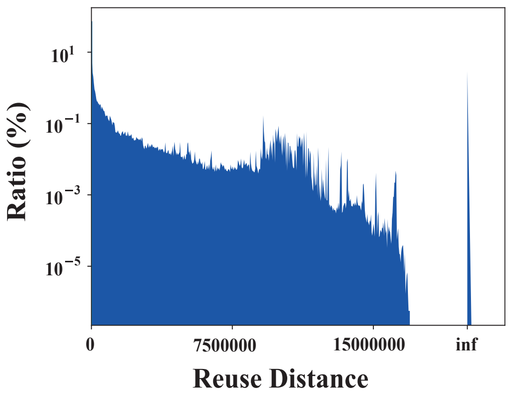


Figure 3: Reuse distance distribution of a one-day long trace from a CBS storage node.

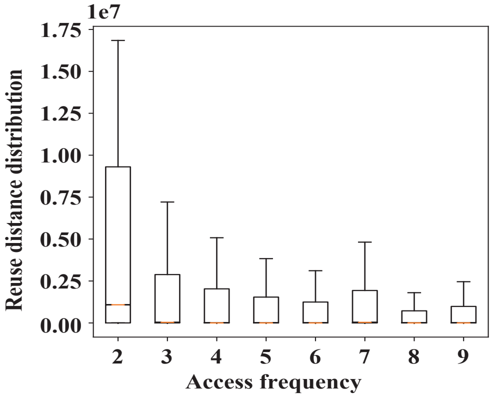

Figure 4: The reuse distance distribution of blocks of a one-day long trace from a CBS storage node, grouped by the access frequencies.

blocks accessed from the time it enters the cache to the time it is evicted from the cache. For a given sequence of block reference, the eviction distance of each block is dependent on the adopted cache algorithm. Different cache algorithms could lead to different eviction distances even for the same block in the reference sequence. The LRU algorithm uses one list and always puts the most recently used data block at the head of the list and only evicts the least recently used block at the tail of the list. As a result, the eviction distance of the most recently used block is equal to the cache size. 2Q [26], ARC [23], and LIRS [17] use two-level LRU lists and a data block can enter the second level lists only when it has been hit in the first level list before. Therefore, these algorithms can result in larger eviction distance for the blocks which have been accessed twice. Similarly, MQ [45] uses multiple-level LRU lists and it causes data blocks with more access frequencies to have larger eviction distances.

In this paper, we focus on modeling LRU algorithm for two reasons. First, LRU is widely deployed in many real cloud caching systems [15, 21]. Second, based on our analysis results of realistic cloud cache, when the cache size becomes larger than a certain size, the advanced algorithms would degenerate to LRU. Fig. 4 presents the reuse distance distribution of blocks with different access frequencies using a one-day long trace from a CBS storage node. The trace is collected from Tencent CBS [30] and we are in the process of making it publicly available via the SNIA IOTTA repository [27]. The bottom and top of each box represent the minimum and maximum reuse distance. The reuse distances of blocks whose access frequencies are larger than 2 are smaller than 0.75×10^7. Therefore, when the cache size becomes larger than 229 GB (0.75×10^7 blocks, each size being 32 KB), the data blocks whose frequencies are larger than 2 can all be hit in the LRU cache because their reuse distances are smaller than the cache size. Other advanced algorithms (e.g., 2Q , ARC, and LIRS) which cause blocks whose occurrences are larger than 2 to have larger eviction distance would degenerate to LRU [44]. Therefore, in our caching system where cache size for each storage node is close to 229 GB (assuming EAP is deployed), the performance differences between LRU and other algorithms are negligible.

Existing cache modeling methods (ours included) calculate the hit ratio of the LRU algorithm as the discrete integral sum of the reuse distance distribution (from zero to the cache size) curve (as shown in Eq. 1).

$$hr(C) = \sum_{x=0}^{C} rdd(x) \tag{1}$$

In the above equation, *hr(C)* is the hit ratio at cache size C and *rdd(x)* denotes the distribution function of reuse distance. However, obtaining the reuse distance distribution has an $O(N * M)$ complexity, where N is the total number of references in the access sequence and M is number of the unique data blocks of references [22]. Recent studies have proposed various ways to decrease the computation complexity to $O(N * log(n))$ using Search Tree [24], Scale Tree [43], Interval Tree [1]. These methods use a balanced tree structure to get a logarithmic search time upon each reference to calculate block reuse distances.

SHARDS [34], further decreases the computation complexity with fixed amount of space. To build MRCs, SHARDS first selects a representative subset of the traces through hashing block addresses. It then inputs the selected traces to a conventional cache model to produce MRCs. Since SHARDS only needs to process a subset of the traces, it significantly reduces the computation overheads and memory space to host the traces. Therefore, SHARDS has the potential to be applied in an on-line manner. All sampled traces can be stored in a given amount of memory by dynamically adjusting the sample ratio. It should be noted that it requires to rescale up the results to obtain the eventual reuse distance for the original traces.

In this paper, we propose an on-line cache model called

RAR-CM to build MRC which is based on a metric called re-access ratio. Our approach does not rely on collecting traces beforehand. Both our approach and SHARDS can be practically applied on-line. Our approach is different from SHARDS in the following aspects. First, SHARDS uses a sampled subset of traces to construct MRCs, while our approach processes I/O requests inline and does not store or process a separate I/O trace. Second, on average it takes $O(lg(M*R))$ asymptotic complexity for SHARDS to update the information in the balanced tree for every sampled block access, where M is the total number of unique blocks in the trace. Our approach only requires to update two counters and thus is $O(1)$.

Table 1 summarizes the comparison between SHARDS and *RAR-CM* in four primary aspects. M, n, and R denotes the total number of unique blocks, the maximum number of records that can be contained in the fixed memory(SHARDS), and the sampling ratio (SHARDS). From the table, we can see that both SHARDS and *RAR-CM* can potentially be applied to construct MRCs in an on-line manner. We can choose to use either of them based on specific scenarios. A general guidance is if we are more concerned about saving computational resources and the available memory can hold support all unique blocks, then our *RAR-CM* is the choice. If we are more constrained by memory and computing resources is not an issue (e.g., we have GPU available), then SHARDS is the choice. In fact, SHARDS and *RAR-CM* are two similar and complementary approaches that can achieve an optimal trade-off point between computation complexity and space overhead. As can be seen from Table 1, one major disadvantage with our approach is that it requires $O(M)$ space to store the information about each unique block. Therefore, in cases where memory is constrained and the working set is relatively large, SHARDS is a better choice.

Table 1: The comparison of *RAR-CM* and SHARDS. M is the number of unique data blocks in the access stream. R denotes the sampling ratio in SHARDS, and n is the number of the sampled unique blocks in the fixed memory. Reuse distribution generation complexity is O(1) for both methods.

	SHARDS	*RAR-CM*
Use full trace	No	Yes
Space Complexity	$O(M*R)$ fixed sample $O(1)$ fixed memory	$O(M)$
Block Access Overhead	$O(log(M*R))$ fixed sample $O(log(n))$ fixed memory	$O(1)$

Simulation-based cache modeling and recently proposed miniature simulation based on the idea of SHARDS [33] need to concurrently run multiple simulation instances to determine the cache hit ratio in different cache sizes. While SHARDS can be applied on-line to process currently sampled traces to obtain the miss ratio curve, the miniature simulation constructs the miss ratio curves based on collected trace beforehand, which could incur no-trivial overhead. We have conducted an experiment with the miniature simulation [33]. Specifically, we run 20 simulation routines (each routine starts 20 threads) simultaneously on a 12-core CPU (i.e., Intel Xeon CPU E5-2670 v3), and this method takes around 69 minutes to analyze a one-day-long IO trace file and most of the time is consumed in trace reading (1.067 µs / record) and IO mapping (2.406 µs / record).

3 Design and Implementation

3.1 Design Overview

OSCA performs three steps, online cache modeling, optimization target defining, and the optimal configuration searching. Fig. 5 illustrates the overall architecture of *OSCA*. Upon receiving a read request from the client, CBS first partitions and routes the request to the storage node and finds the data in the index map of the corresponding cache instance. If it is found in the map on the cache server, the data will be returned to the client directly, and the request will not need to go to the storage server node. Otherwise, the data located in the corresponding physical disk is fetched and returned. A write request is always first written to the cache, and then flushed to the back-end HDD storage asynchronously. All I/O requests are monitored and analyzed by the cache controller for cache modeling. Then the cache controller will find the optimal configuration scheme according to the cache model and the optimization target and finally reassign the cache resource for each cache instance periodically.

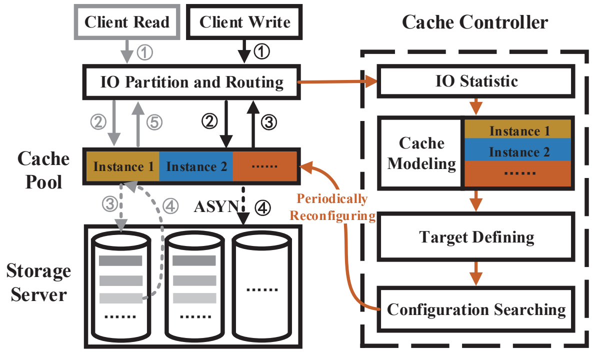

Figure 5: The overall architecture of *OSCA*. Each cache instance is paired with a physical disk which provides storage space for cloud disks. The cache controller monitors the access traffic to physical disks and construct cache models to guide the reassignment of cache resources among cache instances.

3.2 Re-access Ratio Based Cache Model

The main purpose of cache modeling is to obtain the miss ratio curve, which describes the relationship between miss ratio and cache size. The resultant curve can be used in practical applications to instruct cache configurations. We propose a novel online re-access ratio cache model (*RAR-CM*), which can be constructed without the computational overhead of trace collection and processing, when compared with existing cache models. Fig. 6 shows the main components of *RAR-CM*. For a request to block B, we first check its history information in a hash map and obtain its last access timestamp (*lt*) and last access counter (*lc*, a 64-bit number denoting the total number of requests which have been seen so far at the time of last access timestamp, or equivalently the block sequence number of the last reference to block B). We then use *lt*, *lc* and *RAR* curve to calculate the reuse distance of block B. Then the resultant reuse distance is used to calculate the miss ratio curve.

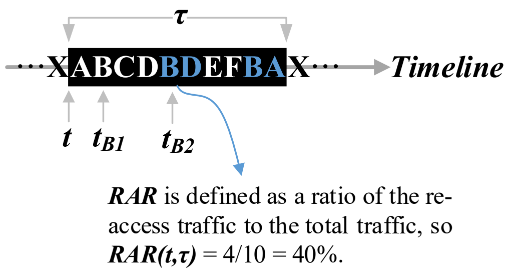
lc(B) : last access counter at block B
rd(B) : reuse distance of block B
hr(c) : the hit ratio of cache size c
mr: miss ratio
rdd(x) : the ratio of data with the reuse distance x

Figure 6: The overview of re-access ratio based cache modeling. It calculates the reuse distance using re-access ratio and then constructs the miss rate curve based on reuse distance.

RAR, which is defined as the ratio of the re-access traffic to the total traffic during a time interval τ after time t, is expressed as $RAR(t,\tau)$. It essentially represents a metric reflecting how blocks in the following time interval are re-accessed. Fig. 7 shows the re-access ratio during a time interval τ with block access sequence {A, B, C, D, B, D, E, F, B, A}. The number of reaccessed blocks (which includes reaccess to the same block, e.g., B) is 4 (the blue letters marked in Fig. 7), and the total traffic is 10. Therefore, we obtain $RAR(t,\tau)$ = 4 / 10 = 40%.



τ
···XABCDBDEFBAX···
Timeline
t
tB1
tB2
RAR is defined as a ratio of the re-access traffic to the total traffic, so RAR(t,τ) = 4/10 = 40%.

Figure 7: The definition of re-access ratio of an access sequence during a time period $[t, t+\tau]$.

We use the obtained *RAR* for cache modeling because it has a number of favorable properties:

- It can be easily translated to the locality characteristics.
- It can be obtained with low overhead given it's complexity of O(1).
- It can be stored with low overhead of memory footprint.

Locality characteristics. *RAR* can be translated to the commonly used footprint and reuse distance characteristics. As mentioned, the reuse distance is the unique accesses between two consecutive references to the same data block. Assuming that the time interval between two consecutive references of block B is τ, then the reuse distance of block B, $rd(B)$, can be represented by Eq. 2, where $RAR(t,\tau)$ and $T(t,\tau)$ means the re-access ratio and total block accesses between the two consecutive references to block B, respectively. t indicates the last access timestamp of block B. For instance, to calculate the reuse distance of the second B at time t_{B2}, we use $t_{B2} - t_{B1}$ as the τ value for RAR function and 3 as the value of $T(t,\tau)$ in Eq. 2.

$$rd(B) = (1 - RAR(t,\tau)) \times T(t,\tau) \tag{2}$$

Complexity of O(1). Fig. 8 describes the process of obtaining the re-access ratio curve. $RAR(t_0,t_1\text{-}t_0)$ is calculated by dividing the re-access-request count (RC) by the total request count (TC) during $[t_0,t_1]$. To update RC and TC, we first lookup the block request in a hash map to determine whether it is a re-access-request. If found, it is a re-access-request and both TC and RC should be increased by 1. Otherwise, only TC is increased by 1.

RAR(t_0 , t_1-t_0) = RC / TC
t_0 : the start timestamp
t_1 : current timestamp
B : the block-level request
TC : total request count
RC : the re-access-request count

Figure 8: The process of obtaining re-access ratio curve. For each incoming block access, it only needs to update two counters, i.e., RC and TC.

Memory footprint. Fig. 9 shows the RAR curves calculated at the end of each of the six trace days. As can be seen, those curves have similar shapes and can be approximated by logarithmic curves which have the form of $RAR(\tau) = a * log(\tau) + b$, where τ is the time variable. Therefore, we only store the two parameters to represent the curve, which has negligible overhead. Note that the presented logarithmic curves are obtained from our traces. Others ways of compactly representing the distribution are possible (e.g., a Weibull distribution [36]). Moreover, for different workloads the shapes of the *RAR* curves may vary and correspondingly we could approach that with other distributions.

In summary, we calculate the *RAR* curve using a hash map to decide whether a block reference is a re-access or not and then based on the *RAR* curve we obtain the reuse distance distribution according to Eq. 2. Finally, the reuse distance distribution is translated to the miss ratio curve leveraging Eq. 1. With the miss ratio curve in place, we then perform cache reconfiguration. Ideally, we want to obtain all the *RAR* curve at each timestamp which is cost-ineffective. Fortunately, we observe that $RAR(t, \tau)$ is relatively insensitive to time t by analyzing a week-long cloud block storage trace (a mixed-trace consisting of tens of thousands of cloud disks' requests). Specifically, although cloud workloads are highly dynamic, we observe that the RAR curves are stable over a couple of days, which means changes of *RAR* curve are negligible over days. Therefore, in our experiment we only calculate the *RAR* curve once a day to represent the *RAR* curve for the next coming day. Specifically, assume the starting time of next day is t_0 and a block is accessed at time t_1. Then we use $t_1 - t_0$ as input to the *RAR* curve function to calculate it's reuse distance using Eq. 2. Note that if the block is accessed the first time, then it's reuse distance is to set to infinitely large, meaning it is a miss.

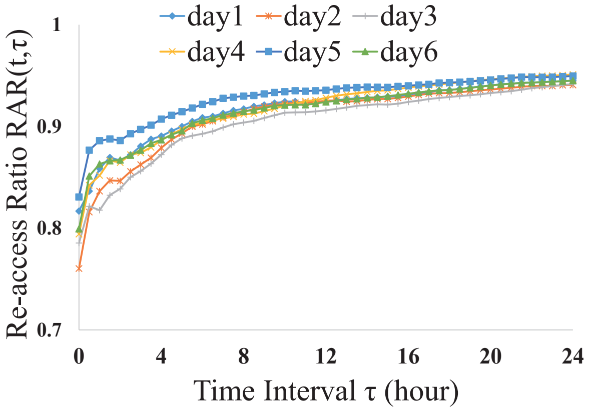

Figure 9: The *RAR* curves of the six days are similar and can be fitting-curved using as logarithmic functions. These *RAR* curves are calculated based on the traces collected from one storage node of Tencent CBS.

3.3 Optimization Target

After obtaining cache modeling, we should define a cache efficiency function as the optimization target. Previous studies have suggested a number of different optimization target (e.g. RECU [41], REF [42], et al.). For instance, RECU considers the elastic miss ratio baseline (EMB) and the elastic space baseline (ECB) to balance tenant-level fairness and the overall performance. Considering our case being cloud server-end caches, in this work we use the function E in Eq. 3 as our optimization target. $HitRatio_{node}$ represents the hit rate of the node and $Traffic_{node}$ denotes the I/O traffic to this node. Therefore, this expression represents the overall hit traffic among all nodes. The bigger the value of E is, the less traffic is sent to the backend HDD storage. Admittedly, other optimization targets are also possible and can be decided taking into service level objective account. Based on this target function, our aim is to find a cache assignment method which leads to the largest hit traffic and the smallest traffic to the back-end storage server.

$$E = \sum_{node=1}^{N} HitRatio_{node} \times Traffic_{node} \qquad (3)$$

3.4 Searching for Optimal Configuration

Based on the cache modeling and defined target mentioned above, our *OSCA* searches for the optimal configuration scheme. More specifically, the configuration searching process tries to find the optimal combination of cache sizes of each cache instance to get the highest efficiency E.

To speed up the search process, we use dynamic programming (DP), since a large part of calculations are repetitive. A DP method can avoid repeated calculations using a table to store intermediate results and thus reduce the exponential computational complexity to a linear level.

3.5 Implementation Details

Algorithm 1 presents the pseudocode of the process of our *RAR-CM*. The content of block history information is shown in Fig. 6. The re-access ratio curve and the reuse distance distribution are arrays. The subroutine *update_reuse_distance* (Algorithm 2) is used to update the reuse distance distribution *RD* according to the re-access ratio curve *RAR*. And the subroutine *get_miss_ratio_curve* (Algorithm 3) is used to obtain the miss ratio curve according to the reuse distance distribution *RD*. Specifically, *RD* is formed by an array containing 1024 elements, each denoting 1 GB wide (32768 cache blocks of size 32 KB), representing the reuse distances up to 1 TB. The *get_miss_ratio_curve* calculates the cumulative distribution function for *RD*.

From the pseudocode, we can know that the reuse distance calculation of each block is very lightweight which only involves several simple operations and takes hundreds of nanoseconds. This means *RAR-CM* has a negligible influence on the storage server. And the history information of each referenced block contains two 64-bit numbers, occupying very little memory space. More details for the discussion of CPU, memory, network usage can be referenced to Section 4.5.

4 Evaluation

4.1 Experimental Setup

Trace Collection. To evaluate *OSCA*, we have collected six-day long I/O traces from a production cloud block storage system using a proxy server which is responsible for I/O forwarding between client and storage server. The cloud block storage system has served tens of thousands of cloud disks. The trace files record every I/O request issued by the tenants and each item of the trace file contains the *request timestamp*, *cloud disk id*, *request offset*, *I/O size*, and so on. To not influence tenants' I/O performance, we have optimized the collection tasks by merging and reporting I/O traces to the trace storage server periodically. We trigger the collection tasks to scan the local I/O logs on the proxy server and report the merged I/O traces every hour, which is an appropriate time interval that can balance the number of tasks with the size of the merged trace files.

Algorithm 1: The pseudocode of the *RAR-CM* process

```
Data: Initialize the global variable: hash map for block
      history information $H$, current timestamp $CT$,
      current block sequence number $CC$, and the
      re-reference count $RC$. The re-access ratio curve
      $RAR$. The reuse distance distribution $RD$
Input: a sequence of block accesses
Output: output the miss ratio curve
while has unprocessed block access do
    $B \leftarrow next\ block$
    $CC \leftarrow CC + 1$
    $CT \leftarrow current\ timestamp$
    if $B$ in $H$ then
        $RC \leftarrow RC + 1$
        $RAR(H(B).lt, CT - H(B).lt) = RC/CC$
        $H(B).lc \leftarrow CC$
        $H(B).lt \leftarrow CT$
    end
    else
        Initialize H($B$)
        $H(B).lc \leftarrow CC$
        $H(B).lt \leftarrow CT$
        Insert $H(B)$ into $H$
    end
    $update\_reuse\_distance(B)$
end
return $get\_miss\_ratio\_curve(RD)$
```

Algorithm 2: Subroutine *update_reuse_distance*

```
Input: currently accessed block $B$
if $B$ in $H$ then
    $time\_interval = CT - H(B).lt$
    $traffic = CC - H(B).lc$
    $rd(B) = (1 - RAR(H(B).lt, time\_interval)) * traffic$
    $RD(rd(B)) \leftarrow RD(rd(B)) + 1$
end
```

Algorithm 3: Subroutine *get_miss_ratio_curve*

```
Input: the reuse distance distribution $RD$
$total = sum(RD)$
$tmp = 0$
for $element$ in $RD$ do
    $tmp \leftarrow tmp + element$
    $MRC.append(1 - tmp/total)$
end
return $MRC$
```

Simulator Design. We have implemented a trace-driven simulator in C++ language for the rapid verification of the optimization strategy. The architecture of the simulator consists of an *I/O generator*, an *I/O router*, *cache instances* and *storage nodes*, etc. The *I/O generator* is for trace reading and transforming the trace records to the specific I/O structure of the simulator. The *I/O router* is responsible for request routing and forwarding, which is used to simulate the forwarding layer (shown in Fig. 1) to map each request to a specific storage node. The *storage nodes* simulate the nodes at the storage server layer (shown in Fig. 1). Each node is responsible for one magnetic storage drives and maintains the data mapping relationships inside that node. The *cache instances* is between the *I/O router* and the *storage nodes* and is part of the cache layer of the storage system. Each instance belongs to only one storage node and consists of the index map, metadata list, configuration structure, statistic housekeeping data structure, etc. The index map is implemented by using the *unordered_map* in C++ STL and the metadata list is organized according to the cache algorithm. Considering our cloud simulator is designed to be cloud storage system oriented, we choose only to use our own CBS trace in our evaluations. In our future work, we plan to evaluate our approach using other available traces, especially for comparing the efficacy of constructing MRCs.

4.2 Basic Comparisons

In this section we compare the cache model based on re-access ratio (hereafter called *RAR-CM*) with other three methods, including existing even-allocation method (*Original*), miniature simulation with the sampling idea from SHARDS [33] (*Mini-Simulation*), and an ideal case (*Ideal*) where exact miss ratio curves are used in placement of constructed cache models. We uses the jhash [35] function in implementing *Mini-Simulation* for the uniform randomized spatial sampling. This method leverages jhash to map each I/O record (using attributes like volume ID and data offset) to a location address. The accesses to the same physical block will be hashed to the same value. The I/O record will be selected only when $(V \ mod \ P) < T$, where P and T means the modulus and threshold, respectively. As in SHARDS, $SR = T/P$ represents the sampling ratio. In our experiments, we adopt a fixed sampling ratio of 0.01. We use the *RAR* curves in the prior 12 hours when calculating reuse distance. As illustrated in Fig. 9, the *RAR* curves exhibit good stability, i.e., they show minimum variations in the following days.

Table 2 shows the overall experimental results. In our configuration, we set the average cache size for each storage node as 200 GB (currently-practical configuration). All cache models perform comparably in terms of hit ratio. However, we have observed important back-end traffic savings despite of the seemingly negligible hit ratio improvements. *RAR-CM* compared to *Original* assignment policy with same amount of cache space reduces I/O traffic to back-end storage server by 13.2%. To achieve the same improvement, the *Original* method would require 50% additional cache space on each storage node (i.e., increase from 200 GB / Node to 300 GB / Node) based on the traces we collected from the production CBS system.

Table 2: The overall experimental results

	Hit Ratio	Back-end Traffic	Average Error	Extra Traffic
Original	94.45%	1	-	No
Mini-Simulation	94.85%	0.929	0.017	Yes
RAR-CM	95.14%	0.868	0.005	No
Ideal	95.49%	0.806	0	No

Note: The back-end traffic are normalized to that of *Original* method.

The hit ratio of *Mini-Simulation* is also quite high: 0.29% and 0.64% less than our cache model and the ideal model, respectively. This is consistent with the results in the earlier studies [33].

4.3 Miss Ratio Curves

We next take a closer look at the miss ratio curves of the three cache models. Fig. 10 shows the miss ratio curves of *RAR-CM* (the blue solid line with the cross), *Mini-Simulation* based on SHARDS (the green dotted line), and the exact simulation (the orange solid line). This figure shows the results of 20 randomly selected, but representative storage nodes. Other storage nodes have similar results. The cache space requirements vary among storage nodes and the curves of *RAR-CM* are closer to the curves of the exact simulation than that of *Mini-Simulation* in most cases. The advantage might be attributed to *RAR-CM* constructing the cache model based on the full set of trace and *Mini-Simulation* using spatial sampling causing some fidelity loss.

To evaluate the deviations of curves against the exact miss ratio curves, we report the metric of Mean Absolute Error (MAE) commonly used in evaluating cache models [33, 34]. In our experiments, we compute miss ratio curves at cache sizes 10, 20, 30, 40, 50, 60, 70, 80, 90, 100, 110, 120, 130, 140, 150, 200, 300, 400 and 500 GB. Fig. 11 presents the MAE error distributions of *RAR-CM* and *Mini-Simulation* for the selected 20 storage nodes. The MAE averaged across all 20 storage nodes (labeled "Total") for *RAR-CM* is smaller than for Mini-Simulation: 0.005 vs 0.017, in addition to being smaller for each of the 17 out of the 20 nodes.

4.4 Overall Efficacy of OSCA

In this section, we compare the overall efficacy of *OSCA* in terms of hit ratio and backend traffic using the above mentioned three cache models, respectively. We present the results

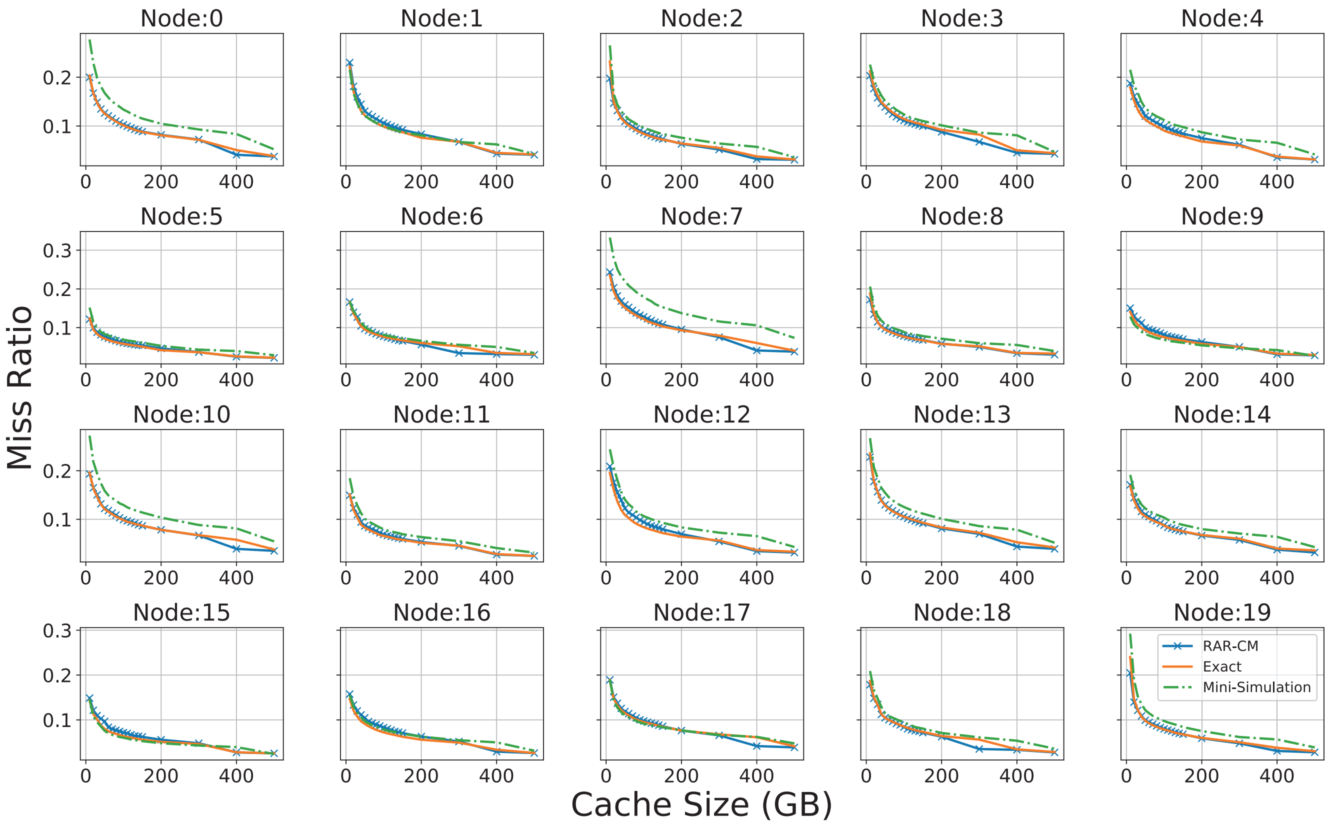

Figure 10: The miss ratio curve of 20 storage nodes. The cache space requirements vary among storage nodes and the curves of *RAR-CM* are closer to the curves of the exact simulation than that of *Mini-Simulation in most cases*.

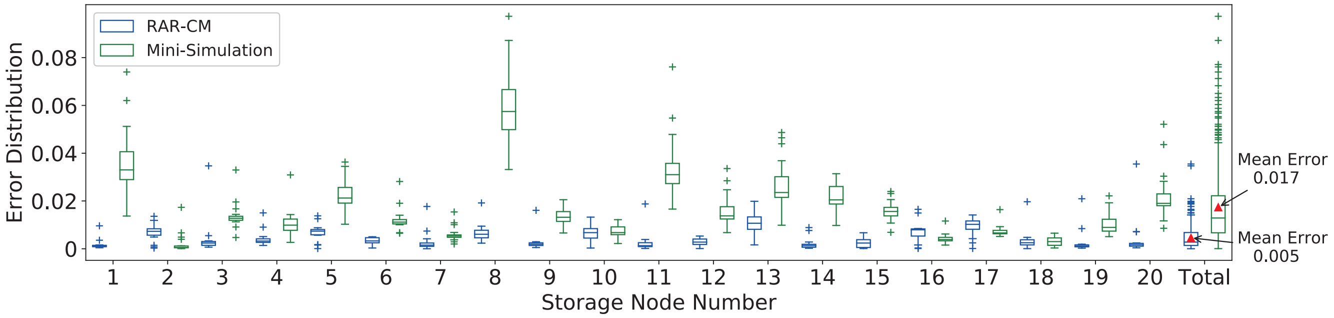

Figure 11: The MAE error distribution of our method *RAR-CM* and *Mini-Simulation* among storage nodes. The last two boxes are total MAE results. The middle lines in boxes indicate the middle values. The bottom and top side of the box represent the quartiles and the lines that extend out of the box (whiskers) represent data outside the upper and lower quartiles.

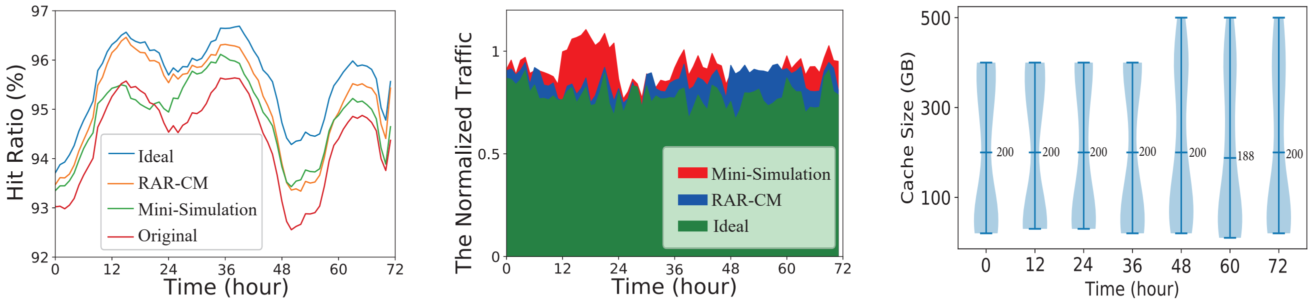
from the last three days of the trace, using the first 3 days as warm up periods. As shown in Fig. 12-a, *OSCA* based on *RAR-CM* can outperform the original assignment policy in the cache hit ratio without requiring additional cache space. Fig. 12-b shows the back-end traffic with different cache management policies. The back-end traffic is normalized to that of *Original* method. From the figure, we can know that on average, *OSCA* based on *RAR-CM* can reduce I/O traffic to back-end storage server by 13.2%. As shown in Fig. 12, *RAR-CM* results in slightly better hit ratios that *Mini-Simulation* except for hours $48-60$.

Fig. 12-c show the cache size configuration for each node at different times determined by our *OSCA* algorithm with *RAR-CM*. It can be seen that the demand for cache space varies considerably between nodes and our approach did respond correspondingly to meet the needs at different times.



(a) (b) (c)

Figure 12: Fig. (a) and Fig. (b) represents the hit ratio results for the last three days and the normalized back-end traffic using the three cache models, respectively. Fig.(c) shows OCSA adjusts the cache space for 20 storage nodes dynamically in response to their respective cache requirements decided by our cache modeling. The middle line in Fig. (c) represents the average cache size for each node. The results are obtained from traces mentioned in Section 4.1.

Based on the optimal cache size configuration scheme, *OSCA* periodically reassigns the corresponding cache size to each cache node every 12 hours.

4.5 Discussion

When trace collection and processing present a significant cost, *RAR-CM* offers an attractive alternative to other state-ot-the-art techniques. In this section, we make a comparison between *RAR-CM* and *Mini-Simulation* in terms of CPU, memory, network usage.

As mentioned in Section 3.2, upon each block request, *RAR-CM* first checks its history information in a hash map and calculates the block reuse distance. The history information of each referenced block contains two 64-bit numbers denoting the last access timestamp and the block sequence number of the last reference to each block, respectively. In our experiment, there are approximately 55.8 million unique blocks referenced each day in a storage node, occupying only 0.87 GB memory space via using *RAR-CM*. Besides the low memory resource usage, *RAR-CM* does not induce extra network traffic as all the computation is completed on the storage server nodes, enabling the miss ratio curves to be constructed and readily available in an online fashion. As for the CPU resource usage, as shown in Section 3.2, the reuse distance calculation of each block is very lightweight which only involves several simple operations and takes hundreds of nanoseconds.

Mini-Simulation needs to concurrently run multiple simulation instances to construct the cache miss ratio in different cache sizes. However, for very long traces, this method can consume a large number of computation resources (in our implementation, we start a thread in the main routine for each cache algorithm in a specific cache size). More importantly, I/O traces (there are about 4.46 billion I/O records per day in a typical CBS system) ought to be transmitted to and analyzed by a dedicated analysis system to avoid influencing service times. According to our experimental results, the transmission of the I/O records from these 20 nodes consumes approximately 72 GB of network bandwidth each day.

To quantify the runtime overhead, we have experimented with the *Mini-Simulation* algorithm. Specifically, we run 20 simulation routines (each routine starts 20 threads) simultaneously on a 12-core CPU (i.e., Intel Xeon CPU E5-2670 v3). The traces are stored in a storage server and each thread accesses the traces via the network file system. This method takes around 69 minutes to analyze a one-day-long I/O trace file and most of the time is consumed in trace reading (1.067 µs / record) and I/O mapping (2.406 µs / record). The I/O mapping determines which storage node should a record be assigned to based on the MD5 digest from the information of the record. We maintain the total time for the trace reading and I/O mapping and divide them by the total number of records processed to obtain the overhead per record.

5 Related Work

Our work is mostly related to the management of shared cache resource, which widely exists in various contexts, including multi-core processors, web applications, cloud computing and storage. A variety of methods have been proposed and they can be generally classified into heuristic methods, model-based quantitative methods.

Heuristic Methods: To achieve fairness in cache partitioning, the max-min fairness (MMF) and weighted max-min fairness methods are popularly used [12]. These two methods fairly satisfy the minimum requirements of each user and then evenly allocate unused resources to users having additional requirements. Different from MMF, Parihar et al. [25] propose the method of cache rationing, which ensures that the program cache space is not less than a set value and free cache space is allocated to a specific program. Kim, et al. [19] propose TCM which divides threads into delay-sensitive and bandwidth-sensitive groups and apply different cache policies to them. Similar to the TCM method, Zhuravlev et al. [46] proposed a scheduling algorithm called Distributed Intensity (DI), which adjusts the scheduling algorithm by analyzing the classification schemes of each thread through a novel methodology. Other methods, like [32], [12], and [42], have been proposed based on the game theory principles.

Model-based Quantitative Methods: Besides heuristic methods mentioned above, there have also been proposed many quantitative methods. These methods use locality metrics (e.g., Working Set Size, Average Footprint, Reuse Distance, and so on) to quantify the locality of the access patterns so as to predict the hit (or miss) ratio [7]. Reasonably, a shared-cache partition can be efficient using quantitative methods. **Working Set Size**. Inspired by the principle of locality, there are many studies [2, 9, 10] modeling the locality characteristics using working set size (WSS). For instance, based on the WSS theory, Arteaga et al. [2] propose an on-demand cloud cache management method. Specifically, they used Reused Working Set Size (RWSS) model, which only captures data with strong temporal locality, to denote the actual demand of each virtual machine (VM). Using the RWSS model, they can satisfy VM cache demand and slow down the wear-out of flash cache as well. **Footprint**. Footprint, which is defined as the number of unique data blocks referenced in a time interval, has been widely applied to cache resources allocation. Various methods have been proposed to estimate the footprint of workloads [6, 8, 28, 37] and they make trade-off between the complexity and accuracy of the measurement. Xiang et al. [38] propose the HOTL theory, which calculates the average footprint in a linear time complexity and apply the HOTL theory to transfer the average data footprint to reuse distance and predict the miss ratio in their following work [39]. By using this method, they can predict the interference of cache sharing without the need of parallel testing with multiple of cache sizes, and thus the miss ratio can be evaluated with low overhead. **Reuse Distance**. Reuse distance, defined as the unique accesses between two consecutive references to the same data, can be translated to hit ratio and a host of research efforts have been put to efficiently obtain reuse distance. Mattson et al. [22] give the definition of reuse distance and propose a specific method to measure reuse distance. Later researches use tree-based structure to optimize the computation complexity of reuse distance calculation [1, 5, 24, 43]. Waldspurger et al. [34] propose a spatially hashed approximate reuse distance sampling (SHARDS) algorithm to efficiently obtain reuse distance distribution and construct approximate miss rate curve. Hu et al. [14] propose the concept of average eviction time (AET) and relate the miss ratio at cache size c with AET using the formula mr(c) = P(AET(c)), which indicates that the miss ratio is the proportion of data whose reuse distance is greater than AET. In this study, AET is obtained through the Reuse Time Histogram (RTH) with a certain sampling method.

6 Conclusion

Cloud block storage (CBS) systems employ cache servers to improve the performance for cloud applications. Most existing cache management policies fall short of being applied to CBSs due to their high complexity and overhead, especially in the cloud context with large amount of I/O activity. In this paper, we propose a cache allocation scheme named *OSCA* based on a novel cache model leveraging re-access ratio. *OSCA* can search for a near optimal configuration scheme at a very low complexity. We have experimentally verify the efficacy of *OSCA* using trace-driven simulation with I/O traces collected from a production CBS system. Evaluation results show that *OSCA* offers lower MAE and computational and representational complexity compared with miniature simulation based on the main idea of SHARDS. The improvement in hit ratio leads to a reduction of I/O traffic to the back-end storage server by up to 13.2%. We are working on releasing our traces via the SNIA IOTTA repository [27] and integrating our proposed technique into the real CBS product system.

Acknowledgments

We would like to thank the anonymous reviewers for the valuable feedbacks and comments. We are especially grateful to our shepherds Jiri Shindler and Michael Mesnier for their tremendous help in improving the presentation and paper quality. We would also like to thank Tencent Technology (Shenzhen) Co., Ltd. for experimental environment, I/O trace support and releasing the trace to the community. Lock-free Concurrent Level Hashing for Persistent Memory

Abstract

With high memory density, non-volatility, and DRAM-scale latency, persistent memory (PM) is promising to improve the storage system performance. Hashing-based index structures have been widely used in storage systems to provide fast query services. Recent research proposes crash-consistent and write-efficient hashing indexes for PM. However, existing PM hashing schemes suffer from limited scalability due to expensive lock-based concurrency control, thus making multi-core parallel programing inefficient in PM. The coarse-grained locks used in hash table resizing and queries (i.e., search/insertion/update/deletion) exacerbate the contention. Moreover, the cache line flushes and memory fences for crash consistency in the critical path increase the latency. In order to address the lock contention for concurrent hashing indexes in PM, we propose *clevel* hashing, a lock-free concurrent level hashing, to deliver high performance with crash consistency. In the clevel hashing, we design a multi-level structure for concurrent resizing and queries. Resizing operations are performed by background threads without blocking concurrent queries. For concurrency control, atomic primitives are leveraged to enable lock-free search/insertion/update/deletion. We further propose context-aware schemes to guarantee the correctness of interleaved queries. Using real Intel Optane DC PMM, experimental results with real-world YCSB workloads show that clevel hashing obtains up to 4.2× speedup than the state-of-the-art PM hashing index.

1 Introduction

Non-volatile memory (NVM) deployed as persistent memory (PM) offers the salient features of large capacity, low latency, and real time crash recovery for storage systems [12, 30, 38]. Recently, Intel Optane DC persistent memory module (PMM) [2], the first commercial product of PM, is available on the market. Compared with DRAM, PM has 3× read latency and similar write latency [23,24,36]. In the meantime, the read and write bandwidths of PM achieve $1/3$ and $1/6$ of those of DRAM [23, 24, 27, 36]. PM delivers higher performance than SSD and the maximal 512 GB capacity for a single PM module is attractive for in-memory applications [23].

Building high-performance index structures for PM is important for large-scale storage systems to provide fast query services. Recent schemes propose some crash-consistent tree-based indexes, including NV-Tree [37], wB$^+$-Tree [14], FP-Tree [32], WORT [26], FAST&FAIR [22] and BzTree [9]. However, traversing through pointers in hierarchical trees hinders fast queries. Unlike tree-based schemes, hashing-based index structures leverage hash functions to locate data in flat space, thus enabling constant-scale point query performance. As a result, hash tables are widely used in many in-memory applications, e.g., redis [7] and memcached [4].

Existing hashing-based indexes for PM put many efforts in crash consistency and write optimizations but with little consideration for non-blocking resizing (also called rehashing) [27, 30, 40]. A hash function maps different keys into the same location, called hash collisions. In general, when the hash collisions can't be addressed or the *load factor* (the number of inserted items divided by the capacity) of a hash table approaches the predefined thresholds, the table needs to be expanded to increase the capacity. Traditional resizing operations acquire global locks and move all items from the old hash table to the new one. Level hashing [40] is a two-level write-optimized PM hashing index with cost-efficient resizing. The expansion of level hashing only rehashes items in the smaller level to a new level, which only migrates items in 1/3 buckets. However, the resizing operation in the level hashing is single-threaded and still requires a global lock to ensure correct concurrent executions. P-CLHT [27] is a crash consistent variant of Cache-Line Hash Table (CLHT) [17] converted by RECIPE [27]. The search operation in P-CLHT is lock-free, while the writes into stale buckets (all stored items have been rehashed) would be blocked until the full-table resizing completes. Hence, both schemes suffer from limited resizing performance, since the global lock for resizing blocks queries in other threads. Cacheline-Conscious Extendible Hashing (CCEH) [30], a persistent extendible hashing scheme, supports concurrent lock-based dynamic resizing, however coarse-grained locks for shared resources significantly increase the latency. Specifically, CCEH splits a segment, an array of 1024 slots by default, to increase the capacity, which requires the writer lock for the whole segment. Moreover, when the directory needs to be doubled, the global writer lock for directory is needed before doubling the directory. The Copy-on-Write (CoW) version of CCEH avoids the segment locks with the cost of extra writes due to the migration of inserted items. Hence, the insertion performance of CCEH with CoW is poorer than the default version with lazy deletion [30]. The concurrent_hash_map (cmap) in pmemkv [6] leverages lazy rehashing by amortizing data migration over future queries. However, the deferred rehashing may aggregate to a recursive execution in the critical path of queries, thus leading to non-deterministic query performance. Hence, current PM hashing indexes suffer from poor concurrency and scalability during resizing.

A scalable PM hashing index with concurrent queries is important to exploit the hardware resources and provide high throughput with low latency. Nowadays, a server node is able to provide tens of or even hundreds of threads, which enables the wide use of concurrent index structures. Existing hashing-based schemes for PM [27, 30, 40] leverage locks for inter-thread synchronization. However, coarse-grained exclusive locks in a critical path increase the query latency and decrease the concurrent throughput. Moreover, in terms of PM, the persist operations (e.g., logging, cache line flushes, and memory fences), when holding locks, further increase the waiting time of other threads. Fine-grained locks decrease the critical path but may generate frequent locking and unlocking for multiple shared resources. Moreover, the correctness guarantee is harder than coarse-grained locks.

In summary, in addition to crash consistency, we need to address the following challenges to build a high performance concurrent hashing index for PM.

1) Performance Degradation during Resizing. For concurrent hash tables, resizing operations need to be concurrently executed without blocking other threads. However, the resizing operation accesses and modifies the shared hash tables and metadata. Coarse-grained locks for global data ensure thread safety, but lead to high contention and significant performance degradation when the hash table starts resizing.

2) Poor Scalability for Lock-based Concurrency Control. Locking techniques have been widely used to control concurrent accesses to shared resources. The coarse-grained locks protect the hash table, but they also prevent concurrent accesses and limit the scalability. Moreover, the updates of shared data are often followed by flushing data into PM, which exacerbates lock contention. An efficient concurrent hashing scheme for PM needs to have low contention for high scalability while guarantee the concurrency correctness.

In order to address the above challenges, we propose *clevel hashing*, a crash-consistent and lock-free concurrent hash table for PM. Motivated by our level hashing [40], we further explore write-efficient open-addressing techniques to enable write-friendly and memory-efficient properties for PM in the context of concurrency. Different from the level hashing, our proposed clevel hashing aims to provide scalable performance and guarantee the correctness for concurrent executions. Unlike existing schemes [27, 30] that convert concurrent DRAM indexes to persistent ones, we propose a new and efficient way to enable persistent indexes to be concurrent with small overheads and high performance. Hence, the clevel hashing bridges the gap between scalability and PM efficiency.

To alleviate the performance degradation for resizing, we propose a dynamic multi-level index structure with asynchronous rehashing. Levels are dynamically added for resizing and removed when all stored items are migrated to a new level. The rehashing of items is offloaded into background threads, thus never blocking foreground queries. Background threads migrate the items from the last level to the first level via rehashing until there are two remaining levels. The two levels ensure a maximal load factor over 80% and the limited accesses to buckets for queries. Therefore, when rehashing is not running (the usual case for most workloads), the time complexity for search/insertion/update/deletion is constant-scale.

To provide high scalability with low latency, we design write-optimal insertion and lock-free concurrency control for search/insertion/update/deletion. The new items are inserted into empty slots without any data movements, hence ensuring write efficiency. For concurrent modifications to the hash table, clevel hashing exploits the atomicity of pointers and uses Compare-And-Swap (CAS) primitives for lock-free insertion, update, and deletion. Guaranteeing the correctness for lock-free queries with simultaneous resizing is challenging, since interleaved operations can be executed in any order and lead to failures and duplicate items. In the clevel hashing, we propose context-aware algorithms by detecting the metadata information changes to avoid inconsistencies for insertion, update, and deletion. The duplicate items are detected and properly fixed before modifying the hash table. In summary, we have made the following contributions in the clevel hashing.

- **Concurrent Resizing.** In order to address the bottleneck of resizing, we propose a dynamic multi-level structure and concurrent resizing without blocking other threads.
- **Lock-free Concurrency Control.** We design lock-free algorithms for all queries in the clevel hashing. The correctness for lock-free concurrency control is guaranteed with low overheads.
- **System Implementation.** We have implemented the clevel hashing using PMDK [5] and compared our proposed clevel hashing with state-of-the-art schemes on

real Intel Optane PM hardware. The evaluation results using YCSB workloads show the efficacy and efficiency of the clevel hashing. We have released the open-source code for public use.[1]

2 Background

2.1 Crash Consistency in Persistent Memory

Persistent memory (PM) provides the non-volatility for data stored in main memory, thus requiring crash consistency for data in PM. For store instructions, the typical maximal atomic CPU write size is 8 bytes. Therefore, when data size is larger than 8 bytes, system failures during sequential writes of data may lead to partial updates and inconsistency. In the meantime, the persist order of data in write-back caches is different from the issue order of store instructions, thus demanding memory barriers to enforce the consistency. To guarantee consistency, recent CPUs provide instructions for cache line flushes (e.g., *clflush*, *clflushopt*, and *clwb*) and memory barriers (e.g., *sfence*, *lfence*, and *mfence*) [1]. With these instructions, users can use logging or CoW to guarantee crash consistency for data larger than 8 bytes [27, 38]. However, logging and CoW generate extra writes causing the overheads for PM applications [30,40]. In our implementation, we use the interface provided by PMDK [5], which issues clwb and sfence instructions in our machine, to persist the data into PM.

2.2 Lock-free Concurrency Control

Compare-And-Swap (CAS) primitives and CoW have been widely used in existing lock-free algorithms for atomicity. The CAS primitive compares the stored contents with the expected contents. If the contents match, the stored contents are swapped with new values. Otherwise, the expected contents are updated with the stored contents (or just do nothing). The execution of CAS primitives is guaranteed to be atomic, thus avoiding the use of locks. CAS primitives are used in concurrent index structures to provide high scalability [21,34]. However, CAS primitives don't support data sizes larger than the CPU write unit size (e.g., 8 bytes). CoW is used to atomically update data larger than 8 bytes [30]. CoW first copies the data to be modified and performs in-place update in the copied data. Then the pointer is atomically updated with the pointer to new data using a CAS primitive. The drawback of CoW is the extra writes for the copy of unchanged contents. In PM, frequent use of CoW causes severe performance degradation [30, 40]. In our clevel hashing, we design the lock-free algorithms using CAS primitives for most writes and lightweight CoW for infrequent metadata updates, thus achieving high scalability with limited extra PM writes.

2.3 Basic Hash Tables

Unlike tree-based index structures, hashing-based indexes store the inserted items in flat structures, e.g., an array, thus obtaining $O(1)$ point query performance. Some hashing schemes, e.g., CLHT [17], store key-value items in the hash table, which mitigates the cache line accesses. However, such design doesn't support the storage of variable-length key-value items. Reserving large space in hash tables causes heavy space overheads, since most key-value pairs in real-world scenarios are smaller than a few hundreds of bytes [10, 18]. In order to efficiently support variable-length key-value items, many open-source key-value stores (e.g., redis [7], memcached [4], libcuckoo [28], and the cmap engine in pmemkv [6]) store pointers in hash tables and actual key-value items out of the table. In our clevel hashing, we store pointers in hash tables to support variable-length key-value items.

A typical hash table leverages hash functions to calculate the index of a key-value item. Different key-value items can be indexed to the same storage position, called *hash collisions*. Existing hashing schemes leverage some techniques to address hash collisions, e.g., linear probing [30], multi-slot buckets [18, 28, 30, 40], linked list [6, 16, 27, 29], and data relocation [18, 28, 34, 40]. If hash collisions cannot be addressed, the hash table needs to be resized to increase the capacity. Typical resizing operations consist of three steps: (1) Allocate a new hash table with 2× as many buckets as the old table. (2) Rehash items from the old table to the new table. (3) When all items in the old table have been rehashed, switch to the new table. The resizing in conventional hashing schemes involves intensive data movements [40] and blocks concurrent queries [30].

2.4 Hashing-based Index Structures for PM

Recently, researchers have proposed several hashing-based indexes for PM [6, 16, 30, 40]. Different from DRAM indexes, PM indexes need to remain consistent after system failures. However, the write bandwidth of PM is one sixth as much as DRAM [23, 24, 36], which indicates the significance of write efficiency for concurrent PM hashing indexes.

2.4.1 The Level Hashing Scheme

Our clevel hashing is based on the level hashing index structure [40]. Level hashing has three goals: low-overhead crash consistency, write efficiency, and resizing efficiency. Below, we briefly introduce the relevant components in level hashing.

Level hashing has two levels and the top level has twice the buckets of the bottom level. Each *level* is an array of 4-slot buckets. Besides the 4 slots, a bucket has 4 tokens and each token is one bit corresponding to one slot for crash

[1] https://github.com/chenzhangyu/Clevel-Hashing

Table 1: The Comparisons of Our Clevel Hashing with State-of-the-art Concurrent Resizable Hashing Indexes for PM. *(For abbreviation, "LEVEL" is the level hashing, "CCEH" is the default CCEH version using the MSB segment index and lazy deletion. "CMAP" is the concurrent_hash_map in pmemkv, and "CLEVEL" is our clevel hashing. For the memory efficiency and crash consistency, "✓" and "-" indicate good and moderate performance, respectively.)*

	Concurrency Control			Correctness Guarantee		Memory Efficiency	Crash Consistency
	Search	*Insertion/Update/Deletion*	*Resizing*	*Duplication*	*Missing*		
LEVEL	Slot lock	Slot lock	Global metadata lock	No	No	✓	✓
CCEH	Segment reader lock	Segment writer lock	Global directory lock	No	Yes	-	✓
CMAP	Bucket reader lock	Bucket writer lock	Bucket writer lock + lazy rehashing	Yes	Yes	✓	✓
P-CLHT	Lock-free	Bucket lock	Global metadata lock	Yes	Yes	✓	✓
CLEVEL	Lock-free	Lock-free	Asynchronous	Yes	Yes	✓	✓

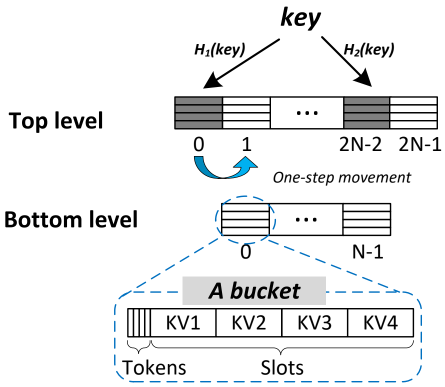

Figure 1: The level hashing index structure

consistency. The overview of level hashing index structure is shown in Figure 1.

By using two independent hash functions, each item has two candidate buckets in one level for storage (16 slots in total for two levels). When the two buckets are full, level hashing tries to perform one-step movement to obtain an empty slot for the item to be inserted. For example, the key in Figure 1 has two candidate buckets in the top level: the first bucket and the second to last bucket. If the two buckets are full and one stored item in the first bucket has empty slots in its alternative candidate bucket (e.g., the second bucket), the stored item is moved to the second bucket so that the key can be inserted to the first bucket. The one-step movement in level hashing improves the maximal load factor before resizing by 10% [40].

For resizing, level hashing creates a new level with 2× (e.g., 4N in Figure 1) as many buckets as the top level and migrates stored items in the bottom level to the new level. The items in the top level are reused without rehashing.

Level hashing uses slot-grained locks for concurrent queries. A fine-grained slot lock is acquired before accessing the corresponding slot and released after completing the access. For resizing, level hashing rehashes items using one thread and blocks concurrent queries of other threads. The concurrency control in level hashing has two correctness problems:

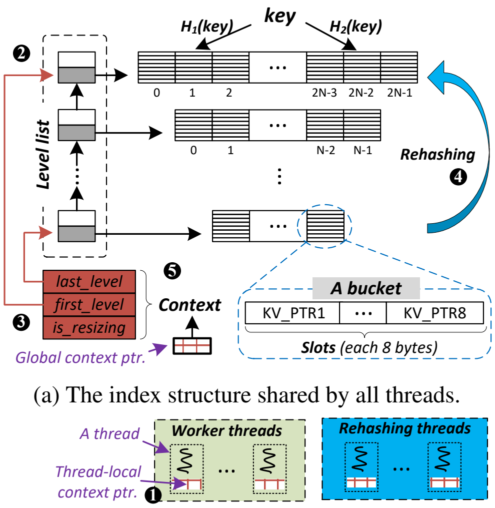
1) Duplicate items. An insertion thread with a single slot lock for an item cannot prevent other threads from inserting items with the same key into other candidate positions, since one item has 16 slots (2 candidate buckets for each level) for storage. Duplicate items in the hash table violate the correctness for updates and deletions: one thread updates or deletes one item while future queries may access the duplicate items that are unmodified.

2) Missing items. Items in level hashing are movable due to one-step movement and rehashing, while a slot lock cannot stop the movements. As a result, one query with a slot lock may miss inserted items due to concurrent moving of other threads.

2.4.2 Concurrent Hashing Indexes for PM

Recent schemes design some crash-consistent PM hashing indexes with lock-based concurrency control. CCEH [30] organizes 1024 slots as a segment for dynamic hashing. For concurrent execution, the segment splitting during insertion requires an exclusive writer lock for the segment. Moreover, when the number of segments reaches a predefined threshold, a global directory of segments needs to be doubled with a global directory lock. In pmemkv [6], there is a concurrent linked-list based hashing engine for PM, called cmap, which uses bucket-grained reader-writer locks for concurrency control. The cmap leverages lazy rehashing to amortize data migration in future queries. However, the aggregation of rehashing in the critical path of queries leads to uncertainty and increases the tail latency. P-CLHT [27] is a crash-consistent version of CLHT [17], a cache-efficient hash table with lock-free search. However, when P-CLHT starts resizing, concurrent insertions to the stale buckets (i.e., buckets whose items have been rehashed) have to wait until the resizing completes.

As shown in Table 1, we summarize state-of-the-art concurrent hashing-based index structures with resizing support for PM and compare our clevel hashing with them. All comparable schemes are the open-source versions with default parameter settings. For concurrent queries, CCEH uses coarse segment reader-writer locks, while level hashing and cmap adopt fine-grained locks. P-CLHT leverages bucket-grained



(a) The index structure shared by all threads.

(b) The local context for each thread.

Figure 2: The clevel hashing index overview.

locks for insertion/update/deletion and provides lock-free search. In terms of resizing, level hashing, CCEH, and P-CLHT suffer from the global locks. Though cmap avoids expensive global locks for resizing, the lazy rehashing is in the critical path of queries and affects the scalability. For concurrency correctness, as discussed in §2.4.1, level hashing suffers from duplicate items and missing inserted items. Since CCEH doesn't check if a key to be inserted is present in the hash table, CCEH also has the problem of duplicate items. For memory efficiency, CCEH sets a short linear probing distance (16 slots) by default to trade storage utilization for query performance. Unlike existing schemes, our clevel hashing achieves lock-free queries with asynchronous background resizing while guarantees the concurrency correctness and memory efficiency.

3 The Clevel Hashing Design

Our proposed clevel hashing leverages flexible data structures and lock-free concurrency control mechanism to mitigate the competition for the shared resources and improve the scalability. The design of clevel hashing aims to address the three problems in hashing index structures for PM: (1) ***How to support concurrent resizing operations without blocking the queries in other threads?*** (2) ***How to avoid lock contention in concurrent execution?*** (3) ***How to guarantee crash consistency with low overheads?*** In this Section, we first illustrate the dynamic multi-level structure (§3.1), which provides high memory efficiency and supports the low-cost resizing operation. We further present the lock-free concurrency control and correctness guarantee in the clevel hashing (§3.2), i.e., lock-free search/insertion/update/deletion. We finally discuss crash recovery (§3.3).

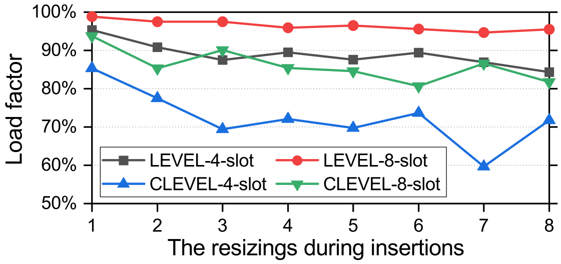


Figure 3: The load factors of level hashing and clevel hashing with different slots per bucket when the resizing occurs.

3.1 The Clevel Hashing Index Structure

3.1.1 Dynamic Multi-level Structure

The global index structure of clevel hashing shared by all threads is shown in Figure 2(a). The hash table in the clevel hashing consists of several levels and each level is an array of buckets. All these levels are organized by a linked list, called *level list*. For two adjacent levels, the upper level has 2× as many buckets as the lower one. The *first level* is interpreted as the level with the most buckets while the *last level* is interpreted as the level with the least buckets. Each key-value item is mapped to two candidate buckets in each level via two hash functions. To guarantee high storage utilization, clevel hashing maintains at least two levels [40]. Unlike the 4-slot bucket in the level hashing [40], each bucket in clevel hashing has 8 slots. Each slot consists of 8 bytes and stores a pointer to a key-value item. The actual key-value item is stored outside of the table via dynamic memory allocation. Hence, the 8-slot bucket is 64 bytes and fits the cache line size. By only storing the pointers to key-value items in slots, clevel hashing supports variable-length key-value items. Hence, the content in each slot can be modified using atomic primitives. The atomic visibility of pointers is one of the building blocks for lock-free concurrency control (§3.2) in our clevel hashing.

Different from the level hashing, our clevel hashing index structure is write-optimal for insertion while maintaining high storage utilization. The level hashing tries to perform one movement (one-step movement) for inserted items by copying them into their second candidate bucket in the same level, which causes one extra write for PM. For clevel hashing, the one-step movement is skipped, which decreases the storage utilization. Figure 3 shows the load factors of level hashing and clevel hashing with different slot numbers when successive resizings occur during insertion. Compared with level hashing having the same number of slots per bucket, the load factor of clevel hashing becomes lower due to the lack of one-step movement. However, 8-slot buckets in clevel hashing increase the number of candidate slots for a key in one level, thus achieving a comparable load factor (80%) than the level hashing with 4-slot buckets (default configuration). The number of slots per bucket also affects the throughput, which is discussed in §4.2.

3.1.2 The Support for Concurrent Resizing

Clevel hashing leverages the dynamic multi-level design and context to support concurrent resizing operations. The number of levels in clevel hashing is dynamic: levels are added for resizing and removed when rehashing completes. The *context* in clevel hashing is interpreted as an object containing two level list nodes and the `is_resizing` flag. The two nodes point to the first and last levels while the flag denotes if the table is being resized. There is a global pointer to the context (Figure 2(a)) and each thread maintains a thread-local copy of the context pointer (Figure 2(b)). Hence, the context can be atomically updated using CoW + CAS. Since the context size is 17 bytes (i.e., two pointers and one Boolean flag) and the context changes only when we add/remove a level, the CoW overheads of context are negligible for PM.

The resizing operation in clevel hashing updates the level list and the context. Specifically, when hash collisions can't be addressed, the resizing is performed in the following steps: (Step ❶) Make a local copy of the global pointer to context. (Step ❷) Dereference the local copy of context pointer, and append a new level with twice the buckets of the original first level to the level list using CAS. If the CAS fails, update the local copy of the context pointer and continue with the next step, since other threads have successfully added a new level. (Step ❸) Use CoW + CAS to update the global context by changing the first level to the new level (e.g., L_{new}) and setting `is_resizing` to true. When the CAS fails, check if the new first level's capacity is no smaller than L_{new} and the `is_resizing` is true: if so, update the local context pointer and continue; otherwise, retry the CoW + CAS with the `is_resizing` (true) and optional new level L_{new} (if the first level's capacity is smaller than L_{new}). (Step ❹) Rehash each item in the last level. The rehashing includes two steps: copy the item's pointer to a candidate bucket in the first level via CAS, and delete the pointer in the last level (without CAS, and the correctness for possible duplicate items is guaranteed in insertion §3.2.2 and update §3.2.3). If the CAS fails, find another empty slot. If no empty slot is found, go to step ❷ to expand the table. (Step ❺) When rehashing completes, update the last level and optional `is_resizing` (if only two levels remain after resizing) in the global context atomically using CoW + CAS. If the CAS fails, try again if the last level in current context is unmodified. The resizing workflow is shown in Figure 2. Note that the reasons for three possible CAS failures in resizing are different: the CAS failures in step ❷ come from the concurrent expansion of other threads, i.e., the step ❷ in other threads; the failures in steps ❸ and ❺ are due to the concurrent execution of these two steps (steps ❸ and ❺) in different threads. As a result, the strategies for corresponding CAS failures are different as presented above.

To mitigate the insertion performance degradation due to resizing, clevel hashing leverages background threads to enable asynchronous rehashing. Specifically, we divide the resizing into two stages, including *expansion* (steps ❶, ❷, and ❸) and *rehashing* (steps ❹ and ❺) *stages*. The time-consuming rehashing stage is offloaded into background threads, called *rehashing threads*. Rehashing threads continuously rehash items until there are two levels left. Therefore, when the table is not being resized, the queries in clevel hashing guarantee constant-scale time complexity. The threads serving query requests are called *worker threads*. When the hash collisions can not be addressed by worker threads, they perform the three steps in the expansion stage and then continue the queries. Since the main operations for table expansion are simple memory allocation and lightweight CoW for context (17 bytes), the expansion overheads are low. Moreover, there is no contention for locks during expansion. As a result, the resizing operation no longer blocks queries.

Rehashing performance can be improved by using multiple rehashing threads. To avoid contention for rehashing, a simple modular function is used to partition buckets into independent batches for rehashing threads. For example, if there are two rehashing threads, one thread rehashes odd-number buckets while the other rehashes even-number buckets. After both rehashing threads finish, they update the global context following step ❺.

3.2 Lock-free Concurrency Control

In order to mitigate the contention for shared resources, we propose lock-free algorithms for all queries, i.e., search, insertion, update, and deletion.

3.2.1 Search

The search operation needs to iteratively check possible buckets to find the first key-value item that matches the key. There are two main problems for lock-free search in the clevel hashing: (1) *High read latency for the pointer dereference costs.* Since clevel hashing only stores the pointers in hash tables to support variable-length items, dereferencing is needed to fetch the corresponding key, which results in high cache miss ratios and extra PM reads. (2) *Missing inserted items due to the data movement.* The concurrent resizing moves the items in the last level, and therefore, searching without any locks may miss inserted items.

For the pointer dereference overheads, our proposed clevel hashing leverages a summary tag to avoid the unnecessary reads for full keys. A tag is the summary for a full key, e.g., the leading two bytes of the key's hash value. The hash value is obtained when calculating the candidate buckets via hash functions (e.g., the `std::hash` from C++ [8]). The tag technique is inspired from MemC3 [18] and we add atomicity for the pair of tag and pointer. For each inserted item, its tag is stored in the table. For a search request, only when the tag of a request matches the stored tag of an item, we fetch the stored full key by pointer dereferencing and compare the two keys. A *false positive* case for tags appears when different keys have the same tag. For 16-bit tags, the false positive rate is $1/2^{16}$. Since we check full-size keys when two tags match, the false positives can be identified and will not cause any problem of correctness. Instead of allocating additional space for tags in MemC3, clevel hashing leverages the unused 16 highest bits in pointers to store the tags. Current pointers only consume 48 bits on x86_64, thus leaving 16 bits unused in 64-bit pointers [31,35]. The reuse of reserved bits enables the atomic updates of pointers and tags.

To address the problem of missing inserted items, we propose to search from the last level to the first level, called *bottom-to-top* (*b2t*) search strategy. The intuition behind b2t searching is to follow the direction of bottom-to-top data movement in hash table expansion, which moves items from the last level to the first level. However, a rare case for missing is: after a search operation starts, other threads add a new level through expansion and rehashing threads move the item that matches the key of the search to the new level. To fix this missing, clevel hashing leverages the atomicity of context. Specifically, when no matched item is found after b2t search, clevel hashing checks the global context pointer with the previous local copy. If the two pointers are different, redo the search. The overheads for the re-execution of search are low, since changes of the context pointer are rare, occurring only when a level is added to or removed from the level list. Therefore, the correctness for the lock-free search is guaranteed with low costs.

3.2.2 Insertion

For insertion, a key-value item is inserted if the key does not exist in the table. The insertion first executes lock-free b2t search (§3.2.1) to determine if an item with the same key exists. If none exists, the pointer (with its summary tag) to the key-value item is atomically inserted into a less-loaded candidate bucket. When there is no empty slot, we resize the table by adding a new level with background rehashing (§3.1.2) and redo the insertion. However, lock-free insertion leads to two correctness problems: (1) *Duplicate items from concurrent insertions*. Without locks, concurrent threads may insert items with the same key into different slots, which results in failures for update and deletion. (2) *Loss of new items inserted to the last level*. When new items are inserted into the buckets in the last level that have been processed by rehashing threads, these inserted items are lost after we reclaim the last level.

For concurrent insertions to different slots, it is challenging to avoid the duplication in a lock-free manner, since atomic primitives only guarantee the atomicity of 8 bytes. However, each one of the duplicate items is correct. Hence, we fix the duplication in future updates(§3.2.3) and deletions(§3.2.4).

In order to fix the loss of new items, we design a context-aware insertion scheme to guarantee the correctness of insertion. The context-aware scheme includes two strategies: (1) Before the insertion, we check the global context and do not insert items into the last level when the hash table is resizing, i.e., when the `is_resizing` is true. (2) After the insertion, if the table starts resizing and the item has been already inserted into the last level, we redo the insertion using the same pointer without checking duplicate items. The re-execution of insertion leads to possible duplicate pointers in the hash table. However, duplicate pointers don't affect the correctness of search, because they refer to the same key-value items. Future updates and deletions are able to detect and address the duplication.

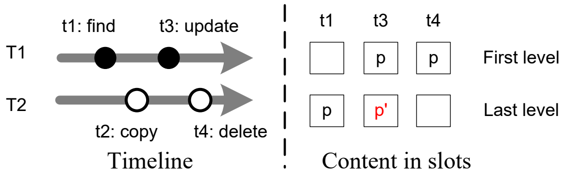

Figure 4: The update failure. (*"T1": an update thread, "T2": a rehashing thread, "t1-t4": timestamps, "p": pointer to the old item, "p′": pointer to the updated item.*)

3.2.3 Update

The update operation in the clevel hashing atomically updates the pointers to the matched key-value items. Different from the insertion, the update needs to fix duplicate items. Otherwise, duplicate items may lead to inconsistency after being updated. Moreover, the concurrent executions of resizing and update may cause update failures due to the data movement for rehashing. This section focuses on our solutions for the two correctness problems.

1) Content-conscious Find to Fix Duplicate Items. There are three cases for duplicate items in our clevel hashing: concurrent insertion with the same key, the retry of the context-aware insertion, and data movement for rehashing. Note that re-insertion after system crash would not generate duplication due to checking of the key before insertion. We observe that duplication from two concurrent insertions leads to two pointers to different items and keeping any one of the two is acceptable. Re-insertion or rehashing generates two pointers to the same item. In this case, we keep the pointer which is closer to the first level, since rehashing threads may delete the pointer in the last level. If two pointers are in the same level, keeping either pointer is identical. With this knowledge, we design a content-conscious Find process to handle duplication in two steps. First, we apply b2t search to find two slots storing the pointer to the matched key. Second, if two pointers refer to different locations, we delete the item and the pointer that first occurs in the b2t search. If two pointers point to the same location, we simply delete the pointer that first occurs. By removing duplicate items, the Find process returns at most one item for the atomic update.

2) Rehashing-aware Scheme to Avoid Update Failures. As the example shown in Figure 4, even with the Find process, the interleaved execution of update and rehashing is possible to lose the updated values. The updated item referred by p′ is deleted by the rehashing thread. A straightforward solution is to issue another Find process after the update. However, frequent two-round Find increases the update latency. To decrease the frequency, we design a rehashing-aware scheme by checking the rehashing progress. Specifically, before the first Find process, we record the bucket index (e.g., RB_{idx}) being rehashed by one rehashing thread. After the atomic update, we read the rehashing progress again (e.g., RB'_{idx}). If the global context doesn't change, an additional Find is triggered only when meeting the following constraints: (1) the table is during resizing; (2) the updated bucket is in the last level; (3) the updated bucket index B_{idx} satisfies $RB_{idx} \leq B_{idx} \leq RB'_{idx}$ for all rehashing threads. Since it's a rare case that three constraints are simultaneously satisfied, our rehashing-aware update scheme guarantees the correctness with low overheads.

3.2.4 Deletion

For deletion, clevel hashing atomically deletes the pointers and matched items. Like the update, the deletion also needs to remove duplicate items. Compared with the update, we optimize the scheme to handle duplication in deletion. Briefly speaking, clevel hashing deletes all the matched items through the b2t search. The lock-free deletion also has failures like the lock-free update. Hence, we use the rehashing-aware scheme presented in lock-free update(§3.2.3) to guarantee the correctness.

3.3 Recovery

The fast recovery requires the guarantee for crash consistency, which is nontrivial for PM. Recent studies [16, 35] show that a crash-consistent lock-free PM index needs to persist after stores and not modify PM until all dependent contents are persisted. The crash consistency guarantee in clevel hashing follows this methodology. Specifically, clevel hashing adds cache line flushes and memory fences after each store and persists dependent metadata, e.g., the global context pointer, after the load in insertion/update/deletion. The persist overheads for crash consistency can be further optimized by persisting in batches [16].

For the crash consistency in rehashing, clevel hashing records the index of bucket (e.g., RB_{idx}) in PM after successfully rehashing the items in the bucket. To recover from failures, rehashing threads read the context and bucket index and continue the rehashing with the next bucket (e.g., $RB_{idx}+n$, n is the number of rehashing threads). A crash during the data movement of rehashing may lead to duplicate items, which are fixed in future update (§3.2.3) and deletion (§3.2.4).

To avoid permanent memory leakage [16], we leverage existing PM atomic allocators from PMDK [5] and design lock-free persistent buffers for secure and efficient memory management. The PM atomic allocators atomically allocate and reclaim memory to avoid expensive transactional memory management [5]. A persistent buffer is a global array of persistent pointers (used by the PM allocators for atomic and durable memory management) attached to the root object (an anchor) of the persistent memory pool. The array size is equal to the thread number. Each thread uses the persistent pointer corresponding to its thread ID. Hence, there is no contention for the persistent buffers. When recovering from failures, we scan the persistent buffers and release the unused memory.

4 Performance Evaluation

4.1 Experimental Setup

Our experiments run on a server equipped with six Intel Optane DC PMM (1.5 TB in total), 128 GB DRAM, and 24.75 MB L3 cache. The Optane DC PMMs are configured in the *App Direct* mode and mounted with ext4-DAX file system. There are 2 CPU sockets (i.e., NUMA nodes) in the server and each socket has 36 threads. For a processor in one NUMA node, the latency of accessing local memory (attached to the NUMA node) is lower than non-local memory [13, 25, 33]. Conducting experiments across multiple NUMA nodes introduces the disturbance of non-uniform memory latencies. To avoid the impact of NUMA architectures, we perform all the experiments on one CPU socket by pinning threads to an NUMA node for all schemes, like RECIPE [27]. Existing NUMA optimizations, e.g., Node-Replication [13] to maintain per-node replicas of hash tables and synchronize these replicas through a shared log, are possible to improve the scalability with more NUMA nodes.

In our evaluation, we compare the following concurrent hashing-based index structures for PM:

- **LEVEL**: This is the original concurrent level hashing [40] with consistency support. The level hashing uses slot-grained reader-writer lock for queries and a global resizing lock for resizing.

- **CCEH**: CCEH [30] organizes an array of slots as a segment (e.g., 1024 slots) and uses a directory as an address table. Linear probing (e.g., 16 slots) is used to improve the load factor. CCEH supports dynamic resizing through segment splitting and possible directory doubling. We adopt the default lazy deletion version since it has higher insertion throughput than the CoW version. CCEH uses reader-writer locks for segments and the directory.

- **CMAP**: The concurrent_hash_map storage engine in pmemkv [6] is a linked list based concurrent hashing scheme for PM. It uses reader-writer locks for concurrent accesses to buckets and supports lazy rehashing (rehash the buckets in a linked list when accessing).

Table 2: Workloads from YCSB for macro-benchmarks.

Workload	Read ratio (%)	Write ratio (%)
Load A	0	100
A	50	50
B	95	5
C	100	0

- **P-CLHT**: P-CLHT [27] is a linked list based cache-efficient hash table. Each bucket has 3 slots. P-CLHT supports lock-free search while the bucket-grained lock is needed for insertion and deletion. The resizing in P-CLHT requires a global lock. When one thread starts rehashing, another helper thread (one helper at most) is allowed to perform concurrent rehashing, which is called helping resizing. The helping resizing mechanism is enabled by default.

- **CLEVEL**: This is our proposed scheme, clevel hashing, which provides asynchronous resizing and lock-free concurrency control for all queries with high memory efficiency.

Since open-source cmap is implemented using PMDK with C++ bindings [5], we implement our clevel hashing with PMDK (version 1.6) and port level hashing, CCEH, and P-CLHT to the same platform for fair comparisons. Like cmap and clevel hashing, we optimize level hashing, CCEH, and P-CLHT to support variable-length items by storing pointers in the hash table. For level hashing and CCEH, we use the same type of reader/writer locks from cmap to avoid the disturbance of lock implementations. During the porting, in addition to the reported bugs of the inconsistencies in directory metadata [27], we observe a concurrent bug for the directory in original CCEH: a thread performing search can access a directory deleted by other threads that are doubling the directory. As a result, failures may occur in search when accessing the reclaimed directory via pointer dereferencing. To ensure the correctness and avoid such failures in experiments, we add the missing reader lock for the directory. The hash functions for all schemes are the same: the `std::hash` from the C++ Standard Template Library (STL) [8]. In addition to conventional locks, we also evaluate the performance of level hashing, CCEH, and cmap with the spinlocks from Intel TBB library [3]. For abbreviation, *LEVEL-TBB*, *CCEH-TBB*, and *CMAP-TBB* are TBB-enabled.

We use YCSB [15] to generate micro-benchmarks in zipfian distribution with default 0.99 skewness [40] to evaluate the throughput of different slot numbers and latencies of different queries. The results using uniformly distributed workloads are similar due to the randomness of hash functions [30]. Different queries are executed in the micro-benchmarks: insertion (unique keys), positive search (queried keys exist), negative search (queried keys not exist), update, and deletion. The items to be updated or deleted are present in the table. To evaluate the concurrent throughput, we leverage the real-world workloads from YCSB as macro-benchmarks, following RECIPE [27]. The workload patterns are described in Table 2. We initialize all indexes with similar capacity (64 thousand for micro-benchmarks and 256 thousand for macro-benchmarks) and use 15-byte keys and 15-byte values for all experiments. The experiment with YCSB workloads consists of two phases: load and run phases. In the load phase, indexes are populated with 16 million and 64 million items for micro- and macro-benchmarks, respectively. In the run phase, there are 16 million queries for micro-benchmarks and 64 million for macro-benchmarks. For concurrent execution, each scheme has the same number of threads in total. During our evaluation of clevel hashing, we observe that one rehashing thread for 35 insertion threads can guarantee the number of levels is under 4. Hence, we set one thread as the rehashing thread by default. The reported latency and throughput are the average values of 5 runs.

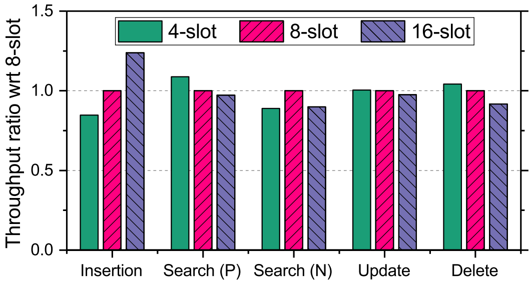

Figure 5: The normalized concurrent throughput of clevel hashing with different slots per bucket. *("Search (P)" is positive search and "Search (N)" is negative search.)*

4.2 Different Slot Numbers and Load Factor

In clevel hashing, the slots per bucket affects not only memory efficiency but also concurrent performance. We run the micro-benchmarks with different slot numbers in clevel hashing and measure the concurrent throughput with 36 threads. The throughput is normalized to that of an 8-slot bucket, as shown in Figure 5. With the increase of slots, the insertion throughput increases. The reason is that more slots per bucket indicate more candidate positions for a key so that it's easier to find an empty slot without resizing. Decreasing the slots per bucket reduces the number of slots to be checked and cache line accesses (a 16-slot bucket requires two cache lines), thus improving the search, update, and deletion throughputs. According to the results shown in Figure 5, 8-slot bucket is a trade-off between 4-slot and 16-slot buckets. Therefore, we set the slot number to 8.

In order to evaluate the memory efficiency of different schemes, we use an insert-only workload to record the load factor (the number of inserted items divided by the number of slots in the table) after every 10K insertions. Since the slot in cmap is allocated on demand for insertions, the load factor is always 100%. The load factors of the other schemes

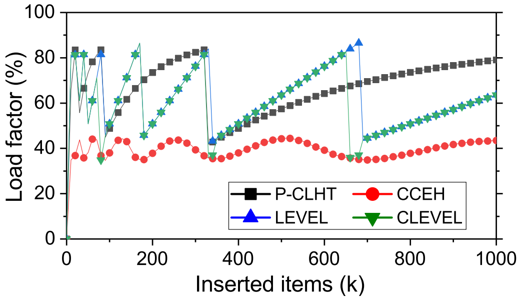

Figure 6: The load factor per 10K insertions. *(The even symbols are skipped for clearness.)*

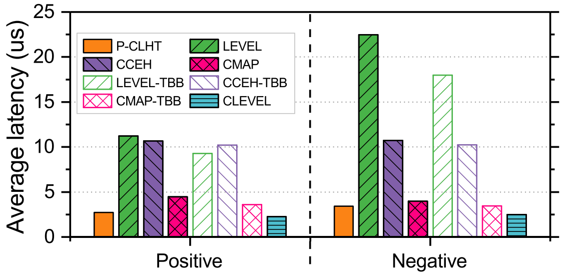

Figure 7: The average latency for concurrent search.

are shown in Figure 6. The maximal load factor of CCEH is no more than 45%, because CCEH probes only 16 slots to address the hash collisions. Though CCEH is able to increase the linear probing distance for higher memory efficiency, long probing distance leads to more memory accesses and pointer dereferencing, thus decreasing the throughputs for all queries. P-CLHT resizes when the number of inserted items approaches the initial capacity of current hash table. By using the three-slot bucket with linked list, the load factor of P-CLHT is up to 84%. Compared with level hashing, clevel hashing doesn't move items in the same level. However, clevel hashing increases the number of slots per bucket to 8. As a result, the maximal load factor of clevel hashing is comparable with original level hashing, i.e., 86%.

4.3 Micro-benchmarks

We use the micro-benchmarks to evaluate the average query latencies in different PM hashing indexes. The latency of a query is interpreted as the time for executing the query, not including the time waiting for execution. All experiments run with 36 threads. Note that the latencies of micro-benchmarks for search, update, and deletion demonstrate the performance of corresponding queries without the impact on resizing, since there is no insertion in these workloads. For the insert-only workload, the expansion of hash table occurs in the run phase.

For the concurrent search, we measure the average latencies when all keys exist (positive search) or not (negative search) in the table. As shown in Figure 7, the level hashing suffers from frequent locking and unlocking of candidate slots, especially

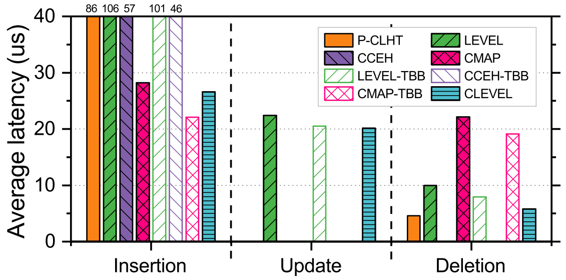

Figure 8: The average latencies for concurrent insertion, update, and deletion.

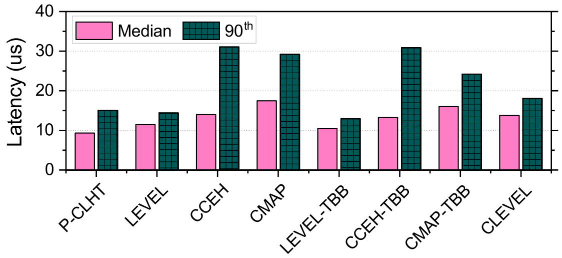

Figure 9: The median and 90^{th} percentile latencies for concurrent insertion.

for the negative search, i.e., 16 slot locks in total for 4 candidate 4-slot buckets. The coarse-grained segment lock (1024 slots) in CCEH leads to high search latency. The search in cmap only requires one bucket lock and ensures low latency. Due to the lock-free search, P-CLHT achieves lower latency than lock-based indexes. For clevel hashing, there are only two levels when the table is not resizing, thus ensuring the number of candidate buckets to be checked is at most 4. Moreover, the lock-free search avoids the contention for buckets. Tags filter unnecessary retrievals for keys. As a result, clevel hashing achieves 1.2×−5.0× speedup for positive search latency and 1.4×−9.0× speedup for negative search latency, compared with other PM hashing indexes.

The average latencies for insertion/update/deletion are shown in Figure 8. Some bars are missing because the corresponding schemes haven't implemented update (i.e., P-CLHT, cmap, and CCEH) or deletion (i.e., CCEH) in their open-source code.

Insertion: During insertion, all schemes have to expand to accommodate 16 million items. The resizing may block several requests (the number depends on the resizing times and thread numbers) and significantly increase their execution time, thus increasing the average latencies. P-CLHT, level hashing, and CCEH suffer from the global lock for resizing. By amortizing the rehashing over future queries, cmap achieves low average latency for insertions. The average latency of clevel hashing is slightly higher than the cmap with TBB because the expansion needs to durably allocate a large new level via the persistent allocator from PMDK, which is achieved by expensive undo logging [38].

Figure 9 shows the median and 90^{th} percentile insertion

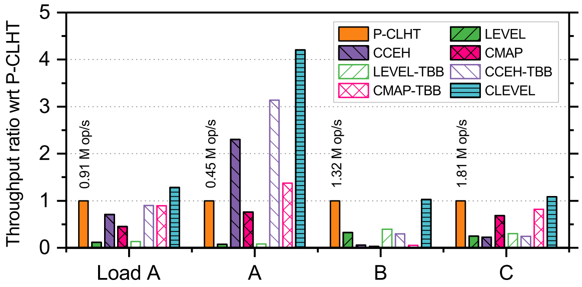

Figure 10: The concurrent throughput of YCSB normalized to P-CLHT.

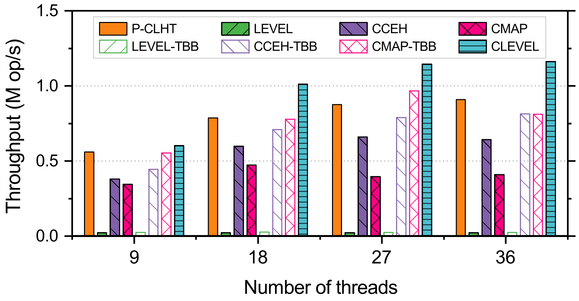

Figure 11: The insertion scalability.

latencies. Unlike the average latency, median and 90^{th} percentile latencies demonstrate the insertion performance without the impact of resizing. The reason is that the ratio of insertions which encounter resizing during their executions is less than 10%. In the meantime, the queuing time for execution is not included in the latency. CCEH suffers from high percentile latencies due to the coarse-grained segment lock. Though cmap leverages fine-grained bucket locks, the amortized rehashing in queries increases the insertion time. Due to the context-aware insertion for correctness guarantee, the median and 90^{th} percentile latencies of clevel hashing are slightly higher than level hashing and P-CLHT but lower than CCEH and cmap.

Update: Compared with original level hashing, clevel hashing obtains slightly lower update latency. The reason is that the benefits of lock-free update compensate for the overheads of correctness guarantee in the clevel hashing, e.g., additional Find operation for duplicate items and checking for update failures.

Deletion: The deletion latency in cmap is higher than other schemes due to rehashing the bucket if necessary before accessing. Level hashing has higher deletion latency than P-CLHT and clevel hashing due to the frequent locking and unlocking when accessing candidate slots. To fix duplication during deletion, clevel hashing checks all candidate slots, thus resulting in a slightly higher latency than P-CLHT.

4.4 Macro-benchmarks

Figure 10 shows the concurrent throughput normalized to P-CLHT of different PM hashing schemes with real-world workloads from YCSB. We run the experiment with 36 threads for all schemes. Since workload Load A is used to populate indexes with 64 million items in the load phase, all indexes resize multiple times (e.g., more than 10 times in clevel hashing) from small sizes. Resizing also occurs in the workload A.

The locks used for concurrency control hinder the index performance. Specifically, the global resizing lock in the level hashing blocks all queries until the single-threaded rehashing completes, which leads to low throughput in workload Load A and A. The global directory lock in CCEH is only used for directory doubling. Therefore, the insertion throughput is much higher than level hashing. Due to the helping mechanism in P-CLHT, there are two threads concurrently rehashing items, which mitigates the overheads of the global resizing lock in the load phase of YCSB (Load A). However, when the table size increases, the two threads are not enough to rehash all items in a short time, which accounts for the low throughput for P-CLHT in workload A. Due to the multiple resizing, the aggregated rehashing hinders the throughput of cmap. Unlike these lock-based indexes, the lock-free concurrency control in clevel hashing avoids the lock contention during insertions. Hence, clevel hashing obtains 1.4× speedup than cmap for insertion throughput. In summary, our clevel hashing achieves up to 4.2× speedup than the state-of-the-art PM hashing index (i.e., P-CLHT).

To evaluate the scalability of clevel hashing, we measure the insertion throughput with different number of threads using the Load A. As shown in Figure 11, with the increase of threads, the throughput of clevel hashing increases and is consistently higher than other schemes. This trend in search throughput is similar.

4.5 Discussion

The reduction of hash table size. The current design of clevel hashing doesn't support the reduction of the hash table size. When most stored items in the hash table are deleted, the table may reduce the table size to improve space utilization. Clevel hashing needs to be adapted to support the reduction. Specifically, to reduce the table size in clevel hashing, we need to create a new level with half of the buckets in the last level and rehash the items from the first level to the last level. When all the items of the first level are rehashed, the first level is reclaimed. The migration of items for the reduction generates data movement from the top level to the bottom one (i.e., top-to-bottom movement), which is opposite to expansion (i.e., bottom-to-top movement). Therefore, to support concurrent reduction, we carry out top-down search strategy instead of down-top search (§3.2.1) to avoid missing inserted items. Note that all threads need to leverage the same search strategy: either top-down searching for reduction or down-top searching for expansion. The clevel hashing with non-blocking concurrent reduction is our future work.

The isolation level. For the isolation in transactions, clevel hashing has dirty reads, since there is no lock to isolate data. Hence, the isolation level is *read uncommitted* [11]. To support higher isolation levels in a transaction, additional locks or version control schemes are required [11, 22].

Space overhead. The metadata overhead in clevel hashing mainly comes from the persistent buffers (§3.3), which are the arrays of persistent pointers to the allocated memory, for efficient management without contention. Persistent buffers have separate entries for each thread. Therefore, the metadata overhead is proportional to the number of threads. Clevel hashing achieves a maximal load factor over 80% before resizing. During resizing, hashing collisions that cannot be addressed increase the number of levels to more than 3. Due to the randomness of hash functions, the possibility of continuous hash collisions for one position is very low. Moreover, rehashing threads migrate items in the last level until only two levels remain. Hence, the number of total levels is usually small, which enables high storage utilization.

5 Related Work

5.1 Hashing-based Index Structures for PM

In order to optimize the hashing performance on PM, recent work have designed some hashing-based index structures for PM. Path hashing [39] and level hashing [40] leverage sharing-based index structures and write-efficient open-addressing techniques for high memory efficiency with limited extra writes. Level hashing introduces a cost-efficient resizing scheme by only rehashing the items in the old bottom level to the new top level, which only account for 1/3 of total inserted items. LF-HT [16] uses lock-free linked list for each bucket to address hash collisions. However, these three schemes all suffer from poor resizing performance, since the resizing operations require exclusive global lock for metadata. CCEH [30] is based on extendible hashing, which dynamically expands the hash table by segment splitting and optional directory doubling. Although the resizing in CCEH is concurrent with other queries, the use of coarse-grained locks for segments or even directory during resizing causes performance degradation. The cmap storage engine in pmemkv [6] supports concurrent lazy rehashing. The rehashing of items in a bucket is trigger when accessing the bucket. As a result, cmap distributes the rehashing of items to future search/insertion/update/deletion. However, cmap is possible to encounter recursive rehashing due to the lazy rehashing. The rehashing in the critical path of queries decreases the throughputs, especially for search operations. Unlike existing schemes, clevel hashing has dynamical multi-level structure for concurrent asynchronous resizing and designs lock-free algorithms to improve the scalability with low latency.

5.2 Lock-free Concurrent Hashing Indexes

Lock-free algorithms mitigate the lock contention for shared resources and are hard to design because of the challenging concurrency control. The lock-free linked list proposed by Harris [21] is widely used in lock-free concurrent hashing indexes [16, 29]. This class of schemes add a lock-free linked list to each bucket. Though the lock-free linked list enables lock-free insertion in these hash tables, it causes high search overheads due to the sequential iteration over linked lists. The lock-free cuckoo hashing [31] uses marking techniques with helping mechanism to support lock-free cuckoo displacements. However, the recursive data movements bring lots of extra PM writes [40]. Recent work [20] uses PSim [19] to build a wait-free resizable hash table. The wait-free technique relies on copying the shared object and helping mechanism, which still leads to extra writes on PM and introduces overheads due to helping. Moreover, the extendible hashing structures are memory inefficient as shown in our evaluation. Different from existing lock-free hashing schemes built on DRAM, clevel hashing designs PM friendly and memory efficient multi-level structures with simple but effective context-aware mechanism to guarantee correctness and crash consistency.

6 Conclusion

Persistent memory offers opportunities to improve the performance of storage systems, but suffers from the lack of efficient and concurrent index structures. Existing PM-friendly hashing indexes only focus on the consistency and write reduction, which overlook the concurrency and resizing of hash tables. In this paper, we propose clevel hashing, a lock-free concurrent hashing scheme for PM. Clevel hashing leverages the dynamic memory-efficient multi-level design and asynchronous resizing to address the blocking issue due to resizing. The lock-free concurrency control avoids the lock contention for all queries while guarantees the correctness. Our results using Intel Optane DC PMM demonstrate that clevel hashing achieves higher concurrent throughput with lower latency than state-of-the-art hashing indexes for PM.

Abstract

Memory-mapped I/O provides several potential advantages over explicit read/write I/O, especially for low latency devices: (1) It does not require a system call, (2) it incurs almost zero overhead for data in memory (I/O cache hits), and (3) it removes copies between kernel and user space. However, the Linux *memory-mapped I/O* path suffers from several scalability limitations. We show that the performance of Linux *memory-mapped I/O* does not scale beyond 8 threads on a 32-core server. To overcome these limitations, we propose *FastMap*, an alternative design for the *memory-mapped I/O* path in Linux that provides scalable access to fast storage devices in multi-core servers, by reducing synchronization overhead in the common path. *FastMap* also increases device queue depth, an important factor to achieve peak device throughput. Our experimental analysis shows that *FastMap* scales up to 80 cores and provides up to 11.8× more IOPS compared to *mmap* using *null_blk*. Additionally, it provides up to 5.27× higher throughput using an Optane SSD. We also show that *FastMap* is able to saturate state-of-the-art fast storage devices when used by a large number of cores, where Linux *mmap* fails to scale.

1 Introduction

The emergence of fast storage devices, with latencies in the order of a few μs and IOPS rates in the order of millions per device is changing the I/O landscape. The ability of devices to cope well with random accesses leads to new designs for data storage and management that favor generating small and random I/Os to improve other system aspects [2, 35, 42, 43]. Although small and random I/Os create little additional pressure to the storage devices, they result in significantly higher CPU overhead in the kernel I/O path. As a result, the overhead of performing I/O operations to move data between memory and devices is becoming more pronounced, to the point where a large fraction of server CPU cycles are consumed only to serve storage devices [11, 46].

In this landscape, *memory-mapped I/O*, i.e. Linux *mmap*, is gaining more attention [8, 13, 24, 42, 43] for data intensive applications because of its potentially lower overhead compared to read/write system calls. An off-the-shelf NVMe block device [28] has access latency close to 10 μs and is capable of more than 500 KIOPS for reads and writes. Byte-addressable, persistent memory devices exhibit even better performance [29]. The traditional read/write system calls in the I/O path incur overheads of several μs [11, 46] in the best case and typically even higher, when asynchronous operations are involved.

In contrast, when using *memory-mapped I/O* a file is mapped to the process virtual address space where the user can access data with processor *load*/*store* instructions. The kernel is still responsible for moving data between devices and memory; *mmap* removes the need for an explicit system call per I/O request and incurs the overhead of an implicit page fault only when data does not reside in memory. In the case when data reside in memory, there is no additional overhead due to I/O cache lookups and system calls. Therefore, the overhead for hits is reduced dramatically as compared to both the kernel buffer cache but also to user-space I/O caches used in many applications. In several cases *memory-mapped I/O* removes the need to serialize and deserialize user data, by allowing applications to have the same format for both in-memory and persistent data, and also the need for memory copies between kernel and user space.

A major reason for the limited use of *memory-mapped I/O*, despite its advantages, has been that *mmap* may generate small and random I/Os. With modern storage devices, such as NVMe and persistent memory, this is becoming less of a concern. However, Figure 1 shows that the default *memory-mapped I/O* path (*mmap* backed by a device) for random page faults does not scale well with the number of cores. In this experiment (details in Section 4), we use *null_blk*, a Linux driver that emulates a block device but does not issue I/Os to a real device (we use 4TB dataset and 192GB of

[1] Also with the Department of Computer Science, University of Crete, Greece.

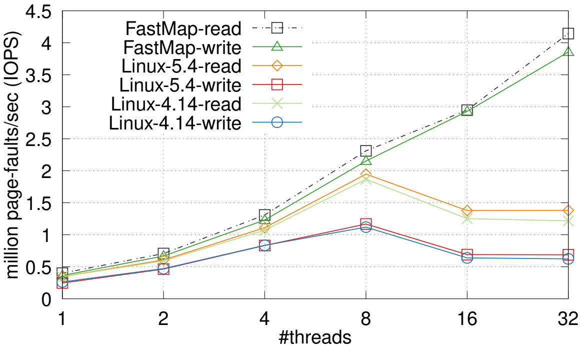

Figure 1: Scalability of random page faults using two versions of Linux *memory-mapped I/O* path (v4.14 & v5.4) and *FastMap*, over the *null_blk* device.

DRAM cache). Using *null_blk* allows us to stress the Linux kernel software stack while emulating a low-latency, next-generation storage device. Linux *mmap* scales up to only 8 cores, achieving 7.6 GB/s (2M random IOPS), which is about 5× less compared to a state-of-the-art device [29]; servers with multiple storage devices need to cope with significantly higher rates. We observe that from Linux kernel 4.14 to 5.4 the performance and the scalability of the *memory-mapped I/O* path has not improved significantly. Limited scalability also results in low device queue depth. Using the same micro-benchmark for random read page faults with 32 threads on an Intel Optane SSD DC P4800X, we see that the average device queue depth is 27.6. A large queue depth is essential for fast storage devices to provide their peak device throughput.

In this paper, we propose *FastMap*, a novel design for the *memory-mapped I/O* path that overcomes these two limitations of *mmap* for data intensive applications on multi-core servers with fast storage devices. *FastMap* (a) separates clean and dirty-trees to avoid all centralized contention points, (b) uses full reverse mappings instead of Linux object-based reverse mappings to reduce CPU processing, and (c) introduces a scalable DRAM cache with per-core data structures to reduce latency variability. *FastMap* achieves both higher scalability and higher I/O concurrency by (1) avoiding all centralized contention points that limit scalability, (2) reducing the amount of CPU processing in the common path, and (3) using dedicated data-structures to minimize interference among processes, thus improving tail latency. As a further extension to *mmap*, we introduce a user-defined read-ahead parameter to proactively map pages in application address space and reduce the overhead of page faults for large sequential I/Os.

We evaluate *FastMap* using both micro-benchmarks and real workloads. We show that *FastMap* scales up to 80 cores and provides up to 11.8× more random IOPS compared to Linux *mmap* using *null_blk*. *FastMap* achieves 2× higher throughput on average for all YCSB workloads over Kreon [43], a persistent key-value store designed to use *memory-mapped I/O*. Moreover, we use *FastMap* to extend the virtual address space of memory intensive applications beyond the physical memory size over a fast storage device. We achieve up to 75× lower average latency for TPC-C over Silo [54] and 5.27× better performance with the Ligra graph processing framework [50]. Finally, we achieve 6.06% higher throughput on average for all TPC-H queries over MonetDB [8] that mostly issue sequential I/Os.

In summary, our work optimizes the *memory-mapped I/O* path in the Linux kernel with three main contributions:

1. We identify severe performance bottlenecks of Linux *memory-mapped I/O* in multi-core servers with fast storage devices.
2. We propose *FastMap*, a new design for the *memory-mapped I/O* path.
3. We provide an experimental evaluation and analysis of *FastMap* compared to Linux *memory-mapped I/O* using both micro-benchmarks and real workloads.

The rest of the paper is organized as follows. §2 provides the motivation behind *FastMap*. §3 presents the design of *FastMap* along with our design decisions. §4 and §5 present our experimental methodology and results, respectively. Finally, §6 reviews related work and §7 concludes the paper.

2 Motivation

With storage devices that exhibit low performance for random I/Os, such as hard disk drives (HDDs), *mmap* results in small (4KB) random I/Os because of the small page size used in most systems today. In addition, *mmap* does not provide a way for users to manage page writebacks in the case of high memory pressure, which leads to unpredictable tail latencies [43]. Therefore, historically the main use of *mmap* has been to load binaries and shared libraries into the process address space; this use-case does not require frequent I/O, uses read-mostly mappings, and exhibits a large number of shared mappings across processes, e.g. libc is shared by almost all processes of the system. Reverse mappings provide all page table translations for a specific page and they are required in order to unmap a page during evictions. Therefore, Linux *mmap* uses object-based reverse mappings [37] to reduce memory consumption and enable fast *fork* system calls, as they do not require copying full reverse mappings.

With the introduction of fast storage devices, where the throughput gap between random and sequential I/O is small, *memory-mapped I/O* has the potential to reduce I/O path overhead in the kernel, which is becoming the main bottleneck for data-intensive applications. However, data intensive applications, such as databases or key-value stores, have different requirements compared to loading binaries: they can be write-intensive, do not require large amount of sharing, and do not use *fork* system calls frequently. These properties make the

(b) *FastMap*

Figure 2: Linux (left) and *FastMap* (right) high-level architecture for memory-mapped files (acronyms: **PFD**=**P**er-**F**ile-**D**ata, **PVE**=**P**er-**V**ma-**E**ntry, **PPR**=**P**er-**P**ve-**R**map).

use of full reverse mappings a preferred approach. In addition, data intensive applications use datasets that do not fit in main memory and thus, the path of reading and writing a page from the device becomes the common case. Most of these applications are also heavily multithreaded and modern servers have a large number of cores.

3 Design of *FastMap*

The Linux kernel provides the *mmap* and *munmap* system calls to create and destroy memory mappings. Linux distinguishes memory mappings in shared vs. private. Mappings can also be anonymous, i.e. not backed by a file or device. Anonymous mappings are used for memory allocation. In this paper we examine I/O over persistent storage, an inherently shared resource. Therefore, we consider only shared memory mappings backed by a file or block device, as also required by Linux *memory-mapped I/O*.

Figure 2(a) shows the high-level architecture of shared memory mappings in the Linux kernel. Each virtual memory region is represented by a *struct vm_area_struct* (*VMA*). Each *VMA* points to a *struct file* (*file*) that represents the backing file or device and the starting offset of the memory mapping to it. Each *file* points to (a shared between processes) *struct address_space* (*address_space*) which contains information about mapped pages and the backing file or device.

Figure 2(b) illustrates the high-level design of *FastMap*. The most important components in our design are *per_file_data* (*PFD*) and *per_vma_entry* (*PVE*). Combined, these two components provide equivalent functionality as the Linux kernel *address_space* structure. Each *file* points to a *PFD* and each *VMA* points to a *PVE*. The role of a *PFD* is to keep metadata about device blocks that are in the *FastMap* cache and metadata about dirty pages. *PVE* provides full reverse mappings.

3.1 Separate Clean and Dirty Trees in *PFD*

In Linux, one of the most important parts of *address_space* is *page_tree*, a radix tree that keeps track of all pages of a cacheable and mappable file or device, both clean and dirty. This data structure provides an effective way to check if a device block is already in memory when a page fault occurs. Lookups are lock-free (*RCU*) but inserts and deletes require a spinlock (named *tree_lock*). Linux kernel radix trees also provide user-defined *tags* per entry. A *tag* is an integer, where multiple values can be stored using bitwise operations. In this case *tags* are used to mark pages as dirty. Marking a previously read-only page as writable requires holding the *tree_lock* to update the *tag*.

Using the experiments of Figure 1 and *lockstat* we see that *tree_lock* is by far the most contended lock: Using the same multithreaded benchmark as in Figure 1, over a single memory mapped region, *tree_lock* has 126× more contended lock acquisitions, which involve cross-cpu data, and 155× more time waiting to acquire the lock, compared to the second most contended lock. The second more contended lock is a spinlock that protects concurrent modifications in *PTEs* (4th level entries in the page table). This design has remained essentially unchanged from Linux kernel 2.6 up to 5.4 (latest stable version at the time of this writing).

To remove the bottleneck in *tree_lock*, *FastMap* uses a new structure for per-file data, *PFD*. The most important aspects of *PFD* are: (i) a per-core radix tree (*page_tree*) that keeps all (clean and dirty) pages and (ii) a per-core red-black tree (*dirty_tree*) that keeps only dirty pages. Each of these data structures is protected by a separate (per core) spinlock, different for the radix and red-black trees. We assign pages to cores in a round-robin manner and we use the page offset to identify the per-core structure that holds each page.

We use *page_tree* to provide lock-free lookups (RCU), similar to the Linux kernel. We use per-core data structures to reduce contention in case we need to add or remove a page. On the other hand, we do not use *tags* to mark pages as dirty but we use the *dirty_tree* for this purpose. In the case where we have to mark a previously read-only page as read-write, we only acquire the appropriate lock of *dirty_tree* without performing any additional operations to the *page_tree*. Furthermore, having all dirty pages in a sorted data structure (red-black tree) enables efficient I/O merging for the cases of writebacks and the *msync* system call.

3.2 Full Reverse Mappings in *PVE*

Reverse (inverted) mappings are also an important part of *mmap*. They are used in the case of evictions and writebacks and they provide a mechanism to find all existing virtual memory mappings of a physical page. File-backed memory mappings in Linux use object-based reverse mappings [37]. The main data structure for this purpose is a red-black tree, *i_mmap*. It contains all *VMAs* that map at least one page of this *address_space*. A read-write semaphore, *i_mmap_rwsem*, protects concurrent accesses to the *i_mmap* red-black tree. The main function that removes memory mappings for a specific page is *try_to_unmap*. Each page has two fields for this purpose: (i) a pointer to the *address_space* that it belongs to and (ii) an atomic counter (*_mapcount*) that keeps the number of active page mappings. Using the pointer to *address_space*, *try_to_unmap* gets access to *i_mmap* and then iterates over all *VMAs* that belong to this mapping. Through each VMA, it has access to *mm_struct* which contains the root of the process page table (*pgd*). It calculates the virtual address of the mapping based on the *VMA* and the page, which is required for traversing the page table. Then it has to check all active *VMAs* of *i_mmap* if the specific page is mapped, which results in many useless page table traversals. This is the purpose of *_mapcount*, which limits the number of traversals. This strategy is insufficient in some cases but it requires a very small amount of memory for the reverse mappings. More specifically, in the case where *_mapcount* is greater than zero, we may traverse the page table for a *VMA* where the requested page is not mapped. This can happen in the case where a page is mapped in several different *VMAs* in the same process, i.e. with multiple *mmap* calls, or mapped in the address space of multiple different processes. In such a case, we have unnecessary page table traversals that introduce overheads and consume CPU cycles. Furthermore, during this procedure, *i_mmap_rwsem* is held as a read lock and as a write lock only during *mmap* and *munmap* system calls. Previous research shows that even a read lock can limit scalability in multicore servers [15].

The current object-based reverse mappings in Linux have two disadvantages: (1) with high likelihood they result in unnecessary page table traversals, originating from *i_mmap*, and (2) they require a coarse grain read lock to iterate *i_mmap*. Other works have shown that in multi-core servers locks can be expensive, even for read-write locks when acquired as read locks [15]. These overheads are more pronounced in servers with a NUMA memory organization [10].

To overcome these issues *FastMap* provides finer grained locking, as follows: *FastMap* uses a structure with an entry for each VMA, *PVE*. Each *PVE* keeps a per-core list of all pages that belong to this *VMA*. A separate (per core) spinlock protects each of these lists. The lists are append-only as unmapping a page from a different page table does not require any ordering. We choose the appropriate list based on the core that runs the append operation (*smp_processor_id()*). These lists contain *per_pve_rmap* (*PPR*) entries. Each *PPR* contains a tuple $(VMA, virtual\_address)$. These metadata are sufficient to allow iterating over all mapped pages of a specific memory mapping in the case of an *munmap* operation. Furthermore, each page contains an append-only list of active *PPRs*, which are shared both for *PVEs* and pages. This list is used when we need to evict a page that is already mapped in one or more address spaces, in the event of memory pressure.

3.3 Dedicated DRAM Cache

An *mmap address_space* contains information about the backing file or device and the required functions to interact with the device in case of page reads and writes. To write back a set of pages of a memory mapping, Linux iterates *page_tree* in a lock-free manner with RCU and writes only the pages that have the dirty tag enabled. Linux also keeps a per-core LRU to find out which pages to evict. In the case of evictions, Linux tries to remove clean pages in order not to wait for dirty pages to do the writeback [37].

The Linux page-cache is tightly coupled with the swapper. For the *memory-mapped I/O* path, this dependency results in unpredictable evictions and bursty I/O to the storage devices [43]. Therefore, *FastMap* implements its own DRAM cache, managing evictions via an approximation of LRU. *FastMap* has two types of LRU lists: one containing only clean pages (*clean_queue*) and one containing only dirty pages (*dirty_queue*). *FastMap* maintains per-core *clean_queues* to reduce lock contention. We identify the appropriate *clean_queue* as clean_queue_id = page_offset % num_cores.

When there are no free pages during a page fault, *FastMap* evicts only clean pages, similar to the Linux kernel [37], from the corresponding *clean_queue*. We evict a batch (with a configurable size, currently set to 512) of clean pages to amortize the cost of page table manipulation and TLB invalidations. Each page eviction requires a TLB invalidation with the *flush_tlb* function, if the page mapping is cached. *flush_tlb* sends an IPI (Inter-Processor-Interrupt) to all cores, incurring significant overheads and limiting scalability [3,4]. We implement a mechanism to reduce the number of calls to *flush_tlb* function, using batching, as follows.

A TLB invalidation requires a pointer to the page table and the *page_offset*. *FastMap* keeps a pointer to the page table and a range of *page_offsets*. Then, we invoke *flush_tlb* for the whole range. This approach may invalidate more pages, but reduces the number of *flush_tlb* calls by a factor of the batch-size of page evictions (currently 512). As the file mappings are usually contiguous in the address space in data intensive applications, in the common case false TLB invalidations are infrequent. Thus, *FastMap* manages to maintain a high number of concurrent I/Os to devices and increase device throughput. *LATR* [33] proposes the use of an asynchronous TLB invalidation mechanism based on message passing. In our case, we cannot delay TLB invalidations as the pages should be used immediately for page fault handling.

FastMap uses multiple threads to write dirty pages to the underlying storage device (writeback). Each of these manages its own *dirty_queue*. This design removes the need of synchronization when we remove dirty pages from a *dirty_queue*. During writebacks, *FastMap* merges consecutive I/O requests to generate large I/O operations to the underlying device. To achieve this, we use *dirty_trees* that keep dirty pages sorted based on the device offset. As we have multiple *dirty_trees*, we initialize an iterator for each tree and we combine the iterator results using a min-max heap. When a writeback occurs, we also move the page to the appropriate *clean_queue* to make it available for eviction. As page writeback also requires a TLB invalidation, we use the same mechanism as in the eviction path to reduce the number of calls to the kernel *flush_tlb* function. Each writeback thread checks the ratio of dirty to clean pages and starts the writeback when the percentage is higher than 75% of the total cache pages. The cache in *FastMap* currently uses a static memory buffer, allocated upon module initialization and does not create any further memory pressure to the Linux page cache. We also provide a way to grow and shrink this cache at runtime, but we have not yet evaluated alternative sizing policies.

To keep track of free pages *FastMap* uses a per-core free list with a dedicated spinlock. During a major page fault i.e., when the page does not reside in the cache, the faulting thread first tries to get a page from its local free list. If this fails, it tries to steal a page from another core's free list (randomly selected). After *num_cores* unsuccessful tries, *FastMap* forces page evictions to cleanup some pages. To maintain all free lists balanced, each evicted page is added to the free list from which we originally obtained the page.

Overall, *FastMap* with per-core data structures requires more memory compared to the native Linux *mmap*. *FastMap* requires a single *PFD*, which is 1120 bytes, per file for all memory mappings. A single *PVE* is about 512 bytes and a single *PPR* is 24 bytes. We require a single *PVE* for each mmap call, i.e. 1 : 1 with the Linux VMA struct. *FastMap* requires a single *PPR* entry per *PVE* for each mapped page, independently of how many threads access the same page. In the setups we target, there is little sharing of files across processes and we can therefore, assume that we only need one *PPR* entry for each page in our DRAM cache. For instance, assume that a single application maps 1000 files and uses $8GB$ of DRAM cache. This results in $1.64MB$ of additional memory, independently of the size of files and the number of threads. *FastMap* targets storage servers with large memory spaces and can be applied selectively for the specific mount points that hold the files of data-intensive applications. While it is, in principle, possible to allow more fine-grain uses of *FastMap* in Linux, we leave this possibility for future work.

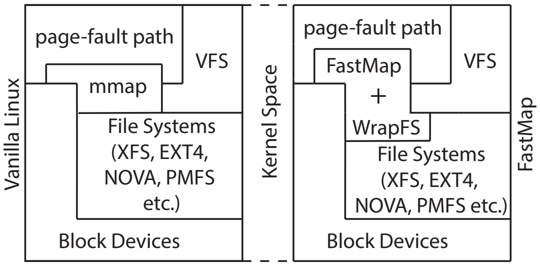

Figure 3: FastMap I/O path.

Finally, the Linux kernel also provides private, file-backed memory mappings. These are Copy-On-Write mappings and writes to them do not reach the underlying file/device. Such mappings are outside the scope of this paper, but they share the same path in the Linux kernel to a large extent. Our proposed techniques also apply to private file-backed mappings. However, these mappings are commonly used in Linux kernel to load binaries and shared libraries, resulting in a large degree of sharing. We believe that it is not beneficial to use the increased amount of memory required by *FastMap* to optimize this relatively uncommon path.

3.4 Implementation

Figure 3 shows the I/O path in the Linux kernel and indicates where *FastMap* is placed. *FastMap* is above *VFS* and thus is independent of the underlying file system. This means that common file systems such as *XFS*, *EXT4*, and *BTRFS* [1] can benefit from our work.

FastMap provides a user interface for accessing both a block device but also a file system through a user-defined mount point. For the block device case, we implement a virtual block device that uses our custom *mmap* function. All other block device requests (e.g. *read*/*write*) are forwarded to

[1] *FastMap* has been successfully tested with all of these file systems.

the underlying device. Requests for fetching or evicting pages from *FastMap* are issued directly to the underlying device.

For the file system implementation we use WrapFS [59], a stackable file system that intercepts all *mmap* calls to a specific mount point so that *FastMap* is used instead of the native Linux *mmap* implementation. For fetching or evicting pages from within *FastMap* we use direct I/O to the underlying file system, bypassing the Linux page cache. All other file system calls are forwarded to the underlying file system.

4 Experimental Methodology

In this section, we present the experimental methodology we use to answer the following questions:

1. How does *FastMap* perform compared to Linux *mmap*?
2. How much does *FastMap* improve storage I/O?
3. How sensitive is *FastMap* to (a) file system choice and (b) false TLB invalidations?

Our main testbed consists of a dual-socket server that is equipped with two Intel(R) Xeon(R) CPU E5-2630 v3 CPUs running at 2.4 GHz, each with 8 physical cores and 16 hyper-threads for a total of 32 hyper-threads. The primary storage device is a PCIe-attached Intel Optane SSD DC P4800X series [28] with 375 GB capacity. For the purposes of evaluating scalability, we use an additional four-socket server. This four-socket server is equipped with four Intel(R) Xeon(R) CPU E5-4610 v3 CPUs running at 1.7 GHz, each with 10 physical cores and 20 hyper-threads for a total of 80 hyper-threads. Both servers are equipped with 256 GB of DDR4 DRAM at 2400 MHz and run CentOS v7.3, with kernel 4.14.72.

During our evaluation we limit the available capacity of DRAM (using a kernel boot parameter) as required by different experiments. In our evaluation we use datasets that both fit and do not fit in main memory. This allows us to provide a more targeted evaluation and separate the costs of the page-fault path and the eviction path. To reduce variability in our experiments, we disable swap and Transparent Huge Pages (THP), and we set the CPU scaling governor to "performance". In experiments where we want to stress the software path of the Linux kernel we also use the *null_blk* [40] and *pmem* [47] block devices. *null_blk* emulates a block device but ignores the I/O requests issued to it. For *null_blk* we use the bio-based configuration. *pmem* emulates a fast block device that is backed by DRAM.

In our evaluation we first use a custom multithreaded microbenchmark. It uses a configurable number of threads that issue *load/store* instructions at randomly generated offsets within the memory mapped region. We ensure that each *load/store* results in a page fault.

Second, we use a persistent key-value store. We choose Kreon [43], a state-of-the-art persistent key-value store that is designed to work with *memory-mapped I/O*. The design of Kreon is similar to the LSM-tree, but it maintains a separate B-Tree index per-level to reduce I/O amplification. Kreon uses a log to keep user data. It uses *memory-mapped I/O* to perform all I/O between memory and (raw) devices. Furthermore, it uses Copy-On-Write (COW) for persistence, instead of Write-Ahead-Logging. Kreon follows a single-writer, multiple-reader concurrency model. Readers operate concurrently with writers using Lamport counters [34] per node for synchronization to ensure correctness. For inserts and updates, it uses a single lock per database; however, by using multiple databases Kreon can support concurrent updates.

	Workload
A	50% reads, 50% updates
B	95% reads, 5% updates
C	100% reads
D	95% reads, 5% inserts
E	95% scans, 5% inserts
F	50% reads, 50% read-modify-write

Table 1: Standard YCSB Workloads.

To improve single-database scalability in Kreon and make it more suitable for evaluating *FastMap*, we implement the second protocol that Bayer et al. propose [7]. This protocol requires a read-write lock per node. It acquires the lock as a read lock in every traversal from the root node to a leaf. In the case of inserts or rebalance operations it acquires the corresponding lock as a write lock. As every operation has to acquire the root node read lock, this limits scalability [15]. To overcome this limitation, we replace the read/write lock of the root node with a Lamport counter and a lock. Every operation that modifies the root node acquires the lock, changes the Lamport counter, performs a COW operation, and then writes the update in the COW node.

For Kreon we use the YCSB [18] workloads and more specifically a C++ implementation [48] to remove overheads caused by the JNI framework, as *Kreon* is highly efficient and is designed to take advantage of fast storage devices. Table 1 summarizes the YCSB workloads we use. These are the proposed workloads, and we execute them in the author's proposed sequence [18], as follows: LoadA, RunA, RunB, RunC, RunF, RunD, clear the database, and then LoadE, RunE.

Furthermore, we use Silo [54], an in-memory database that also provides scalable transactions for modern multicore machines. In this case, we use TPC-C [52], a transactional benchmark, which models a retail operation and is a common benchmark for OLTP workloads. We also use Ligra [50], a lightweight graph processing framework for shared memory with OpenMP-based parallelization. Specifically, we use the Breadth First Search (BFS) algorithm. We use Silo and Ligra to evaluate *FastMap*'s effectiveness in extending the virtual address space of an application beyond physical memory over fast storage devices. For this reason we convert all *malloc/free* calls of Ligra and Silo to allocate space over a memory-mapped file on a fast storage device. We use the *libvmmalloc* library from the Persistent Memory Development Kit (PMDK) [45]. *libvmmalloc* transparently converts all dy-

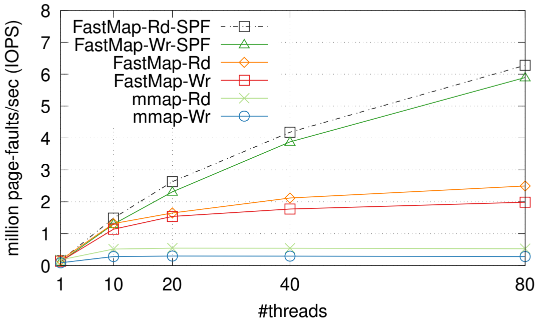

Figure 4: Scalability of random page faults for Linux and *FastMap*, with up to 80 threads, using the *null_blk* device.

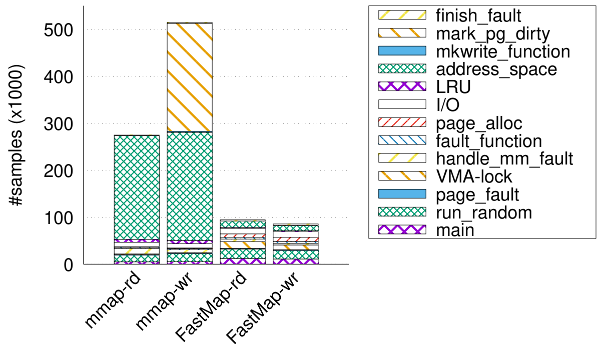

Figure 5: *FastMap* and Linux *mmap* breakdown for read and write page faults, with *null_blk* and 32 cores.

namic memory allocations to persistent memory allocations. This allows the use of persistent memory as volatile memory without modifying the target application. The memory allocator of *libvmmalloc* is based on *jemalloc* [30].

Finally, we evaluate *FastMap* using MonetDB-11.31.7 [8, 39], a column-oriented DBMS that is designed to use *mmap* to access files instead of using the read/write API. We use the TPC-H [53] benchmark, a warehouse read-mostly workload.

We run all experiments three times and we report the averages. In all cases the variation observed across runs is small.

5 Experimental Results

5.1 How does *FastMap* perform compared to Linux *mmap*?

Microbenchmarks: Figure 1 shows that Linux *mmap* fails to scale beyond eight threads on our 32-core server. *FastMap* provides 3.7× and 6.6× more random read and write IOPS, respectively, with 32 threads compared to Linux *mmap*. Furthermore, both versions 4.14 and 5.4 of the Linux kernel achieve similar performance. To further stress *FastMap*, we use our 80-core server and the *null_blk* device. Figure 4 shows that with 80 threads, *FastMap* provides 4.7× and 7× higher random read and write IOPS respectively, compared to Linux *mmap*. Furthermore, in both cases *FastMap* performs up to 38% better even in the case where there is little or no concurrency, when using a single thread.

Figure 4 shows that not only *FastMap* scales better compared to Linux *mmap*, but also that *FastMap* sustains more page faults per second. On the other hand *FastMap* does not achieve perfect scalability. For this reason, we profile *FastMap* using the random read page faults microbenchmark. We find that the bottleneck is the read-write lock (*mmap_sem*) that protects the red-black tree of active *VMAs*. This is the problem that *Bonsai* [15] tackles. Specifically, with 10 cores the cost of *read_lock* and *read_unlock* is 7.6% of the total execution time, with 20 cores it becomes 25.4%, with 40 cores 32%, and with 80 cores 37.4%. To confirm this intuition, we apply Speculative Page Faults (SPF) [20], and attempt to use SRCU (Sleepable RCU) instead of the read-write lock to protect the red-black tree of active *VMAs*, an approach similar to *Bonsai*. We use the Linux kernel patches from [19] as, at the time of writing, they have not been merged in the Linux mainline. As SPF works only for anonymous mappings, we modify it to use *FastMap* for block-device backed memory-mappings. Figure 4 shows that *FastMap* with *SPF* provides even better scalability: 2.51× and 11.89× higher read IOPS compared to *FastMap* without SPF and to Linux kernel, respectively. We do not provide an evaluation of *SPF* without *FastMap* as it (1) works only for anonymous mappings and (2) it could use the same Linux kernel path that has scalability bottlenecks, as we show in Section 3.1.

Figure 5 shows the breakdown of the execution time for both random reads and writes. We profile these runs using *perf* at 999Hz and plot the number of samples (y axis) that *perf* reports. First, we see that for random reads Linux *mmap* spends almost 80% of the time in manipulating the *address_space* structure, specifically in the contented *tree_lock* that protects the *radix_tree* which keeps all the pages of the mapping (see Section 3). In *FastMap* we do not observe a single high source of overhead. In the case of writes the overhead of this lock is even more pronounced in Linux *mmap*. For each page that is converted from read-only to read-write, Linux has to acquire this lock again to set the *tag*. *FastMap* removes this contention point as we keep metadata about dirty pages only in the per-core red-black trees (Section 3.3). Therefore, we do not modify the *radix_tree* upon the conversion of a read-only page to a read-write page.

Figure 6 shows how each optimization in *FastMap* affects I/O performance. Vanilla is the Linux *mmap* and *basic* is *FastMap* with all the optimizations disabled, except the per-core red-black tree. The *per-core radix-tree* optimization is important, because with increasing core counts on modern

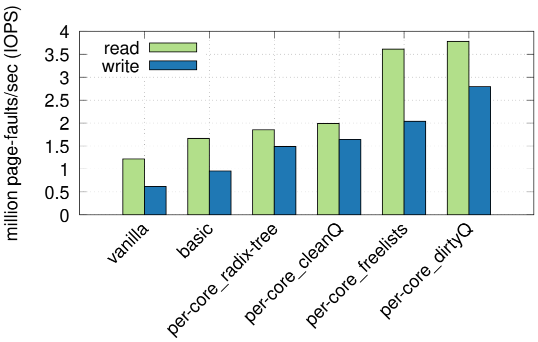

Figure 6: Performance gains from different optimizations in *FastMap*, as compared to "vanilla" Linux using *null_blk* and 32 cores.

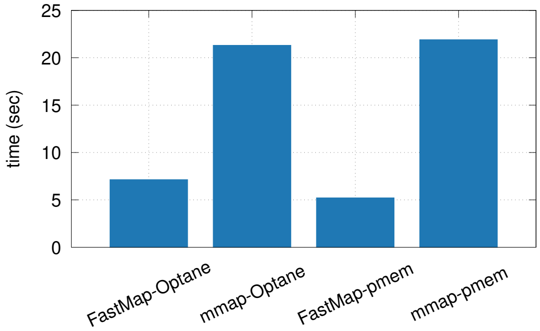

Figure 7: Execution time for Ligra running BFS with 32 threads and using an Optane SSD and a *pmem* device.

servers (Section 3.1) the single *radix tree* lock is by far the most contended lock. *per-core cleanQ* enables the per-core LRU list for clean pages. The *per-core freelists* optimization allows for scalable page allocation, resulting in significant performance gains. Finally, the main purpose of *per-core dirtyQ* is to enable higher concurrency when we convert a page from read-only to read-write and allow for multiple eviction threads with minimal synchronization. This optimization mainly improves the write path, as is shown in Figure 6.

In-memory Graph Processing: We evaluate *FastMap* as a mechanism to extend the virtual address space of an application beyond the physical memory and over fast storage devices. Using *mmap* (and *FastMap*) a user can easily map a file over fast storage and provide an extended address space, limited only by device capacity. We use Ligra [50], a graph processing framework, a demanding workload in terms of memory accesses and commonly operating on large datasets. Ligra assumes that the dataset (and metadata) fit in main memory. For our evaluation we generate a R-Mat [12] graph of 100M vertices, with the number of directed edges is set to 10× the number of vertices. We run BFS on the resulting 18GB graph, thus generating a read-mostly random I/O pattern. Ligra requires about 64GB of DRAM throughout execution. To evaluate *FastMap* and Linux *mmap*, we limit the main memory of our 32-core server to 8 GB and we use the Optane SSD device.

Figure 7 shows that BFS completes in 6.42s with *FastMap* compared to 21.3s with default *mmap* and achieves a 3.31× improvement. *FastMap* requires less than half the system time (10.3% for *FastMap* vs. 27.38% for Linux) and stresses more the underlying storage device as seen in iowait time (19.31% for *FastMap* vs. 9.5% for Linux). This leaves 2.11× more user-time available for the Ligra workload execution. Using a *pmem* device the benefits of *FastMap* are even higher. Linux *mmap* requires 21.9s for BFS, while *FastMap* requires only 4.15s, i.e. a 5.27× improvement. Overall, Ligra induces a highly concurrent I/O pattern that stresses the default *mmap*, resulting in lock contention as described in Section 3.1 and as evidenced by the increased system time. The default *mmap* results in a substantial slowdown, even with a *pmem* device that has throughput comparable to DRAM.

5.2 How much does *FastMap* improve storage I/O?

Kreon Persistent Key-value Store: In this section we evaluate *FastMap* using Kreon, a persistent key-value store that uses *memory-mapped I/O* and a dataset of 80M records. The keys are 30 bytes long, with 1000 byte values. This results in a total footprint of about 76GB. We issue 80M operations for each of the YCSB workloads. For the in-memory experiment, we use the entire DRAM space (256GB) of the testbed, whereas for the out-of-memory experiment we limit available memory to 16GB. In all cases we use the Optane SSD device.

Figure 8(a) illustrates the scalability of Kreon, using *FastMap*, Linux *mmap*, and *mmap-filter*, with a dataset that fits in main memory. The *mmap-filter* configuration is the default Linux *mmap* implementation augmented with a custom kernel module we have created to remove the unnecessary read I/O from the block device for newly allocated pages. Using 32 threads (on the 32-core server), *FastMap* achieves 1.55× and 2.77× higher throughput compared to *mmap-filter* and *mmap* respectively, using the LoadA (insert only) workload. Using the RunC (read only) workload, *FastMap* achieves 9% and 28% higher throughput compared to *mmap-filter* and *mmap* respectively. As we see *mmap-filter* performs always better, therefore, for the rest of the Kreon evaluation we use this configuration as our baseline.

Figure 8(b) shows the scalability of Kreon with *FastMap* and *mmap-filter* (denoted as *mmap*) using a dataset that does not fit in main memory. Using 32 threads (on the 32-core

(c) Average queue & request size

Figure 8: Kreon scalability with increasing the number of threads (*(a)* and *(b)*). Average queue size and average request size for an out-of-memory experiment *(c)*. In all cases we use the Optane SSD.

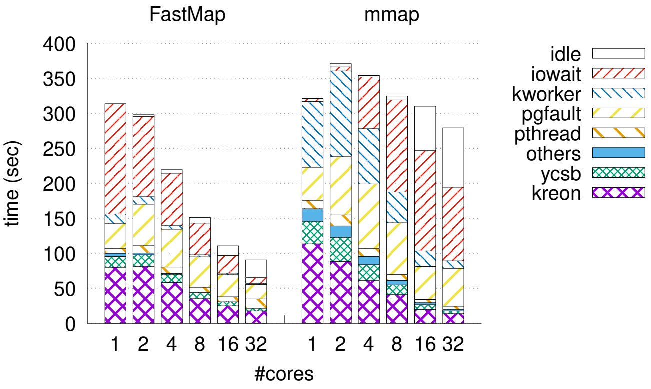

Figure 9: Kreon breakdown using *FastMap* and Linux *mmap* for an out-of-memory experiment for LoadA YCSB workload, with an increasing number of cores, an equal number of YCSB threads, and the Optane SSD.

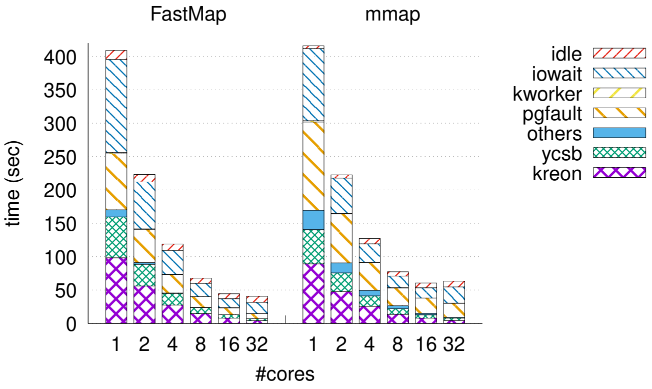

Figure 10: Kreon breakdown using *FastMap* and Linux *mmap* for an out-of-memory experiment with the RunC YCSB workload, with increasing number of cores (and equal number of YCSB threads) and the Optane SSD.

server) *FastMap* achieves 3.08× higher throughput compared to *mmap* using LoadA (insert only) workload. Using the RunC (read only) workload, *FastMap* achieves 1.65× higher throughput compared to *mmap*. We see that even for the lower core counts, *FastMap* outperforms *mmap* significantly. Next, we provide an analysis on what affects scalability in *mmap* and how *FastMap* behaves with an increasing number of cores.

Figure 9 shows the execution time breakdown for the out-of-memory experiment with an increasing number of threads for LoadA. *kworker* denotes the time spent in the eviction threads both for Linux *mmap* and *FastMap*. *pthread* refers to pthread locks, both mutexes and read-write locks as described in Section 4. First, we observe here that in the case of Linux *mmap* both *iowait* and *idle* time increases. For *iowait* time, the small queue depth that *mmap* generates (discussed in detail later) leads to sub-optimal utilization of the storage device. Furthermore, the idle time comes from sleeping in mutexes in the Linux kernel. We also observe that the *pgfault* time is lower in *FastMap* and this is more pronounced with 32 threads. In summary, the optimized page-fault path results in 2.64× lower *pgfault* time and 12.3× lower *iowait* time due to higher concurrency and larger average request size. In addition, the optimized page-fault path results in 3.39× lower idle time due to spinning instead of sleeping in the common path. This is made possible as we apply per-core locks to protect our data structures, which are less contended in the common case. Similar to the previous figure, Figure 10 shows the same metrics for RunC. In this case the breakdown is similar both for *FastMap* and Linux *mmap*. With 32 threads the notable differences are in *pgfault* and *iowait*. Linux *mmap* spends 2.88× and 1.41× more time for *pgfault* and *iowait*, respectively. The difference in *pgfault* comes from our scalable design for the *memory-mapped I/O* path. As in this case both systems always issue 4KB requests (page size), the difference in *iowait* comes from the higher queue depth achieved on average by *FastMap*.

Figure 8(c) shows the average queue depth and average request size for both *FastMap* and Linux *mmap*. Using 32 threads, *FastMap* produces higher queue depths for both LoadA and RunC, which is an essential aspect for high throughput with fast storage devices. With 32 threads in LoadA *FastMap* results in an average queue size of 39.2, while Linux *mmap* results in an average queue size of 17.5. Furthermore, *FastMap* also achieves a larger request size of 100.2 sectors (51.2KB) compared to 51.8 sectors (26.5KB) for Linux *mmap*. For RunC, the average request size is 8 sectors (4KB) for both *FastMap* and Linux *mmap*. However, *FastMap* achieves (with 32 threads) an average queue size of 13 compared to 3 for Linux *mmap*.

For all YCSB workloads, Kreon with *FastMap* outperforms Linux *mmap* by 2.48× on average (between $1.25-3.65\times$).

MonetDB: In this section we use TPC-H over MonetDB, a column oriented DBMS that uses *memory-mapped I/O* instead of *read*/*write* system calls. We focus on out-of-memory workloads, using a TPC-H dataset with a scale factor $SF = 50$ (around 50GB in size). We limit available server memory to 16GB and we use the Optane SSD device. In all 22 queries of TPC-H, system-time is below 10%. The use of *FastMap* further decreases the system time (between 5.4% and 48.6%) leaving more CPU cycles for user-space processing. In all queries, the improvement on average is 6.06% (between -7.2% and 45.7%). There are 4 queries where we have a small decrease in performance. Using profiling we see that this comes from the *map_pages* function that is responsible for the fault-around page mappings, and which is not as optimized in the current prototype. In some cases we see greater performance improvements compared to the reduction in system time. This comes from higher concurrency to the devices (I/O depth) which also results in higher read throughput. Overall, our experiments with MonetDB show that a complex real-life memory-based DBMS can benefit from *FastMap*. The queries produce a sequential access pattern to the underlying files which shows the effectiveness of *FastMap* also for this case.

5.3 How sensitive is *FastMap* to (a) file system choice and (b) false TLB invalidations?

In this section we show how underlying file system affects *FastMap* performance. Furthermore, we also evaluate the impact of batched TLB invalidations. For these purposes we use Silo [54], an in-memory key-value store that provides scalable transactions for multicores. We modify Silo to use a memory-mapped heap over both *mmap* and *FastMap*.

Table 2: Throughput and average latency for TPC-C.

	xput (kops/sec)	latency (ms)
mmap-EXT4-Optane SSD	4.3	7.43
mmap-EXT4-pmem	4.2	7.62
FastMap-*EXT4-Optane SSD*	226	0.141
FastMap-*EXT4-pmem*	319	0.101
FastMap-*NOVA-pmem*	344	0.009

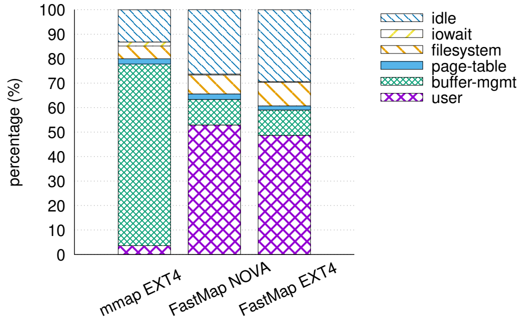

Figure 11: Execution time breakdown for Silo running TPC-C using different file systems and the *pmem* device.

File system choice: Table 2 shows the throughput and average latency of TPC-C over Silo. We use both EXT4 and NOVA. We also use XFS and BTRFS but we do not include these as they exhibit lower performance. We see that *FastMap* with EXT4 provides 52.5× and 75.9× higher throughput using an NVMe and a pmem device respectively, compared to *mmap*. We also see similar improvement in the average latency of TPC-C queries. With NOVA and a pmem device, *FastMap* achieves 1.07× higher throughput compared to EXT4. In all cases we do not use DAX *mmap*, as we have to provide DRAM caching over the persistent device. Therefore, *FastMap* improves performance of memory-mapped files over all file systems, although the choice of a specific file system does affect performance. In this case we see even larger performance improvements compared to Ligra and Kreon. Silo requires more page faults and it accesses a smaller portion of each page. Therefore, Silo is closer to a scenario with a single large file/device and a large number of threads generating page faults at random offsets. Consequently, it exhibits more of the issues we identify with Linux *mmap* compared to the other benchmarks: Kreon performs mostly sequential I/O for writes and a large part of a page is indeed needed when we do reads. From our evaluation we see that Ligra has better spatial locality compared to Silo and this explains the larger improvements we observe in Silo.

Figure 11 shows the breakdown of execution time for the previous experiments. In the case of Linux *mmap* with EXT4, most of the system time goes to buffer management: allocation of pages, LRUs, evictions, etc. In *FastMap*, this percentage is reduced from 74.2% to 10.3%, for both NOVA and EXT4. This results in more user-time available to TPC-C and increased performance. Finally, NOVA reduces system time compared to EXT4 and results in the best performance for TPC-C over Silo.

False TLB invalidations: *FastMap* uses batched TLB invalidations to provide better scalability and thus increased performance. Our approach reduces the number of calls to *flush_tlb_mm_range()*. This function uses Interprocessor Interrupts (IPI) to invalidate TLB entries in all cores and can result in scalability bottlenecks [3, 4, 16]. Batching of TLB invalidations can potentially result in increased TLB misses. In TPC-C over Silo, batching for TLB invalidations results in 25.5% more TLB misses (22.6% more load and 50.5% more store TLB misses). On the other hand, we have 24% higher throughput (ops/s) and 23.8% lower latency (ms). Using profiling, we see that without batching of TLB invalidations the system time spent in *flush_tlb_mm_range()* increases from 0.1% to 20.3%. We choose to increase the number of TLB misses in order to provide better scalability and performance. Other works [3,4,16] present alternative techniques to provide scalable TLB shootdown without increasing the number of TLB invalidations and can be potentially applied in *FastMap* for further performance improvements.

6 Related Work

We categorize related work in three areas: (a) replacing *read*/*write* system calls with *mmap* for persistence, (b) providing scalable address spaces, and (c) extending virtual address spaces beyond physical memory limits.

Using *memory-mapped I/O* in data-intensive applications: Both MonetDB [8] and MongoDB [13] (with *MMAP_v1* storage engine) are popular databases that use *mmap* to access data. When data fits in memory, *mmap* performs very well. It allows the application to access data at memory speed and removes the need for user-space cache lookups. Facebook's RocksDB [24], a persistent key-value store, provides both *read*/*write* and *mmap* APIs to access files. The developers of RocksDB state [26] that using *mmap* for an *in-memory* database with a *read-intensive* workload increases performance. However, they also state [25] that *mmap* sometimes causes problems when data does not fit in memory and is managed by a file system over a block device.

Tucana [42] and Kreon [43] are write-optimized persistent key-value stores that are designed to use *memory-mapped I/O* for persistence. The authors in [42] show that for a write-intensive workload the *memory-mapped I/O* results in excessive and unpredictable traffic to the devices, which results in freezes and increases tail-latency. Kreon [43] provides a custom *memory-mapped I/O* path inside the Linux kernel that improves write-intensive workloads and reduces the latency variability of Linux *mmap*. In this work, we address scalability issues and also present results for *memory-mapped I/O* with workloads beyond key-value stores.

DI-MMAP [22, 23], removes the swapper from the critical path and implements a custom (FIFO based) eviction policy using a fixed-size memory buffer for all *mmap* calls. This approach provides significant improvement compared to the default Linux *mmap* for HPC applications. We evaluate *FastMap* using more data-intensive applications, representative of data analytics and data serving workloads. In particular, our work assumes higher levels of I/O concurrency, and addresses scalability concerns with higher core counts.

FlashMap [27] combines memory (page tables), storage (file system), and device-level (FTL) indirections and checks in a single layer. *FastMap* provides specific optimizations only for the memory level and results in significant improvements in a file system and device agnostic manner.

2B-SSD [6] leverages SSD internal DRAM and the byte addressability of the PCIe interconnect to provide a dual, byte and block-addressable SSD device. It provides optimized write-ahead logging (WAL) over 2B-SSD for popular databases and results in significant improvements. FlatFlash [1] moves this approach further and provides a unified memory-storage hierarchy that results in even larger performance improvements. Both of these works move a large part of their design inside the device. *FastMap* works in a device-agnostic manner and provides specific optimizations in the operating system layer.

UMap [44] is a user-space memory-mapped I/O framework which adapts different policies to application characteristics and storage features. Handling page faults in user-space (using *userfaultfd* [31]) introduces additional overheads that are not acceptable in the case of fast storage devices. On the other hand, techniques proposed by *FastMap* can also be used in user-space memory-mapped I/O frameworks and provide better scalability in the page-fault path.

Similar to [14], *FastMap* introduces a read-ahead mechanism to amortize the cost of pre-faulting and improve sequential I/O accesses. However, our main focus is to reduce synchronization overheads in the common *memory-mapped I/O* path and enhance scalability on multicore servers. A scalable I/O path enables us to maintain high device queue depth, an essential property for efficient use of fast storage devices.

Byte-addressable persistent memory DIMMs, attached in memory slots, can be accessed similarly to DRAM with the processor *load*/*store* instructions. Linux provides Direct Access (DAX), a mechanism that supports direct mapping of persistent memory to user address space. File systems that provide a DAX mmap [17, 21, 56–58] bypass I/O caching in DRAM. On the other hand, other works [29] have shown that DRAM caching benefits applications when the working set fits in DRAM and can hide higher persistent memory latency compared to DRAM (by up to $\sim 3\times$). Accordingly, *FastMap* uses DRAM caching and supports both block-based flash storage and byte-addressable persistent memory. *FastMap* will benefit all DAX mmap file systems that need to provide

DRAM caching for *memory-mapped I/O*, as *FastMap* is file system agnostic.

Providing a scalable virtual address space: *Bonsai* [15] shows that anonymous memory mappings, i.e. not backed by a file or device, suffer from scalability issues. This type of memory mapping is mainly used for user memory allocations, e.g. *malloc*. The scalability bottleneck in this case is due to a contended read-write lock, named *mmap_sem*, that protects access to a red-black tree that keeps VMAs (valid virtual address spaces ranges). In the case of page faults, this lock is acquired as read lock. In the case of *mmap*/*munmap* this lock is acquired as write lock. Even in the read lock case, NUMA traffic in multicores limits scalability. *Bonsai* proposes the use of *RCU*-based binary tree for lock-free lookups, resulting in a system scaling up to 80 cores. *Bonsai* removes the bottleneck from concurrent page faults, but still serializes *mmap*/*munmap* operations even in non-overlapping address ranges.

In Linux, shared mappings backed by a file or device have a different path in the kernel, thus requiring a different design to achieve scalability. There are other locks (see Section 3.1) that cause scalability issues and *mmap_sem* does not result in any performance degradation. As we see from our evaluation of *FastMap*, using 80 cores the time spent in *mmap_sem* is 37.4% of the total execution time; therefore, *Bonsai* is complementary to our work and will also benefit our approach. Furthermore, authors in [32] propose an alternative approach to provide scalable address space operations, by introducing scalable range locks to accelerate non-conflicting virtual address space operations in Linux.

RadixVM [16] addresses the problem of serialization of *mmap*/*munmap* in non-overlapping address space ranges. This work is done in the *SV6* kernel and can also benefit from *FastMap* in a similar way to *Bonsai*.

The authors in [9] propose techniques to scale Linux for a set of kernel-intensive applications, but do not tackle the scalability limitations of *memory-mapped I/O*. In *pedsort* authors modify the application to use one process per core for concurrency and avoid the contention over the shared address space. In this paper we solve this issue at the kernel level, thus providing benefits to all user applications.

Extending the virtual address space over storage: The authors in [51] claim that by using *mmap* a user can effectively extend the main memory with fast storage devices. They propose a page reclamation procedure with a new page recycling method to reduce context switches. This makes it possible to use extended vector I/O – a parallel page I/O method. In our work, we implement a custom per-core mechanism for managing free pages. We also preallocate a memory pool to remove the performance bottlenecks identified in [51]. Additionally, we address scalability issues with *memory-mapped I/O*, whereas the work in [51] examines setups with up to 8 cores, where Linux kernel scales well.

FlashVM [49] uses a dedicated flash device for swapping virtual memory pages and provides flash-specific optimizations for this purpose. SSDAlloc [5] implements a hybrid DRAM/flash memory manager and a runtime library that allows applications to use flash for memory allocations in a transparent manner. SSDAlloc proposes the use of $16-32\times$ more flash than DRAM compared to FlashVM and to handle this increase they introduce a log-structured object store. Instead, *FastMap* targets the storage I/O path and reduces the overhead of *memory-mapped I/O*. *FastMap* is not a replacement for swap nor does it provide specific optimizations to extend the process address space over SSDs.

NVMalloc [55] enables client applications in supercomputers to allocate and manipulate memory regions from a distributed block-addressable SSD store (over FUSE [36]). It exploits the *memory-mapped I/O* interface to access local or remote NVM resources in a seamless fashion for volatile memory allocations. NVMalloc uses Linux *mmap*. Consequently, it can also benefit from *FastMap* at large thread counts combined with fast storage devices.

SSD-Assisted Hybrid Memory [41] augments DRAM with SSD storage as an efficient cache in object granularity for Memcached [38]. Authors claim that managing a cache at a page granularity incurs significant overhead. In our work, we provide an application agnostic approach at page granularity and we optimize scalability in the common path.

7 Conclusions

In this paper we propose *FastMap*, an optimized *memory-mapped I/O* path in the Linux kernel that provides a low-overhead and scalable way to access fast storage devices in multi-core servers. Our design enables high device concurrency, which is essential for achieving high throughput in modern servers. We show that *FastMap* scales up to 80 cores and provides up to $11.8\times$ more random IOPS compared to *mmap*. Overall, *FastMap* addresses important limitations of Linux *mmap* and makes it appropriate for data-intensive applications in multi-core servers over fast storage devices.

A Comprehensive Analysis of Superpage Management Mechanisms and Policies

Weixi Zhu, Alan L. Cox and Scott Rixner

Abstract

Superpages (2MB pages) can reduce the address translation overhead for large-memory workloads in modern computer systems. This paper clearly outlines the sequence of events in the life of a superpage and explores the design space of when and how to trigger and respond to those events. This provides a framework that enables better understanding of superpage management and the trade-offs involved in different design decisions. Under this framework, this paper discusses why state-of-the-art designs exhibit different performance characteristics in terms of runtime, latency and memory consumption. This paper illuminates the root causes of latency spikes and memory bloat and introduces Quicksilver, a novel superpage management design that addresses these issues while maintaining address translation performance.

1 Introduction

The physical memory size of modern computers continues to grow at a rapid pace. Furthermore, there is an ever expanding class of "large-memory" data-oriented applications — including databases, data analysis tools, and scientific computations — that can productively utilize all of this memory. While some of these applications expect the entirety of their data to reside within physical memory, others process data at a scale that far exceeds its size. These others either use out-of-core computation frameworks or implement schemes for caching data from secondary storage that avoid swapping by the virtual memory system. In either case, these applications have large memory footprints, so the cost of virtual-to-physical address translation significantly impacts their performance.

The use of *superpages*, or "huge pages", can reduce the cost of virtual-to-physical address translation. For example, the x86-64 architecture supports 2MB superpages. Using these superpages (1) eliminates one level from the hierarchical page table, thereby reducing the expected number of memory accesses to resolve a TLB miss, and (2) enables more efficient use of the TLB's limited number of entries. Intel's recent processors can store up to 1536 4KB or 2MB page mappings in their TLBs. Superpages can therefore increase these TLBs' coverage from around 6MB (0.009% of the physical memory in a computer with 64GB of DRAM) to 3GB. While this is still a small fraction of the computer's physical memory, it is far more likely to capture an application's short-term working set. The benefits of this increased coverage are obvious. The challenge, however, is for the operating system (OS) to transparently manage superpages in an effective manner.

This paper first defines the five distinct events in the life cycle of a transparently managed superpage, and then it analyzes the various state-of-the-art approaches to handling each event. Briefly, the events are as follows. First, a physical superpage must be allocated. Throughout this paper, unless stated otherwise, "superpage" refers to a 2MB page, so this is the act of acquiring a contiguous, aligned 2MB region from the physical memory allocator. Second, the physical superpage must be prepared. For anonymous memory, the entire 2MB region must be zeroed. For file-backed memory, the entire 2MB region must be read from secondary storage. Third, a superpage mapping from a 2MB aligned virtual memory region to the physical superpage must be created. Fourth, the mapping must be destroyed. Finally, the physical memory must be deallocated. FreeBSD, Linux's Transparent Huge Pages (THP), and two recently proposed systems (Ingens [20] and HawkEye [24]) differ in when these events are triggered (for instance, these events can be independent, grouped, synchronous, asynchronous, etc.) and the granularity of the operations (for instance, some operations can be performed incrementally or all at once). This classification of the events enables a more principled comparison of the policies, behaviors, and performance of these different systems.

This paper also presents several new observations about transparent superpage management. First, coupling physical allocation, preparation, and mapping of superpages, as is done in Linux's THP, leads to memory bloat and fewer superpage mappings. Second, while alleviating tail latency problems in server workloads, state-of-the-art asynchronous, "out-of-place" promotion delays physical superpage allocation and reduces address translation benefits. Third, speculatively allocating physical superpages enables "in-place" promotion and obviates the need for asynchronous, out-of-place promotion. Fourth, in combination, reserving physical superpages and delaying partial deallocation of those superpages as long as possible fights fragmentation, leading to more superpage usage and address translation benefits. Finally, bulk zeroing is more efficient on modern processors than repeated 4KB zeroing. These observations are supported by evidence presented throughout the paper.

Finally, this paper introduces Quicksilver[1], an innovative transparent superpage management system that is based on FreeBSD's reservation-based physical memory allocator. Quicksilver achieves the benefits of aggressive superpage allocation, but mitigates the memory bloat and fragmentation issues that arise from underutilized superpages. Quicksilver is able to match or beat the performance of existing systems in scenarios with either lightly or heavily fragmented memory. For example, when using synchronous preparation, on a heavily fragmented system it achieves a 2x speedup over Linux for GraphChi performing PageRank on a dataset that exceeds the physical memory size. Furthermore, on Redis, Quicksilver is able to maintain the same throughput and tail latency as fragmentation increases, whereas the throughput of other systems degrades and tail latency increases. Finally, Quicksilver is able to limit memory bloat as well as Ingens [20], which is a recent research prototype specifically designed to combat memory bloat.

2 Transparent Superpage Management

Managing superpages transparently to the application involves five distinct events: physical superpage allocation, physical superpage preparation, superpage mapping creation, superpage mapping destruction, and physical superpage deallocation. Figure 1 illustrates the life cycle of a superpage in terms of these events. This section discusses the trade-offs between the possible choices, including those made by production and prototype systems [5, 16, 20, 23, 24], for when to trigger and how to handle these events.

2.1 Physical Superpage Allocation

The OS can choose to allocate a physical superpage to back any 2MB-aligned virtual memory region. A physical superpage could be allocated synchronously upon a page fault, or asynchronously via a background task. If there are free physical superpages, synchronous allocation is a relatively inexpensive operation given the widespread use of buddy allocators for physical memory management.

However, in order to allocate a physical superpage, the physical memory allocator must have an available, aligned, 2MB region. Under severe memory fragmentation, such regions may not be available. A memory manager could attempt to keep as many such regions available as possible (or create them when needed) using smart allocation policies or memory migration. If no such region is available or can be created, then the system must fall back to allocating 4KB pages.

Even after 4KB pages have been allocated for a virtual memory region, it is still possible to allocate a physical superpage for that region asynchronously. In the background, the OS can use migration to create free physical superpages or wait for them to be freed by applications. Once a free physical superpage exists, it could be allocated to a previously accessed virtual memory region. At that point, all previously allocated 4KB pages would need to be migrated into the newly acquired physical superpage.

2.2 Physical Superpage Preparation

Once a physical superpage has been allocated, it must be prepared with its initial data before it can be mapped. A physical superpage can be prepared in one of three ways. First, if the virtual memory region is anonymous, i.e., not backed by a file, then the page simply needs to be zeroed. Second, if the virtual memory region is a memory-mapped file, then the data must be read from the file. Finally, if the virtual memory region is currently mapped to 4KB pages, then the contents of those existing pages must be copied into the physical superpage. Note that any constituent pages that were not already mapped would need to be prepared appropriately, either via zeroing or reading from the backing file.

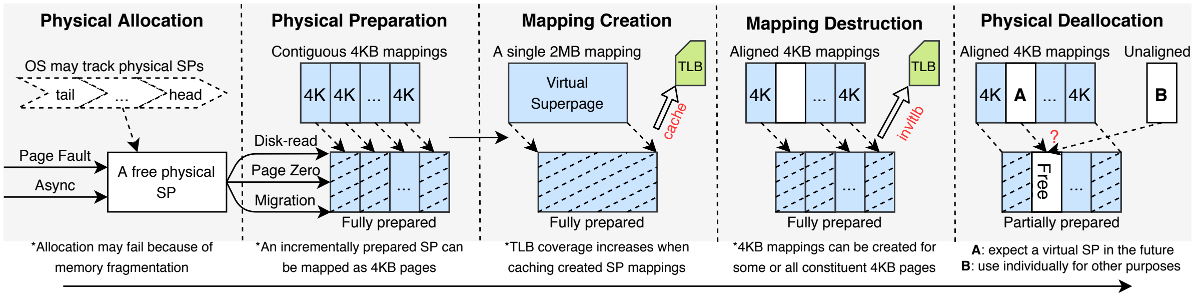
Physical superpages can be prepared all at once or incrementally. Furthermore, as they are prepared, they can have some, or all, of their constituent pages mapped as 4KB pages (each constituent page that is mapped must have already been prepared). At a minimum, on a page fault, the 4KB page that triggered the fault must be prepared immediately in order to allow the application to resume. However, upon a page fault, the OS can choose to prepare the entire physical superpage, only prepare the required 4KB page, or prepare the required 4KB page, allow the application to resume, and prepare the remaining 4KB pages later (either asynchronously or when they are accessed).

The three types of preparation — zeroing, copying, and file reading — have different costs, and so may impact the choice of when and how much of a physical superpage to prepare. Incremental preparation decreases page fault latency and minimizes unnecessary preparation for 4KB pages that may ultimately never get accessed. However, as the page is incrementally prepared, the constituent pages will be using 4KB mappings. In contrast, all at once preparation eliminates future page faults to the virtual memory region and allows for the immediate creation of a superpage mapping.

2.3 Superpage Mapping Creation

Once a physical superpage has been fully prepared, it must then be mapped as such in order to achieve address transla-

[1] https://github.com/rice-systems/quicksilver



*Allocation may fail because of memory fragmentation

*An incrementally prepared SP can be mapped as 4KB pages

*TLB coverage increases when caching created SP mappings

*4KB mappings can be created for some or all constituent 4KB pages

A: expect a virtual SP in the future
B: use individually for other purposes

Figure 1: The five events in the life cycle of a superpage (SP).

tion benefits. Before the superpage is mapped, the physical memory can still be accessed via 4KB mappings; afterwards, the OS loses the ability to track accesses and modifications at a 4KB granularity. Therefore, an OS may delay the creation of a superpage mapping if only some of the constituent pages are dirty in order to avoid unnecessary future I/O.

A superpage mapping is typically created upon a page fault, on either the initial fault to the memory region or a subsequent fault after the entire superpage has been prepared. However, if the physical superpage preparation is asynchronous, then its superpage mapping may also be created asynchronously. Note that on some architectures, *e.g.*, ARM, any 4KB mappings that were previously created must first be destroyed.

2.4 Superpage Mapping Destruction

Superpage mappings can be destroyed at any time, but must be destroyed whenever any part of the virtual superpage is freed or has its protection changed. After the superpage mapping is destroyed, 4KB mappings must be recreated for any constituent pages that have not been freed.

With superpage mappings, the OS cannot track whether constituent pages are accessed or modified. Therefore, in some scenarios, the OS may choose to preemptively destroy a superpage mapping and substitute 512 4KB mappings for it to enable finer-grained memory management. For example, when a clean superpage is first modified, the OS could choose to destroy the superpage mapping in order to only mark the single modified 4KB page as dirty, potentially reducing future I/O operations. This would require the OS to make a read-only superpage mapping and use the page fault caused by the write access to destroy the mapping and replace it with 4KB mappings. Similarly, the OS could choose to destroy a superpage mapping when under memory pressure to enable swapping pages at a finer granularity.

2.5 Physical Superpage Deallocation

Generally, a physical superpage is deallocated when an application frees some or all of the virtual superpage, when an application terminates, or when the OS needs to reclaim memory. If a superpage mapping exists, it must be destroyed before the physical superpage can be deallocated. Then, either the entire 2MB can be returned to the physical memory allocator or the physical superpage can be "broken" into 4KB pages. If the physical superpage is broken into its constituent 4KB pages, the OS can return a subset of those pages to the physical memory allocator. However, returning only a subset of the constituent pages increases memory fragmentation, decreasing the likelihood of future physical superpage allocations.

Before part or all of a physical superpage is returned to the physical memory allocator, any constituent pages that have been prepared but not freed must be preserved. Preservation typically happens in one of three ways. In-use pages can be kept rather than returned to the allocator, and 4KB mappings can be created to those pages. Alternatively, the in-use pages can be copied to other physical pages, allowing the entire physical superpage to be returned. The last option is to write the in-use pages to secondary storage before returning them.

3 State-of-the-art Designs

This section compares the state-of-the-art designs for transparent superpage management in FreeBSD, Linux, and recent research prototypes (Ingens [20] and HawkEye [24]), with a particular focus on how they manage the events described in the previous section.

3.1 FreeBSD

FreeBSD supports transparent superpages for all kinds of memory, including memory-mapped files and executables. It decouples physical superpage allocation from preparation by using a reservation-based memory allocator [23,29]. FreeBSD tries to allocate ("reserves") a physical superpage upon the first page fault to any aligned 2MB region. If physical superpages are available, they are allocated for any memory-mapped file exceeding 2MB in size. Anonymous memory always uses superpages if available, regardless of size, as anonymous memory is expected to grow.

Once a physical superpage is allocated for anonymous memory, only the 4KB page that caused the page fault is prepared, and a reservation entry is created to track all of the constituent pages. Any subsequent page fault to that 2MB region skips page allocation and simply prepares one additional 4KB page of the physical superpage. The physical superpage preparation finishes once all of its constituents have been prepared. For file-backed memory, the process is the same, except memory is prepared in 64KB batches to minimize I/O overhead.

FreeBSD creates superpage mappings synchronously during page faults. FreeBSD only creates a superpage mapping if the characteristics (*e.g.*, protection and modified state) of all the constituent 4KB mappings are the same. Identical protections are required for correctness; identical dirty states ensure that FreeBSD will not do unnecessary I/O to preserve the contents of the page when it is later deallocated.

Superpage mappings are destroyed on partial memory protection changes and partial unmappings. FreeBSD also preemptively destroys clean superpage mappings before modification. As a result, only one 4KB mapping is marked as dirty, instead of the entire superpage. Once the last clean 4KB page is modified, a dirty superpage mapping gets created.

FreeBSD defers physical superpage deallocation as long as possible in order to minimize memory fragmentation and preserve the availability of free physical superpages. However, under memory pressure, FreeBSD looks for a partially prepared physical superpage and breaks the corresponding reservation to allow the unused memory within that 2MB physical memory region to be reclaimed for other uses.

3.2 Linux

Linux's THP only uses superpages for anonymous memory and tries to allocate a physical superpage on the first page fault to a 2MB-aligned virtual memory region. If allocation fails and defragmentation is enabled (the default), it immediately does memory compaction via page migration to create a free physical superpage. This blocks the faulting process, increasing page fault latency. Under severe fragmentation, migration may still fail to create a free physical superpage.

Linux does all-at-once physical superpage preparation: the entire physical superpage is always zeroed right after being allocated. This increases the initial page fault latency, but may reduce the average latency [24]. After this preparation, a superpage mapping is immediately created. The superpage mapping will be destroyed if some or all of the superpage is unmapped or has its protection settings changed. Once some or all of the superpage has been freed, the physical superpage is deallocated and free memory is immediately reclaimed.

This "first-touch" superpage policy only allocates physical superpages at the time of the first page fault. However, Linux also includes a kernel daemon called "khugepaged", which asynchronously scans the system page tables. When it finds an aligned 2MB anonymous virtual memory region that contains at least one dirty 4KB mapping, khugepaged tries to allocate a physical superpage. If a free physical superpage exists, it acquires it; otherwise, it calls Linux's memory compaction to reclaim one by migrating pages.

Before preparing this physical superpage, khugepaged blocks accesses to the virtual 2MB region by blocking page faults within the region and destroying the existing 4KB mappings. It then prepares all of the physical superpage's constituent 4KB pages, one at a time. For a previously mapped page, the contents are copied. Previously unmapped pages are zeroed. Finally, it installs a superpage mapping.

Khugepaged's preparation is more costly than the first-touch preparation that occurs in a page fault. It blocks accesses to the 2MB region, causes TLB shootdowns, and pollutes CPU caches. As a result, it is allowed by default to allocate at most 8 superpages every 10 seconds (1.6 MB/s).

When an application partially frees memory within a superpage without unmapping the virtual memory (*e.g.*, `MADV_DONTNEED`), it triggers the destruction of the superpage mapping and the deallocation of the physical superpage. The remaining in-use memory then gets mapped as 4KB pages. However, when khugepaged scans this 2MB region, it will unnecessarily migrate the mapped memory into another allocated superpage and effectively reallocate the freed memory. It is precisely this behavior of khugepaged which has led to the severe memory bloating reported in recent work [20, 24].

3.3 Ingens and HawkEye

Recent state-of-the-art prototypes (Ingens [20] and HawkEye [24]) attempt to mitigate the page fault latency spikes incurred by Linux's first-touch superpage policy as well as the memory bloat incurred by khugepaged — behaviors which have led many to suggest that Linux's transparent superpage support be disabled for best performance.

Both systems disable Linux's first-touch policy, instead allocating, preparing, and mapping only a single 4KB page on a page fault. They then effectively modify khugepaged to more aggressively manage superpages.

Khugepaged's behavior differs in default Linux, Ingens, and HawkEye in terms of order, threshold, and rate for superpage creation. To prevent excessive memory bloat, Ingens increases the threshold to trigger creation of a superpage from one in-use 4KB page to 90% in-use, meaning there must be at least 460 4KB mappings in a 2MB region in order to create a superpage for that region.

Ingens maintains a list of candidate 2MB-aligned regions on page faults. As long as the list is not empty, Ingens keeps creating superpage mappings. However, asynchronous superpage creation introduces a fairness problem that the scanning order of page tables can lead to long delays for some processes. To alleviate this, Ingens prioritizes processes with fewer superpages. In addition, Ingens actively compacts non-referenced memory at an aggressive rate.

HawkEye uses the same threshold as default khugepaged: one 4KB page. Under memory pressure, it scans mapped superpages and makes their zero-filled 4KB pages copy-on-write to a single zero-filled page to reclaim memory.

HawkEye also maintains a list of candidate 2MB-aligned regions, but further weights them by their memory utilization, the process's resident size, sampled access frequency and

TLB overheads. HawkEye then creates a superpage mapping for the one with the most weight that is believed to bring the highest TLB overhead, called fine-grained superpage management in the paper [24]. It attempts to obtain considerable address translation benefits with fewer superpages.

HawkEye's fine-grained superpage management further consumes CPU resources besides the migration-based superpage mapping creations. To avoid interference with running processes, it uses the same promotion rate (1.6MB/s) as Linux's default khugepaged.

4 Analysis of Existing Designs

This section analyzes the designs for transparent superpage management described in the previous section and presents several novel observations about them. These observations motivate the design of Quicksilver.

Platforms. All designs were evaluated on an Intel E3-1245 v6-based server with maximum turbo performance and hyperthreading enabled. This server has 4 physical cores, 32GB DDR4 2400 ECC RAM, and a 256GB NVMe SSD. Linux version 4.3 was used, as both Ingens and HawkEye are based on that version. FreeBSD version 11.2 was used, upon which Quicksilver is built. Swapping is disabled under every OS.

Benchmarks. A large variety of benchmarks are evaluated. GUPS performs 2^{32} serial random memory accesses to 2^{30} 64-bit integers (8GB) [13]. Graphchi-PR, BlockSVM and ANN use out-of-core implementations to solve big-data tasks [21, 32]. Graphchi-PR computes 3 iterations of PageRank on the preprocessed Twitter-2010 dataset [19]. BlockSVM trains a classification model on the kdd2010-bridge dataset [28]. ANN randomly queries nearest neighbors on 2GB preprocessed hash tables. XSBench is a parallel computation kernel of the Monte Carlo neutron transport algorithm [30]. Canneal and freqmine are PARSEC benchmarks with large memory footprints [10]. Gcc, mcf, DSjeng and XZ are SPEC CPU2017 benchmarks with large memory footprints [11]. Buildkernel compiles the FreeBSD 11.2 kernel.

Graphchi-PR, XSBench, canneal and Buildkernel are multithreaded to fully utilize CPU resources. Cold and Warm are Redis workloads benchmarking throughput and tail latency from a separate client machine with 8 threads and 16 request pipelines. The Cold workload populates an empty Redis instance with 16GB of 4KB objects. The Warm workload queries the fully populated 16GB Redis instance with a set/get ratio of 5:5 using 4KB objects. Del-70, Del-50, Range-S and Range-XL are Redis workloads benchmarking memory consumption. Del-70 and Del-50 insert 2 million 8KB objects and randomly delete 70% and 50% of them, respectively. Range-S and Range-XL insert randomly sized objects from small and large size ranges, respectively. Detailed benchmark settings and scripts can be found in the Quicksilver repository.

Workload	Linux-4KB	Linux-noKhugepaged	Linux
Del-70	11.6 GB	11.7 GB	19.8 GB
Range-XL	14.4 GB	25.7 GB	30.7 GB

Table 1: Redis memory consumption. Linux-noKhugepaged disables khugepaged.

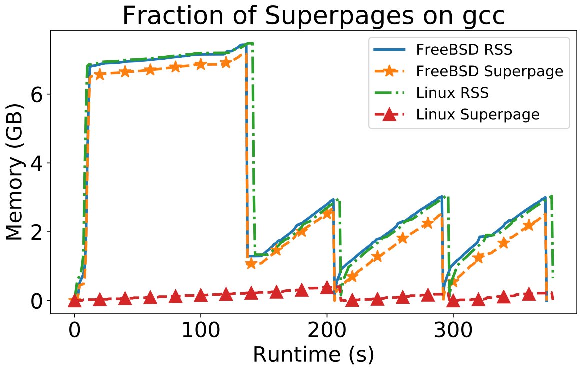


Figure 2: Linux's first touch policy fails to create superpages.

Observation 1: Coupling physical allocation, preparation, and mapping of superpages leads to memory bloat and fewer superpage mappings. It also is not compatible with transparent use of multiple superpage sizes.

Linux's first-touch policy couples physical superpage allocation, preparation and superpage mapping creation together. As a result, it enjoys two obvious benefits. First, it provides immediate address translation benefits, including shorter page walk time and increased TLB efficiency. Second, it eliminates a large number of page faults for a heavily utilized superpage. Therefore, it is usually the best mapping policy when there is abundant contiguous free memory.

However, this coupled policy has several drawbacks. First, it can easily bloat memory and waste time preparing underutilized superpages. In a microbenchmark that sparsely touches 30GB of anonymous memory, Linux's first-touch policy takes 1.4s to run and consumes 30GB compared to 0.06s and 0.2GB when disabling transparent huge pages. While such a corner case is rare when applications use `malloc` to dynamically allocate memory, it may still happen in a long-running server, *e.g.*, Redis. Table 1 shows that Linux's first touch policy bloats memory by 78% compared to Linux-4KB on the workload Range-XL, which inserts objects of random sizes ranging from 256B to 1MB.

Second, it misses chances to create superpage mappings when virtual memory grows. During a page fault, Linux cannot create a superpage mapping beyond the heap's end, so it installs a 4KB page which later prevents creation of a superpage mapping when the heap grows. Figure 2 shows such behavior for gcc [11], which includes three compilations. Linux's first-touch policy creates a few superpage mappings early in each compilation, but fails to create more as the heap grows. Instead, promotion-based policies can create more superpages,

Page Size	Anonymous	NVMe Disk	Spinning Disk
2MB	91 us	**1.7 ms**	**11 ms**
1GB	**46 ms**	**0.9 s**	**7.7 s**

Table 2: Page fault latency. Bold numbers are estimations.

e.g., FreeBSD and Linux's khugepaged.

Third, it cannot be extended to larger anonymous or file-backed superpages. Table 2 estimates the page fault latency on both 1GB anonymous superpages and 2MB/1GB file-backed superpages. Faulting a 2MB file-backed superpage on the NVMe disk costs 1.7ms and faulting a 1GB anonymous superpage takes 46ms. These numbers may cause latency spikes in server applications. Furthermore, it cannot easily determine which page size to use on first touch. This is arguably more of an immediate problem on ARM processors, which support both 64KB and 2MB superpages.

Observation 2: Asynchronous, out-of-place promotion alleviates latency spikes but delays physical superpage allocations.

Promotion-based policies can use 4KB mappings and later replace them with a superpage mapping. This allows for potentially better informed decisions about superpage mapping creation and can easily be extended to support multiple sizes of superpages. Specifically, there are two kinds of promotion policies, named out-of-place promotion and in-place promotion. They differ in whether previously prepared 4KB pages require migration when preparing a physical superpage.

Under out-of-place promotion a physical superpage is not allocated in advance, on a page fault a 4KB physical page is allocated that may neither be contiguous nor aligned with its neighbors. When the OS decides to create a superpage mapping, it must allocate a physical superpage, migrate mapped 4KB physical pages and zero the remaining ones. At this time, previously created 4KB mappings are no longer valid.

Linux and recent prototypes [20,24] perform asynchronous, out-of-place promotion to hide the cost of page migration. As discussed in Section 3.2, Linux includes khugepaged as a supplement to create superpage mappings for growing heaps. The steady, slow increase of Linux's superpages in Figure 2 is from khugepaged's out-of-place promotions. However, khugepaged can easily bloat memory. Table 1 shows a memory bloat from 11.6GB to 19.8GB on workload Del-70, which randomly deletes 70% of the objects. On workload Range-XL, it bloats memory from 25.7GB to 30.7GB.

Ingens and HawkEye [20, 24] disable Linux's first-touch policy and instead improve the behavior and functionality of khugepaged, motivated by avoiding latency spikes in server workloads. Under memory fragmentation, Linux tries to compact memory when it fails to allocate superpages, which blocks the ongoing page fault and leads to latency spikes. Ingens and HawkEye enhanced khugepaged and offloaded superpage allocations from the critical path, alleviating such latency spikes. So khugepaged works as their primary superpage management mechanism.

Workloads	Ingens	Ingens*	HawkEye	HawkEye*	FreeBSD
GUPS	0.87	0.84	0.28	0.88	0.96
Graphchi-PR	0.58	0.58	0.53	0.60	0.77
BlockSVM	0.81	0.79	0.73	0.81	0.96

Table 3: Speedup over Linux with unfragmented memory. All systems have worse performance than Linux.

However, out-of-place promotion delays physical superpage allocations and ultimately superpage mapping creation, because the OS must scan page tables to find candidate 2MB regions and schedule the background tasks to promote them. Table 3 compares in-place promotion (FreeBSD) with out-of-place promotion (Ingens and HawkEye) on applications where superpage creation speed is critical. While GUPS only involves random accesses, both Graphchi-PR and BlockSVM [21, 32] represent important real-life applications – using fast algorithms to process big data that cannot fit in memory. To better illustrate the problem, Ingens* and HawkEye* were tuned to be more aggressive, so that all 2MB regions containing at least one dirty 4KB mapping are candidates for promotion. Specifically, Ingens* uses a 0% utilization threshold instead of 90%; HawkEye* uses a 100% maximum CPU budget to promote superpages. However, Table 3 shows that FreeBSD consistently and significantly outperforms both of them. In other words, the most conservative in-place promotion policy creates superpage mappings faster than the most aggressive out-of-place promotion policy.

Observation 3: Reservation-based policies enable speculative physical page allocation, which enables the use of multiple page sizes, in-place promotion, and obviates the need for asynchronous, out-of-place promotion.

In-place promotion does not require page migration. It creates a physical superpage on the first touch, then incrementally prepares and maps its constituent 4KB pages without page allocation. Therefore, the allocation of a physical superpage is immediate, but its superpage mapping creation is delayed. To bypass 4KB page allocations, it requires a bookkeeping system to track allocated physical superpages, *e.g.*, FreeBSD's reservation system. On x86-64, after it substitutes a superpage mapping for the 4KB mappings, it need not flush the previous 4KB mappings from the TLB.

FreeBSD implements an in-place promotion policy based on its reservation system as described in Section 3.1. It conservatively creates superpage mappings to avoid making performance worse. Navarro, *et al.* reported negligible overheads from the reservation system [23].

FreeBSD immediately allocates physical superpages but delays superpage mapping creation, sacrificing some address translation benefits. Table 3 shows that Linux consistently outperforms FreeBSD when memory is unfragmented, though

	Linux-4KB	Linux
Frag-0	1.04 GB/s (5.6 ms)	1.34 GB/s (4.1 ms)
Frag-50	1.04 GB/s (5.7 ms)	0.92 GB/s (10.2 ms)

Table 4: Mean throughput and 95th latency of Redis Cold workload.

they created similar numbers of anonymous superpage mappings.

However, FreeBSD aggressively allocates physical superpages for anonymous memory. Upon a page fault of anonymous memory, it always speculatively allocates a physical superpage, expecting the heap to grow. This eliminates one of the primary needs for khugepaged in Linux. In Figure 2, FreeBSD has most of the memory quickly mapped as superpages, because most speculatively allocated physical superpages end up as fully-prepared pages.

Observation 4: Reservations and delaying partial deallocation of physical superpages fight fragmentation.

Superpages are easily fragmented on a long-running server. A few 4KB pages can consume a physical superpage, which benefits little if mapped as a superpage. Existing systems deal with memory fragmentation in three ways.

Linux compacts memory immediately when it fails to allocate a superpage. It tries to greedily use superpages, but risks blocking a page fault. Table 4 evaluated the performance of Redis. Under fragmentation, Linux obtains slightly higher throughput but much higher tail latency than Linux-4KB.

FreeBSD delays the partial deallocation of a physical superpage to increase the likelihood of reclaiming a free physical superpage. When individual 4KB pages get freed sooner, they land in a lower-ordered buddy queue and are more likely to be quickly reallocated for other purposes. Therefore, performing partial deallocations only when necessary due to memory pressure decreases fragmentation.

Ingens actively defragments memory in the background to avoid blocking page faults. It preferably migrates non-referenced memory, so that it minimizes the interference with running applications. As a result, Ingens generates fewer latency spikes compared with Linux [20]. These migrations, however, do consume processor and memory resources.

Observation 5: Bulk zeroing is more efficient on modern processors than repeated 4KB zeroing.

Modern OSes have abandoned asynchronous page zeroing because it usually degrades performance in a multiprocess situation. Furthermore, the introduction of ERMS (Enhanced REP MOVSB/STOSB) has accelerated page zeroing. However, existing OSes fail to fully exploit the benefits of ERMS support, because they still zero pages 4KB at a time. Modern CPUs can zero a 2MB page much faster with bulk zeroing, which calls the assembly language page zeroing code at a size larger than 4KB. Table 5 compares 2MB zeroing speed on five modern machines. Existing OSes take 84–409us to zero a 2MB superpage. After using a larger bulk size, the range is improved to 67–334us. Furthermore, these machines have a consistently short non-temporal (`movnti` or `clzero`) bulk zeroing latency (53–106us). The AMD Ryzen 7 2700X CPU achieves 53us with the highest CPU and DRAM frequency and its specific `clzero` implementation.

CPU (GHz)	DRAM	temporal			non-temporal		
Bulk Size:	(MHz)	4KB	32KB	2MB	4KB	32KB	2MB
E3-1231v3 (3.40)	1600	92	88	87	114	99	97
E3-1245v6 (3.70)	2400	84	67	65	92	74	71
E5-2640v3 (2.60)	1866	355	287	280	154	112	106
E5-2640v4 (2.40)	2133	409	334	325	163	113	106
R7-2700X (4.30)	2666	185	183	159	99	60	53

Table 5: 2MB page zeroing time (us) drops consistently using a larger bulk size.

5 Design and Implementation

This section describes Quicksilver, an improved transparent superpage management system based upon the observations from the previous section. To benefit from in-place promotions, Quicksilver is built upon FreeBSD's reservation-based superpage management strategy.

5.1 Design

Aggressive Physical Superpage Allocation. Section 4 shows that aggressive allocation on first touch (as done by Linux and FreeBSD) is effective. Moreover, Observation 3 shows that FreeBSD's reservation system allows speculative physical allocation for anonymous memory and creates even more superpages than Linux, as shown in Figure 2. Since it also supports multiple superpage sizes and avoids memory bloating, Quicksilver retains FreeBSD's reservation system: allocating physical superpages when virtual memory regions that may use superpages are first accessed. Allocation is performed synchronously to avoid page migrations.

The drawbacks of FreeBSD's use of reservations are twofold. First, FreeBSD delays preparation and mapping of superpages, resulting in lower performance than Linux in some scenarios, as shown in Table 3. However, this is not inherent in the use of reservations for allocation, but rather should be addressed via preparation and mapping policies. Second, holding underutilized physical superpages in reservations can prevent future superpage allocations. However, this is better resolved via deallocation policies that recognize and recover from such situations.

Hybrid Physical Superpage Preparation. Quicksilver strikes a balance between incremental and all-at-once preparation. Reservations are initially prepared incrementally. This minimizes the initial page fault latency, but loses prompt address translation benefits. Therefore, Quicksilver has an additional threshold, t. Once t 4KB pages get prepared, it prepares the remainder of the superpage all-at-once.

This reduces bloat, as discussed in Observation 1, because it does not immediately prepare and map the superpage. However, it enables address translation benefits sooner than waiting for the entire superpage to be accessed. The use of a threshold is further based on previous work showing that the utilization of physical superpages is largely bimodal [34]. Once more than about 64 4KB pages have been accessed, it is very likely that the physical superpage will eventually be fully populated (or very nearly so). Therefore, at that point, it is very likely to be beneficial to prepare the remainder of the page and create a superpage mapping for it. Motivated by Observation 5, bulk zeroing is used to accelerate page zeroing when zero-filling the remainder of the superpage.

Relaxed Superpage Mapping Creation. Once an entire physical superpage has been prepared, there is little downside to immediately creating a superpage mapping for anonymous memory, which is rarely, if ever, swapped in modern systems. Therefore, Quicksilver relaxes FreeBSD's current design — which does not create a superpage mapping if the accessed or modified states of the constituent pages differ — to always create a mapping once the physical superpage has been fully prepared, as do Linux, Ingens, and HawkEye.

For file-backed superpages, Quicksilver retains FreeBSD's write-protection mechanism to avoid extra disk I/O, but no longer examines if all constituent pages are accessed. Because memory-mapped files are usually prefetched 64KB at a time, file-backed superpages may not be fully accessed when they get fully prepared. By allowing different access bits, more file-backed superpage mappings can be created. Note that Linux and its variants do not use superpages at all for files.

On-demand Superpage Mapping Destruction. There is no reason to destroy a superpage mapping unless some or all of the memory within the superpage is freed, its protection is changed, or the physical superpage must be deallocated to reclaim memory. Therefore, Quicksilver maintains FreeBSD's policy of only destroying mappings in the aforementioned situations.

Preemptive Physical Superpage Deallocation. As discussed in Observation 4, delaying partial deallocation of physical superpages effectively limits fragmentation. However, to maximize the effectiveness of synchronous physical superpage allocation, there must be available superpages to allocate. Superpage availability can have a considerable impact on performance as was shown in Table 4. Therefore, Quicksilver maintains a target number of free physical superpages.

Underutilized reservations that are inactive for a long period are preemptively deallocated. These partially prepared physical superpages are not yet mapped as superpages, so the deallocation reduces memory bloat and recovers memory contiguity. Such preemptive deallocation copes well with hybrid preparation under a population threshold t. As a result, preemptive deallocation usually evacuates underutilized and less frequently accessed superpages.

This approach has three advantages. First, fewer pages are migrated. Second, the preemptive migration happens in the background, so it does not happen on the critical path of any OS function executed by the application. Finally, it is likely to have minimal impact on running processes, as it is operating on pages that come from less frequently accessed superpages.

5.2 Implementation

Quicksilver was implemented within FreeBSD 11.2. Quicksilver focuses on anonymous memory, with FreeBSD's superpage support for file-backed memory slightly improved (access bit equivalence is no longer required for promotion). This section further describes the page zeroing mechanism and the migration/deallocation daemon.

Hybrid Preparation. A physical superpage is incrementally prepared until it reaches a population threshold, t. Then the remainder of the physical superpage is prepared by zero-filling it. The system can do this either synchronously or asynchronously, named Sync-t and Async-t. Specifically, Async-t periodically scans the linked list of partially populated physical reservations and starts zero-filling from the most active ones reaching the population threshold t. Therefore, it incurs no fairness issue because the order is determined by physical allocation activity, not process IDs.

In both cases, zero-filling uses non-temporal stores. When using Sync-t, pages are zeroed using the largest bulk size possible, as motivated by Observation 5. Since zeroing is done by the page fault handler, the page fault handler can create a superpage mapping immediately after zeroing is complete. When using Async-t, 4KB pages are zeroed individually. While this yields lower zeroing performance, it reduces lock contention when operating on pages. Since zeroing is done asynchronously and independently of any process's virtual address space, a superpage mapping is not created until the first soft page fault after all pages have been zeroed.

Relaxed Mapping Creation. For anonymous memory, the superpage mapping creation condition is relaxed to ignore checking for dirty and access bits. This allows a superpage mapping to be created immediately after Sync-t completes the zero-filling (these pages are clean). For file-backed memory, superpage mappings are created on a soft page fault of a file-backed physical superpage. Default FreeBSD skips mapping creation because the access bits are inferred not to all be set when prefaulting the prefetched disk data. After relaxing the access bit checking, Quicksilver tries to create a superpage mapping at that point.

Preemptive Deallocation. Physical superpages are often underutilized [20, 34]. Given Observation 4, the system delays

Threads	Linux		FreeBSD	
	default	aggressive	default	emulate Linux ELF
1	1.05	1.19	1.15	1.16
8	**1.07**	0.91	1.11	**1.18**

Table 6: Canneal performance speedup. Only bold numbers are comparable.

Linux		FreeBSD		
default	aggressive	default	patched [1]	match Linux
1.01	1.24	1.02	1.07	**1.19**
0.4 K	8.2 K	0.0 K	1.2 K	**8.2 K**

Table 7: Throughput speedup and number of created superpage mappings of a Redis server populated by Del-70. Only bold numbers are comparable.

partial deallocation of physical superpages. However, to ensure that there are sufficient free physical superpages for future allocations, Quicksilver uses an evacuation daemon to reclaim free physical superpages by preemptively deallocating underutilized physical superpages.

The daemon maintains a target number of free physical superpages. It periodically scans the list of partially populated reservations and examines their inactive time, during which they are neither populated nor deallocated. If they are inactive for a long time, *e.g.*, 5 seconds, the daemon then reclaims a free physical superpage by migrating out its constituent 4KB pages. To avoid contention with running applications, the daemon is restricted to use a maximum memory bandwidth of 1GB/s. This is less than 5% of the evaluated machine.

6 Methodology

Fragmentation. Three fragmentation levels are modeled to mimic long-running servers, named Frag-0, Frag-50 and Frag-100. They represent situations from non-fragmented to severely-fragmented. Specifically, Frag-50 leaves 50% of the application's maximum resident memory as free superpages.

The three fragmentation levels are crafted by a user-space tool which works under a first-touch physical superpage allocation policy (available in both Linux and FreeBSD). It first fragments superpages until there is memory pressure, then starts over and fragments a target number of superpages. Unlike a previous memory fragmentation method [24] that only performs the latter step, Linux's memory compaction usually fails either in page faults or khugepaged. To fragment a superpage, the tool touches part of a 2MB-aligned virtual region and unmaps the untouched part. This will trigger a physical superpage allocation and force a partial deallocation, fragmenting that physical superpage.

Library Differences. FreeBSD dynamically links executable files with its natively shipped libc, while Linux uses GNU libc. This makes any performance comparison between FreeBSD and Linux unfair, because a different implementation of a standard function may change performance significantly. For example, the libc string library in FreeBSD 11.2 does not use ERMS optimizations, so memory copy-intense applications have worse performance. To remove this difference, applications were compiled and statically linked on Linux and then run on FreeBSD using FreeBSD's Linux system call emulation. Table 6 shows that natively compiled canneal on FreeBSD runs slower than emulated canneal, because of slower memory copying in dynamic array resizing. Although a libc library with ERMS optimizations could be ported from FreeBSD 12.0, this methodology ensures that the exact same binaries are run on all systems, eliminating any possible library differences.

There are three exceptions. GraphChi-PR uses `dlopen` to dynamically link the openmp library, so it cannot be statically compiled. Redis calls gettimeofday() very frequently, causing huge emulation overhead. Therefore, they are compiled natively on FreeBSD-based systems after porting the libc library from FreeBSD 12.0. They therefore may have minor library-induced performance differences between the Linux-based and FreeBSD-based systems. Lastly, FreeBSD's Linux emulation caused significant performance degradation on GUPS, because of cache misses resulting from an unaligned dynamically allocated data structure. To fix this, GUPS was modified to use `malloc_aligned`.

System Tuning. When there are idle CPUs, tuning Linux's khugepaged to be more aggressive can obtain better performance. Table 6 shows this in a single-threaded case. This tuning also yields higher throughput for single-threaded Redis, as shown in Table 7. However, performance degrades when the application uses all CPUs and competes with khugepaged, so Linux remains unchanged for the remainder of the evaluation.

FreeBSD 11.2 has suboptimal Redis performance due to three reasons. First, it uses a network socket buffer size suitable for 1Gbps NICs. Second, its libc has no ERMS optimizations, while memory copying dominates Redis's performance. Third, it is unlikely to repromote superpages after `MADV_FREE` (Redis uses `MADV_FREE` on FreeBSD to save page faults). Therefore, FreeBSD was tuned to use the correct buffer size for a 40Gbps NIC, and the libc library was ported from FreeBSD 12.0. Additionally, a recent patch [1] to FreeBSD was applied to increase the likelihood of superpage repromotion, creating 1.2K more superpage mappings in Table 7. The dirty bit requirement for anonymous memory was relaxed to match Linux's performance, creating 8.2K superpage mappings.

Ingens and HawkEye are evaluated with their default settings. Ingens promotes superpages with a 90%-utilization threshold. HawkEye promotes superpages at the speed of 1.6MB/s guided by performance counters. Ingens* and HawkEye* are aggressively tuned variants. Specifically, Ingens* uses a utilization threshold of 0% instead of 90% and enables 1GB/s proactive memory compaction. HawkEye* uses a 100% CPU maximum with a promotion threshold of 1.

7 Evaluation

Four variants of Quicksilver are considered, named Sync-1, Sync-64, Async-64 and Async-256. They all handle the five superpage events similarly except for superpage preparation. Therefore, for clarity they are named after their preparation policies. These four variants represent reasonable design points in the Sync-*t* and Async-*t* space, and use the same 1GB/s active defragmentation daemon. They share the same library and system tunings with FreeBSD. All performance numbers are the mean of three runs.

7.1 Non-fragmented (Frag-0) Performance

Sync-1 vs. Linux. Sync-1 uses the same superpage preparation and mapping policy for anonymous memory as Linux. With no fragmentation, Tables 8 and 9 show that they perform similarly. However, there are two notable differences. First, Sync-1 speculatively allocates superpages for growing heaps, which allows it to outperform Linux on canneal and gcc. Their similar speedups on reservation-based systems validate Observation 3. Second, Sync-1 creates file-backed superpages and outperforms Linux on ANN and Graphchi-PR.

Promotion Speed. Under Frag-0, FreeBSD often outperforms Ingens, HawkEye and their aggressively tuned variants, as shown in Table 8. This validates Observation 2, as the issue is that out-of-place promotion has a slower promotion speed. Furthermore, as shown in Table 9, on the Redis Cold workload, Ingens, HawkEye and their aggressively tuned variants even show a slight degradation compared to Linux-4KB. These systems introduce some noticeable interference with running applications when they manage superpages in the background.

Sync-64 mostly outperforms Async-64, because Async-64 zeros pages in the background which can cause interference. The comparable performance of Sync-64 and Sync-1 shows that less aggressive preparation and mapping policies can achieve comparable results to immediately mapping superpages on first touch.

7.2 Performance Under Fragmentation

Table 9 shows that Linux obtains a much higher tail latency on the Redis Cold workload under Frag-50/100 than Linux-4KB, because its on-allocation defragmentation significantly increases page fault latency. In contrast, FreeBSD does not actively defragment memory, so it generates no latency spikes.

Ingens and HawkEye offload superpage allocation from page faults and compact memory in the background, so they reduce interference and generate few latency spikes on the Redis Cold workload. Furthermore, as shown in Table 8, their speedup over Linux increases as fragmentation increases. However, HawkEye does not achieve the same speedups on XSBench that were reported in the original paper [24], because in these application runs, most of its memory compaction fails and its important data was not allocated at the high end of the address space.

The four variants of Quicksilver all consistently perform well on both non-server and server workloads, because their background defragmentation not only avoids increasing page fault latency, but also succeeds in recovering unfragmented performance. Specifically, on the Redis Cold workload, Sync-1 maintained the highest throughput (1.31 GB/s) while providing low (4.5 ms) tail latency under Frag-100. However, the per-second background scanning of the evacuation daemon may fail to improve performance when applications quickly touch all of their memory in the beginning (*e.g.* GUPS and ANN). As a result, there is high performance variation on GUPS and ANN performance is not improved over other systems, as shown in Table 8.

Graphchi-PR. On all applications in Table 8, the Sync-*t* and Async-*t* systems all match or outperform Linux. Since Graphchi-PR is an important and real-world task, it is selected to elaborate how the design choices described in Section 5 contribute to the 2.18 speedup of Sync-1 under Frag-100.

Under Frag-100, Async-64 obtains a speedup of 1.68, which is higher than the 1.15 speedup obtained by Ingens* on Graphchi-PR. When Graphchi-PR terminated, Ingens* has a total of 1,926 (mean of 3 runs) free physical superpages, but Async-64 has 11,955 free physical superpages. Although they have the same memory bandwidth budget (1GB/s) for active defragmentation, Quicksilver's evacuation daemon defragments memory more efficiently by identifying inactive fragmented superpages. The in-place promotions further contribute to the higher speedup of Async-64. When memory is not fragmented, Async-64 obtains a speedup of 0.83, higher than all other non-Quicksilver systems.

Sync-64 obtains an even higher speedup of 2.11. The shared evacuation daemon allows both Async-64 and Sync-64 to allocate a similar number of superpages, but the synchronous all-at-once preparation implemented by bulk zeroing in Sync-64 efficiently removes the delay of creating superpages. With the same number of superpages, Sync-64 is able to reduce page walk pending cycles by 76%. The highest speedup is obtained by Sync-1 with a more aggressive promotion threshold.

7.3 Memory Bloat

All systems suffer less than 1% memory bloat compared to Linux-4KB on the applications shown in Table 8. However, long-running servers may still suffer from memory bloat. When applications frequently allocate and deallocate memory, an aggressive superpage preparation policy may preemptively prepare a superpage and sacrifice free memory for minor address translation benefits, ultimately creating false memory pressure.

Frag-0	GUPS	Graphchi-PR	BlockSVM	XSBench	ANN	canneal	freqmine	gcc	mcf	DSjeng	XZ

Table 8: Performance speedup over Linux under three fragmentation levels. Red boxes indicate that the system performs worse than Linux on that application. The normalized standard deviation of runtime is no greater than 5% unless specified in parentheses.

Table 10 compares the memory consumption of four Redis workloads. Among these workloads, Linux bloats memory the most, consistent with previous findings [20]. However, Sync-1 exhibits lower memory consumption than Linux despite similar policies. In fact, it is khugepaged that bloats memory. When a partially deallocated superpage is scanned, it allocates the memory back to recreate a superpage, undermining the application's efforts to free and defragment memory.

All systems other than Linux limit memory consumption for the first three workloads; they only really differ on Range-XL. HawkEye, FreeBSD, and Async-256 exhibit the lowest memory consumption on Range-XL, whereas the other systems bloat memory by 40–60%. HawkEye stops allocating superpages when the TLB overhead is minor, FreeBSD only promotes fully utilized superpages, and Async-256 has a conservative promotion threshold.

Sync-1 vs. Sync-64 Besides bloating memory, aggressive preparation policies may cause excessive creation of superpages. This is common when many small processes get forked. For example, Table 11 shows what happens in a 9-threaded compilation of the FreeBSD kernel. Sync-1 creates more than 200k superpages, while the less aggressive Sync-64 only creates around 100k. Over half of the superpages created by Sync-1 had less than 13% utilization. Consequently, Sync-1 spends 13.9% more system time preparing them, which outweighs their benefits. In a long running server, using an aggressive policy like Sync-1 could waste both power and memory contiguity by creating underutilized superpages. In contrast, Sync-64 avoids such cases and suffers from less performance degradation than Sync-1 in both Table 8 and Table 9. Therefore, it is more preferable for long-running servers.

8 Related Work

Direct segments have been proposed as a supplement to existing page-based address translation for large-memory applications [9, 14, 18]. While they are effective at reducing the cost of address translation, they are limited to systems that allocate nearly all of the system memory to a single application with the same access rights. While these ideas can be generalized to some degree, they ultimately limit the flexibility of the OS to allocate and use physical memory.

reach of the TLB has been proposed and implemented [26,27]. Essentially, a page walk will load multiple 4KB mappings found in the same cache line. If these mappings refer to contiguous pages and have identical access privileges, then they are merged into a single TLB entry. Although TLB entry coalescing occurs automatically in hardware, it nonetheless requires the OS to allocate physically contiguous memory. AMD Ryzen processors do such coalescing [12].

A large body of work has shown that using superpages can reduce the cost of address translation. Originally, OS support for superpages required the administrator to manually control the use of superpages. For example, Linux has long supported *persistent huge pages* [4]. A huge page pool with a static number of huge pages must be allocated by the administrator before running applications. The persistent huge pages are pinned in memory and can only be used via specific flags to `mmap` system calls. Superpage support in Windows and OS X are similar to Linux persistent huge pages [3,6].

To eliminate the need for manual control, FreeBSD, Linux, and many research prototypes have explored transparent superpage support, as described in Section 3. This support has been extensively described and studied [16,17,20,23,24,29]. As this transparent support for superpages has become widely available in production OSes, many people have argued that effectively handling all of the issues that can arise still requires further improvements to OS memory management support [15–17,20,22,24,25]. For example, some of these people have worked to improve Linux's superpage management by decreasing memory fragmentation and more carefully allocating physical superpages using Linux's idle page tracking mechanisms [20,22,24,25,31]. Others have shown that it is beneficial to decrease memory fragmentation and increase the contiguity of physical memory. To achieve this, several efforts have focused on minimizing migration and reducing its performance impact, while still attempting to reduce fragmentation and increase contiguity [7,8,22,25,31]. The deprecated lumpy reclaim from Linux was also developed to increase contiguity [2]. It reclaims a 2MB superpage by finding an inactive 4KB page and swaps out all dirty 4KB pages inside the 2MB block. Because these dirty 4KB pages may also contain active ones, swapping them out may hurt performance instead. Besides efforts on anonymous superpages, Zhou, *et al.* augmented FreeBSD to synchronously page-in code and pad code sections to create more code superpages [33].

9 Conclusions

This paper has performed a comprehensive analysis of superpage management mechanisms and policies. The explicit enumeration of the five events involved in the life of a superpage provides a framework around which to compare and contrast superpage management policies. This framework and analysis yielded five key observations about superpage management that motivated Quicksilver's innovative design. Quicksilver achieves the benefits of aggressive superpage allocation, while mitigating the memory bloat and fragmentation issues that arise from underutilized superpages. Both the Sync-1 and Sync-64 variants of Quicksilver are able to match or beat the performance of existing systems in both lightly and heavily fragmented scenarios, in terms of application performance, tail latency, and memory bloat. However, Sync-64 is preferable for long-running servers, as it does not aggressively create underutilized superpages.

Effectively Prefetching Remote Memory with Leap

Hasan Al Maruf
University of Michigan

Mosharaf Chowdhury
University of Michigan

Abstract

Memory disaggregation over RDMA can improve the performance of memory-constrained applications by replacing disk swapping with remote memory accesses. However, state-of-the-art memory disaggregation solutions still use data path components designed for slow disks. As a result, applications experience remote memory access latency significantly higher than that of the underlying low-latency network, which itself can be too high for many applications.

In this paper, we propose Leap, a prefetching solution for remote memory accesses due to memory disaggregation. At its core, Leap employs an online, majority-based prefetching algorithm, which increases the page cache hit rate. We complement it with a lightweight and efficient data path in the kernel that isolates each application's data path to the disaggregated memory and mitigates latency bottlenecks arising from legacy throughput-optimizing operations. Integration of Leap in the Linux kernel improves the median and tail remote page access latencies of memory-bound applications by up to 104.04× and 22.62×, respectively, over the default data path. This leads to up to 10.16× performance improvements for applications using disaggregated memory in comparison to the state-of-the-art solutions.

1 Introduction

Modern data-intensive applications [5, 29, 30, 70] experience significant performance loss when their complete working sets do not fit into the main memory. At the same time, despite significant and disproportionate memory underutilization in large clusters [62, 78], memory cannot be accessed beyond machine boundaries. Such unused, stranded memory can be leveraged by forming a cluster-wide logical memory pool via *memory disaggregation*, improving application-level performance and overall cluster resource utilization [11, 45, 48].

Two broad avenues have emerged in recent years to expose remote memory to memory-intensive applications. The first requires redesigning applications from the ground up using RDMA primitives [15, 22, 36, 49, 59, 63, 77]. Despite its efficiency, rewriting applications can be cumbersome and may not even be possible for many applications [10]. Alternatives rely on well-known abstractions to expose remote memory; e.g., distributed virtual file system (VFS) for remote file access [10] and distributed virtual memory management (VMM) for *remote memory paging* [28, 32, 45, 46, 65].

Because disaggregated remote memory is slower, keeping hot pages in the faster local memory ensures better performance. Colder pages are moved to the far/remote memory as needed [9, 32, 45]. Subsequent accesses to those cold pages go through a slow data path inside the kernel – for instance, our measurements show that an average 4KB remote page access takes close to 40 μs in state-of-the-art memory disaggregation systems like Infiniswap. Such high access latency significantly affects performance because memory-intensive applications can tolerate at most single μs latency [28, 45]. Note that the latency of existing systems is many times more than the 4.3 μs average latency of a 4KB RDMA operation, which itself can be too high for some applications.

In this paper, we take the following position: *an ideal solution should minimize remote memory accesses in its critical path as much as possible*. In this case, a *local page cache* can reduce the total number of remote memory accesses – a cache *hit* results in a sub-μs latency, comparable to that of a local page access. An effective prefetcher can proactively bring in correct pages into the cache and increase the cache hit rate.

Unfortunately, existing prefetching algorithms fall short for several reasons. First, they are designed to reduce disk access latency by prefetching sequential disk pages in large batches. Second, they cannot distinguish accesses from different applications. Finally, they cannot quickly adapt to temporal changes in page access patterns within the same process. As a result, being optimistic, they pollute the cache with unnecessary pages. At the same time, due to their rigid pattern detection technique, they often fail to prefetch the required pages into the cache before they are accessed.

In this paper, we propose Leap, an online prefetching solution that minimizes the total number of remote memory accesses in the critical path. Unlike existing prefetching algorithms that rely on strict pattern detection, Leap relies on approximation. Specifically, it builds on the Boyer-Moore majority vote algorithm [17] to efficiently identify remote memory access patterns for each individual process. Relying on an approximate mechanism instead of looking for trends in strictly consecutive accesses makes Leap resilient to short-term irregularities in access patterns (e.g., due to multi-threading). It also allows Leap to perform well by detecting trends only from remote page accesses instead of tracing the full virtual memory footprint of an application, which demands continuous scanning and logging of the hardware access bits of the whole virtual address space and results in high CPU and memory overhead. In addition to identifying

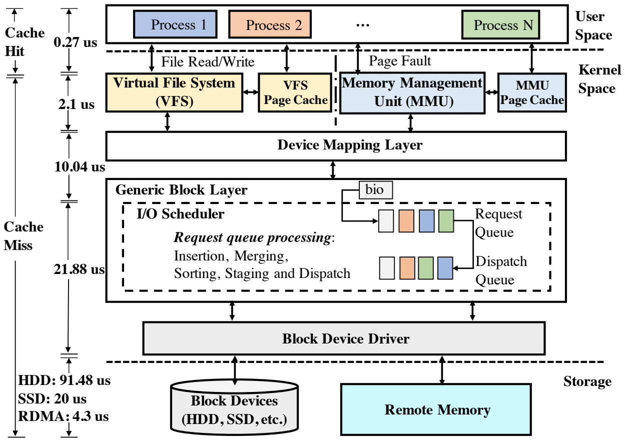

Figure 1: High-level life cycle of page requests in Linux data path along with the average time spent in each stage.

the majority access pattern, Leap determines how many pages to prefetch following that pattern to minimize cache pollution.

While reducing cache pollution and increasing the cache hit rate, Leap also ensures that the host machine faces minimal memory pressure due to the prefetched pages. To move pages from local to remote memory, the kernel needs to scan through the entire memory address-space to find eviction candidates – the more pages it has, the more time it takes to scan. This increases the memory allocation time for new pages. Therefore, alongside a background LRU-based asynchronous page eviction policy, Leap eagerly frees up a prefetched cache just after it gets hit and reduces page allocation wait time.

We complement our algorithm with an efficient data path design for remote memory accesses that is used in case of a cache *miss*. It isolates per-application remote traffic and cuts inessentials in the end-host software stack (e.g., the block layer) to reduce host-side latency and handle a cache miss with latency close to that of the underlying RDMA operations.

Overall, we make the following contributions in this paper:

- We analyze the data path latency overheads for disaggregated memory systems and find that existing data path components can not consistently support single μs 4KB page access latency (§2).
- We propose Leap, a novel online prefetching algorithm (§3) and an eager prefetch cache eviction policy along with a leaner data path, to improve remote I/O latency.
- We implement Leap on Linux Kernel 4.4.125 as a separate data path for remote memory access (§4). Applications can choose either Linux's default data path for traditional usage or Leap for going beyond the machine's boundary using unmodified Linux ABIs.
- We evaluate Leap's effectiveness for different memory disaggregation frameworks. Leap's faster data path and effective cache management improve the median and tail 4KB page access latency by up to 104.04× and 22.62× for micro-benchmarks (§5.1) and by 1.27–10.16× for real-world memory-intensive applications with production workloads (§5.3).
- We evaluate Leap's prefetcher against practical real-time prefetching techniques (Next-K Line, Stride, Linux Read-ahead) and show that simply replacing the default Linux prefetcher with Leap's prefetcher can provide application-level performance benefit (1.1–3.36× better) even when they are paging to slower storage (e.g., HDD, SSD) (§5.2).

2 Background and Motivation

2.1 Remote Memory

Memory disaggregation systems logically expose unused cluster memory as a global memory pool that is used as the slower memory for machines with extreme memory demand. This improves the performance of memory-intensive applications that have to frequently access slower memory in memory-constrained settings. At the same time, the overall cluster memory usage gets balanced across the machines, decreasing the need for memory over-provisioning per machine.

Access to remote memory over RDMA without significant application rewrites typically relies on two primary mechanisms: disaggregated VFS [10], that exposes remote memory as files and disaggregated VMM for remote memory paging [32, 45, 65]. In both cases, data is communicated in small chunks or pages. In case of remote memory as files, pages go through the file system before they are written to/read from the remote memory. For remote memory paging and distributed OS, page faults cause the virtual memory manager to write pages to and read them from the remote memory.

2.2 Remote Memory Data Path

State-of-the-art memory disaggregation frameworks depend on the existing kernel data path that is optimized for slow disks. Figure 1 depicts the major stages in the life cycle of a page request. Due to slow disk access times – average latencies for HDDs and SSDs range between 4–5 ms and 80–160 μs, respectively – frequent disk accesses have a severe impact on application throughput and latency. Although the recent rise of memory disaggregation is fueled by the hope that RDMA can consistently provide single μs 4KB page access latency [11, 28, 32], this is often a wishful thinking in practice [79]. Blocking on a page access – be it from HDD, SSD, or remote memory – is often unacceptable.

To avoid blocking on I/O, race conditions, and synchronization issues (e.g., accessing a page while the page out process is still in progress), the kernel uses a page cache. To access a page from slower memory, it is first looked up in the appropriate cache location; a *hit* results in almost memory-speed page access latency. However, when the page is not found in the cache (i.e., a *miss*), it is accessed through a costly block device I/O operation that includes several queuing and batching stages to optimize disk throughput by merging multiple contiguous smaller disk I/O requests into a single large re-

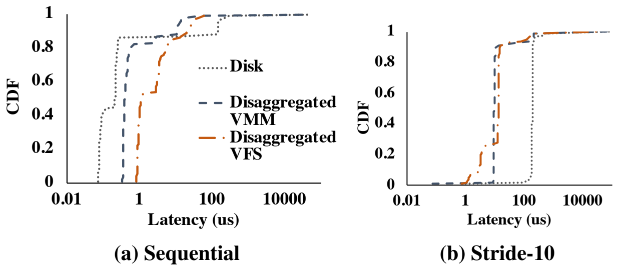

Figure 2: Data path latencies for two access patterns. Memory disaggregation systems have some constant implementation overheads that cap their minimum latency to around 1 μs.

quest. On average, these batching and queuing operations cost around 34 μs and over a few milliseconds at the tail. As a result, a cache miss leads to more than 100× slower latency than a hit; it also introduces high latency variations. For microsecond-latency RDMA environments, this unnecessary wait-time has a severe impact on application performance.

2.3 Prefetching in Linux

Linux tries to store files on the disk in adjacent sectors to increase sequential disk accesses. The same happens for paging. Naturally, existing prefetching mechanisms are designed assuming a sequential data layout. The default Linux prefetcher relies on the last two page faults: if they are for consecutive pages, it brings in several sequential pages into the page cache; otherwise, it assumes that there are no patterns and reduces or stops prefetching. This has several drawbacks. First, whenever it observes two consecutive paging requests for consecutive pages, it over-optimistically brings in pages that may not even be useful. As a result, it wastes I/O bandwidth and causes *cache pollution* by occupying valuable cache space. Second, simply assuming the absence of any pattern based on the last two requests is over-pessimistic. Furthermore, all the applications share the same swap space in Linux; hence, pages from two different processes can share consecutive places in the swap area. An application can also have multiple, inter-leaved stride patterns – for example, due to multiple concurrent threads. Overall, considering only the last two requests to prefetch a batch of pages falter on both respects.

To illustrate this, we measure the page access latency for two memory access patterns: (a) **Sequential** accesses memory pages sequentially, and (b) **Stride-10** accesses memory in strides of 10 pages. In both cases, we use a simple application with its working set size set to 2GB. For disaggregated VMM, it is provided 1GB memory to ensure that 50% of its access cause paging. For disaggregated VFS, it performs 1GB remote write and then another 1GB remote read operations.

Figure 2 shows the latency distributions for 4KB page accesses from disk and disaggregated remote memory for both of the access patterns. For a prefetch size of 8 pages, both perform well for the **Sequential** pattern; this is because 80% of the requests hit the cache. In contrast, we observe significantly higher latency in the **Stride-10** case because all the requests miss the page cache due to the lack of consecutiveness in successive page accesses. By analyzing the latency breakdown inside the data path for **Stride-10** (as shown in Figure 1), we make two key observations. First, although RDMA can provide significantly lower latency than disk (4.3μs vs. 91.5μs), RDMA-based solutions do not benefit as much from that (38.3μs vs. 125.5μs). This is because of the significant data path overhead (on average 34μs) to prepare and batch a request before dispatching it. Significant variations in the preparation and batching stages of the data path cause the average to stray far from the median. Second, the existing sequential data layout-based prefetching mechanism fails to serve the purpose in the presence of diverse remote page access patterns. Solutions based on fixed stride sizes also fall short because stride sizes can vary over time within the same application. Besides, there can be more complicated patterns beyond stride or no repetitions at all.

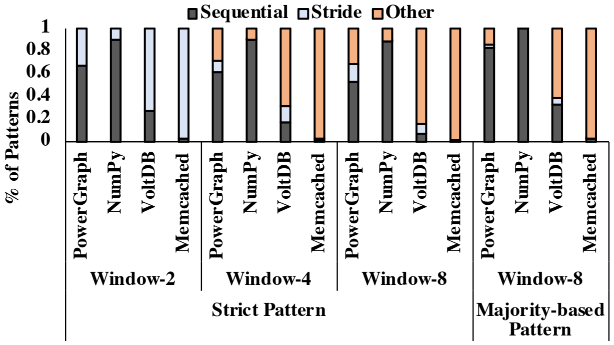

Figure 3: Fractions of sequential, stride, and other access patterns in page fault sequences of length X (Window-X).

Shortcoming of Strict Pattern Finding for Prefetching Figure 3 presents the remote page access patterns of four memory-intensive applications during page faults when they are run with 50% of their working sets in memory (more details in Section 5.3). Here, we consider all page fault sequences within a window of size $X \in \{2,4,8\}$ in these applications. Therefore, we divide the page fault scenarios into three categories: *sequential* when all pages within the window of X are sequential pages, *stride* when the pages within the window of X have the same stride from the first page, and *other* when it is neither sequential nor stride.

The default prefetcher in Linux finds strict sequential patterns in window size $X = 2$ and tunes up its aggressiveness accordingly. For example, page faults in PowerGraph and VoltDB follow 67% and 27% sequential pattern within window size $X = 2$, respectively. Consequently, for these two applications, Linux optimistically prefetches many pages into the cache. However, if we look at the $X = 8$ case, the percentage of sequential pages within consecutive page faults goes down to 53% and 7% for PowerGraph and VoltDB, respectively. Meaning, for these two applications, 14–20% of the prefetched pages are not consumed immediately. This creates

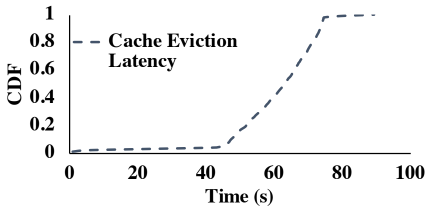

Figure 4: Due to Linux's lazy cache eviction policy, page caches waste the cache area for significant amount of time.

unnecessary memory pressure and might even lead to cache pollution. At the same time, all non-sequential patterns in the $X = 2$ case fall under the stride category. Considering the low cache hit rate, Linux pessimistically decreases/stops prefetching in those cases, which leads to a stale page cache.

Note that strictly expecting all X accesses to follow the same pattern results in not having any patterns at all (e.g., when $X = 8$), because this cannot capture the transient interruptions in sequence. In that case, following the major sequential and/or stride trend within a limited page access history window is more resilient to short-term irregularities. Consecutively, when $X = 8$, a majority-based pattern detection can detect 11.3%–29.7% more sequential accesses. Therefore, it can successfully prefetch more accurate pages into the page cache. Besides sequential and stride access patterns, it is also transparent to irregular access patterns; e.g., for Memcached, it can detect 96.4% of the irregularity.

Prefetch Cache Eviction Linux kernel maintains an asynchronous background thread (`kswapd`) to monitor the machine's memory consumption. If the overall memory consumption goes beyond a critical memory pressure or a process's memory usage hits its limit, it determines the eviction candidates by scanning over the in-memory pages to find out the least-recently-used (LRU) ones. Then, it frees up the selected pages from the main memory to allocate new pages. A prefetched cache waits into the LRU list for its turn to get selected for eviction even though it has already been used by a process (Figure 4). Unnecessary pages waiting for eviction in-memory leads to extra scanning time. This extra wait-time due to lazy cache eviction policy adds to the overall latency, especially in a high memory pressure scenario.

3 Remote Memory Prefetching

In this section, we first highlight the characteristics of an ideal prefetcher. Next, we present our proposed online prefetcher along with its different components and the design principles behind them. Finally, we discuss the complexity and correctness of our algorithm.

3.1 Properties of an Ideal Prefetcher

A prefetcher's effectiveness is measured along three axes:

- *Accuracy* refers to the ratio of total cache hits and the total pages added to the cache via prefetching.
- *Coverage* measures the ratio of the total cache hit from the prefetched pages and the total number of requests (e.g., page faults in case of remote memory paging solutions).
- *Timeliness* of an accurately prefetched page is the time gap from when it was prefetched to when it was first hit.

Trade-off An aggressive prefetcher can hide the slower memory access latency by bringing pages well ahead of the access requests. This might increase the accuracy, but as prefetched pages wait longer to get consumed, this wastes the effective cache and I/O bandwidth. On the other hand, a conservative prefetcher has lower prefetch consumption time and reduces cache and bandwidth contention. However, it has lower coverage and cannot hide memory access latency completely. An effective prefetcher must balance all three.

An effective prefetcher must be adaptive to temporal changes in memory access patterns as well. When there is a predictable access pattern, it should bring pages aggressively. In contrast, during irregular accesses, the prefetch rate should be throttled down to avoid cache pollution.

Prefetching algorithms use prior page access information to predict future access patterns. As such, their effectiveness largely depends on how well they can detect patterns and predict. A real-time prefetcher has to face a trade-off between pattern identification accuracy vs. computational complexity and resource overhead. High CPU usage and memory consumption will negatively impact application performance even though they may help in increasing accuracy.

Common Prefetching Techniques The most common and simple form of prefetching is spatial pattern detection [51]. Some specific access patterns (i.e., stride, stream, etc.) can be detected with the help of special hardware (HW) features [33, 35, 66, 80]. However, they are typically applied to identify patterns in instruction access that are more regular; in contrast, data access patterns are more irregular. Special prefetch instructions can also be injected into an application's source code, based on compiler or post-execution based analysis [27,40,41,60,61]. However, compiler-injected prefetching needs a static analysis of the cache miss behavior before the application runs. Hence, they are not adaptive to dynamic cache behavior. Finally, HW- or software (SW)-dependent prefetching techniques are limited to the availability of the special HW/SW features and/or application modification.

Summary An ideal prefetcher should have low computational and memory overhead. It should have high accuracy, coverage, and timeliness to reduce cache pollution; an adaptive prefetch window is imperative to fulfill this requirement. It should also be flexible to both spatial and temporal locality in memory accesses. Finally, HW/SW independence and application transparency make it more generic and robust.

Table 1 compares different prefetching methods.

3.2 Majority Trend-Based Prefetching

Leap has two main components: *detecting trends* and *deter-*

Table 1: Comparison of prefetching techniques based on different objectives.

Algorithm 1 Trend Detection

```
procedure FINDTREND($N_{split}$)
  $H_{size} \leftarrow$ SIZE($AccessHistory$)
  $w \leftarrow H_{size}/N_{split}$        ▷ Start with small detection window
  $\Delta_{maj} \leftarrow \emptyset$
  while true do
    $\Delta_{maj} \leftarrow$ Boyer-Moore on $\{H_{head}, \ldots, H_{head-w-1}\}$
    $w \leftarrow w * 2$
    if $\Delta_{maj} \neq$ major trend then
      $\Delta_{maj} \leftarrow \emptyset$
    if $\Delta_{maj} \neq \emptyset$ or $w > H_{size}$ then
      return $\Delta_{maj}$
  return $\Delta_{maj}$
```

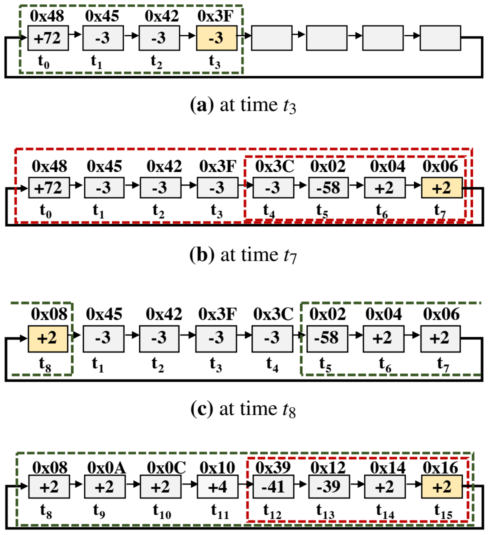
mining what to prefetch. The first component looks for any approximate trend in earlier accesses. Based on the trend availability and prefetch utilization information, the latter component decides how many and which pages to prefetch.

3.2.1 Trend Detection

Existing prefetch solutions rely on strict pattern identification mechanisms (e.g., sequential or stride of fixed size) and fail to ignore temporary irregularities. Instead, we consider a relaxed approach that is robust to short-term irregularities. Specifically, we identify the majority Δ values in a fixed-size (H_{size}) window of remote page accesses (ACCESSHISTORY) and ignore the rest. For a window of size w, a Δ value is said to be the major only if it appears at least $\lfloor w/2 \rfloor + 1$ times within that window. To find the majority Δ, we use the Boyer-Moore majority vote algorithm [17] (Algorithm 1), a linear-time and constant-memory algorithm, over ACCESSHISTORY elements. Given a majority Δ, due to the temporal nature of remote page access events, it can be hypothesized that subsequent Δ values are more likely to be the same as the majority Δ.

Note that if two pages are accessed together, they will be aged and evicted together in the slower memory space at contiguous or nearby addresses. Consequently, the temporal locality in virtual memory accesses will also be observed in the slower page accesses and an approximate stride should be enough to detect that.

Window Management If a memory access sequence follows a regular trend, then the majority Δ is likely to be found in almost any part of that sequence. In that case, a smaller window can be more effective as it reduces the total number of operations. So instead of considering the entire ACCESSHISTORY, we start with a smaller window that starts from the head position (H_{head}) of ACCESSHISTORY. For a window of size w, we find the major Δ appearing in the $H_{head}, H_{head-1}, ..., H_{head-w-1}$ elements.



(a) at time t_3

(b) at time t_7

(c) at time t_8

(d) at time t_{15}

Figure 5: Content of ACCESSHISTORY at different time. Solid colored boxes indicate the head position at time t_i. Dashed boxes indicate detection windows. Here, time rolls over at t_8.

However, in the presence of short-term irregularities, small windows may not detect a majority. To address this, the prefetcher starts with a small detection window and doubles the window size up to ACCESSHISTORY size until it finds a majority; otherwise, it determines the absence of a majority. The smallest window size can be controlled by N_{split}.

Example Let us consider a ACCESSHISTORY with $H_{size} = 8$ and $N_{split} = 2$. Say pages with the following addresses: `0x48`, `0x45`, `0x42`, `0x3F`, `0x3C`, `0x02`, `0x04`, `0x06`, `0x08`, `0x0A`, `0x0C`, `0x10`, `0x39`, `0x12`, `0x14`, `0x16`, were requested in that order. Figure 5 shows the corresponding Δ values stored in ACCESSHISTORY, with t_0 being the earliest and t_{15} being the latest request. At t_i, H_{head} stays at the t_i-th slot.

FINDTREND in Algorithm 1 will initially try to detect a

Algorithm 2 Prefetch Candidate Generation

```
1:  procedure GetPrefetchWindowSize(page $P_t$)
2:    $PW_{size_t}$                          ▷ Current prefetch window size
3:    $PW_{size_{t-1}}$                      ▷ Last prefetch window size
4:    $C_{hit}$                ▷ Prefetched cache hits after last prefetch
5:    if $C_{hit} = 0$ then
6:      if $P_t$ follows the current trend then
7:        $PW_{size_t} \leftarrow 1$              ▷ Prefetch a page along trend
8:      else
9:        $PW_{size_t} \leftarrow 0$                      ▷ Suspend prefetching
10:   else                                   ▷ Earlier prefetches had hits
11:     $PW_{size_t} \leftarrow$ Round up $C_{hit} + 1$ to closest power of 2
12:   $PW_{size_t} \leftarrow \mathbf{min}(PW_{size_t}, PW_{size_{max}})$
13:   if $PW_{size_t} < PW_{size_{t-1}}/2$ then              ▷ Low cache hit
14:     $PW_{size_t} \leftarrow PW_{size_{t-1}}/2$        ▷ Shrink window smoothly
15:   $C_{hits} \leftarrow 0$
16:   $PW_{size_{t-1}} \leftarrow PW_{size_t}$
17:   return $PW_{size_t}$

18: procedure DoPrefetch(page $P_t$)
19:   $PW_{size_t} \leftarrow$ GetPrefetchWindowSize($P_t$)
20:   if $PW_{size_t} \neq 0$ then
21:     $\Delta_{maj} \leftarrow$ FindTrend($N\_split$)
22:     if $\Delta_{maj} \neq \emptyset$ then
23:       Read $PW_{size_t}$ pages with $\Delta_{maj}$ stride from $P_t$
24:     else
25:       Read $PW_{size_t}$ pages around $P_t$ with latest $\Delta_{maj}$
26:   else
27:     Read only page $P_t$
```

trend using a window size of 4. Upon failure, it will look for a trend first within a window size of 8.

At time t_3, FindTrend successfully finds a trend of -3 within the t_0–t_3 window (Figure 5a).

At time t_7, the trend starts to shift from -3 to +2. At that time, t_4–t_7 window does not have a majority Δ, which doubles the window to consider t_0–t_7. This window does not have any majority Δ either (Figure 5b). However, at t_8, a majority Δ of +2 within t_5–t_8 will be adopted as the new trend (Figure 5c).

Similarly, at t_{15}, we have a majority of +2 in the t_8–t_{15}, which will continue to the +2 trend found at t_8 while ignoring the short-term variations at t_{12} and t_{13} (Figure 5d).

3.2.2 Prefetch Candidate Generation

So far we have focused on identifying the presence of a trend. Algorithm 2 determines whether and how to use that trend for prefetching for a request for page P_t.

We determine the prefetch window size (PW_{size_t}) based on the accuracy of prefetches between two consecutive prefetch requests (see GetPrefetchWindowSize). Any cache hit of the prefetched data between two consecutive prefetch requests indicates the overall effectiveness of the prefetch. In case of high effectiveness (i.e., a high cache hit), PW_{size_t} is expanded until it reaches maximum size ($PW_{size_{max}}$). On the other hand, low cache hit indicates low effectiveness; in that case, the prefetch window size gets reduced. However, in the presence of drastic drops, prefetching is not suspended immediately. The prefetch window is shrunk smoothly to make the algorithm flexible to short-term irregularities. When prefetching is suspended, no extra pages are prefetched until a new trend is detected. This is to avoid cache pollution during irregular/unpredictable accesses.

Given a non-zero PW_{size}, the prefetcher brings in PW_{size} pages following the current trend, if any (DoPrefetch). If no majority trend exists, instead of giving up right away, it speculatively brings PW_{size} pages around P_t's offset following the previous trend. This is to ensure that short-term irregularities cannot completely suspend prefetching.

Prefetching in the Presence of Irregularity FindTrend can detect a trend within a window of size w in the presence of at most $\lfloor w/2 \rfloor - 1$ irregularities within it. If the window size is too small or the window has multiple perfectly interleaved threads with different strides, FindTrend will consider it a random pattern. In that case, if the PW_{size} has a non-zero value then it performs a speculative prefetch (line 25) with the previous Δ_{maj}. If that Δ_{maj} is one of the interleaved strides, then this speculation will cause cache hit and continue. Otherwise, PW_{size} will eventually be zero and the prefetcher will stop bringing unnecessary pages. In that case, the prefetcher cannot be worse than the existing prefetch algorithms.

Prefetching During Constrained Bandwidth In Leap, faulted page read and prefetch are done asynchronously. Here, prefetching has a lower priority. In extreme bandwidth constraints, prefetched pages will take a long time to arrive and result in fewer cache hits. This will eventually shrink down PW_{size}. Thus, dynamic prefetch window sizing will help in bandwidth-constrained scenarios.

Effect of Huge Page Linux kernel splits a huge page into 4KB pages before swapping. When transparent huge page is enabled, Leap will be applied on these splitted 4KB pages.

Note that, using huge pages will result in high amplification for dirty data [18]. Besides, average RDMA latencies for 4KB vs 2MB page are 3μs vs 330μs. If huge pages were never split, to maintain single μs latency for 2MB pages, we will need a significantly larger prefetch window size ($PW_{size} \geq 128$), demanding more bandwidth and cache space, and making mispredictions more expensive.

3.3 Analysis

Time Complexity The FindTrend function in Algorithm 1 initially tries to detect trend aggressively within a smaller window using the Boyer-Moor Majority Voting algorithm. If it fails, then it expands the window size. The Boyer-Moor Majority Voting algorithm (line 6) detects a majority element (if any) in $O(w)$ time, where w is the size of the window. In the worst case, it will invoke the Boyer-Moor

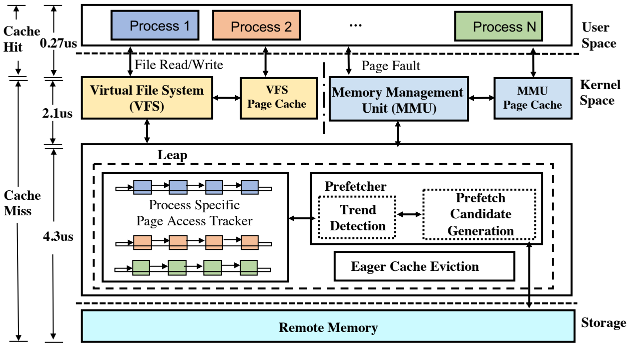


Figure 6: Leap has a faster data path for a cache miss.

Majority Voting algorithm for $O(logH_{size})$ times. However, as the windows are continuous, searching in a new window does not need to start from the beginning and the algorithm never access the same item twice. Hence, the worst-case time complexity of the FindTrend function is $O(H_{size})$, where H_{size} is the size of the AccessHistory queue. For smaller H_{size} the computational complexity is constant. Even for $H_{size} = 32$, the prefetcher provides significant performance gain (§5) that greatly outweighs the slight extra computational cost.

Memory Complexity The Boyer-Moor Majority Voting algorithm operates on constant memory space. FindTrend just invokes the Boyer-Moor Majority Voting algorithm and does not require any additional memory to execute. So, the Trend Detection algorithm needs O(1) space to operate.

Correctness of Trend Detection The correctness of FindTrend depends on that of the Boyer-Moor Majority Voting algorithm, which always provides the majority element, if one exists, in linear time (see [17] for the formal proof).

4 System Design

We have implemented our prefetching algorithm as a data path replacement for memory disaggregation frameworks (we refer to this design as Leap data path) alongside the traditional data path in Linux kernel v4.4.125. Leap has three primary components: a page access tracker to isolate processes, a majority-based prefetching algorithm, and an eager cache eviction mechanism. All of them work together in the kernel space to provide a faster data path. Figure 6 shows the basic architecture of Leap's remote memory access mechanism. It takes only around 400 lines of code to implement the page access tracker, prefetcher, and the eager eviction mechanism.

4.1 Page Access Tracker

Leap isolates each process's page access data paths. The page access tracker monitors page accesses inside the kernel that enables the prefetcher to detect application-specific page access trends. Leap does not monitor in-memory pages (hot pages) because continuously scanning and recording the hardware access bits of a large number of pages causes significant computational overhead and memory consumption. Instead, it monitors only the cache look-ups and records the access sequence of the pages after I/O requests or page faults, trading off a small loss in access pattern detection accuracy for low resource overhead. As temporal locality in the virtual memory space results in a spatial locality in the remote address space, just monitoring the remote page accesses is often enough.

The page access tracker is added as a separate control unit inside the kernel. Upon a page fault, during the page-in operation (`do_swap_page()` under `mm/memory.c`), we notify (`log_access_history()`) Leap's page access tracker about the page fault and the process involved. Leap maintains process-specific fixed-size (H_{size}) FIFO AccessHistory circular queues to record the page access history. Instead of recording exact page addresses, however, we only store the difference between two consecutive requests (Δ). For example, if page faults happen for addresses `0x2`, `0x5`, `0x4`, `0x6`, `0x1`, `0x9`, then AccessHistory will store the corresponding Δ values: 0, +3, -1, +2, -5, +8. This reduces the storage space and computation overhead during trend detection (§3.2.1).

4.2 The Prefetcher

To increase the probability of cache hit, Leap incorporates the majority trend-based prefetching algorithm (§3.2). Here, the prefetcher considers each process's earlier remote page access histories available in the respective AccessHistory to efficiently identify the access behavior of different processes. Because threads of the same process share memory with each other, we choose process-level detection over thread-based. Thread-based pattern detection may result in requesting the same page for prefetch multiple times for different threads.

Two consecutive page access requests are temporally correlated in the sense that they may happen together in the future. The Δ values stored in the AccessHistory records the spatial locality in the temporally correlated page accesses. Therefore, the prefetcher utilizes both temporal and spatial localities of page accesses to predict future page demand.

The prefetcher is added as a separate control unit inside the kernel. While paging-in, instead of going through the default `swapin_readahead()`, we re-route it through the prefetcher's `do_prefetch()` function. Whenever the prefetcher generates the prefetch candidates, Leap bypasses the expensive request scheduling and batching operations of the block layer (`swap_readpage()`/`swap_writepage()` for paging and `generic_file_read()`/`generic_file_write()` for the file systems) and invokes `leap_remote_io_request()` to re-direct the request through Leap's asynchronous remote I/O interface over RDMA (§4.4).

4.3 Eager Cache Eviction

Leap maintains a circular linked list of prefetched caches (PrefetchFifoLruList). Whenever a page is fetched from remote memory, besides the kernel's global LRU lists, Leap adds it at the tail of the linked list. After the prefetch cache gets hit and the page table is updated, Leap marks the page as an eviction candidate. A separate background process continuously removes eviction candidates from PrefetchFifoLruList and frees up those pages to the buddy list. As an accurate prefetcher is timely in using the prefetched data, in Leap, prefetched caches do not wait long to be freed up. For workloads where repeated access to paged-in data is not so common, this eager eviction of prefetched pages reduces the wait time to find and allocate new pages - on average, page allocation time is reduced by 750*ns* (36% less than the usual). Thus, new pages can be brought to the memory more quickly leading to a reduction in the overall data path latency. For workloads where paged-in data is repeatedly used, Leap considers the frequency of access for prefetched pages and exempt them from eager eviction.

However, if the prefetched pages need to be evicted even before they get consumed (e.g., at severe global memory pressure or extreme constrained prefetch cache size scenario), due to the lack of any access history, prefetched pages will follow a FIFO eviction order among themselves from the PrefetchFifoLruList. Reclamation of other memory (file-backed or anonymous page) follows the existing LRU-based eviction technique by `kswapd` in the kernel. We modify the kernel's Memory Management Unit (`mm/swap_state.c`) to add the prefetch eviction related functions.

4.4 Remote I/O Interface

Similar to existing works [10, 32], Leap uses an agent in each host machine to expose a remote I/O interface to the VFS/VMM over RDMA. The host machine's agent communicates to another remote agent with its resource demand and performs remote memory mapping. The whole remote memory space is logically divided into fixed-size memory slabs. A host agent can map slabs across one or more remote machine(s) according to its resource demand, load balancing, and fault tolerance policies.

The host agent maintains a per CPU core RDMA connection to the remote agent. We use the multi-queue IO queuing mechanism where each CPU core is configured with an individual RDMA dispatch queue for staging remote read/write requests. Upon receiving a remote I/O request, the host generates/retrieves a slot identifier, extracts the remote memory address for the page within that slab, and forwards the request to the RDMA dispatch queue to perform read/write over the RDMA NIC. During the whole process, Leap completely bypasses the expensive block layer operations.

Resilience, Scalability, & Load Balancing One can use existing memory disaggregation frameworks [10, 32, 65] with respective scalability and fault tolerance characteristics and still have the performance benefits of Leap. We do not claim any innovation here. In our implementation, the host agent leverages the power of two choices [53] to minimize memory imbalance across remote machines. Remote in-memory replication is the default fault tolerance mechanism in Leap.

5 Evaluation

We evaluate Leap on a 56 Gbps InfiniBand cluster on CloudLab [3]. Our key results are as follows:

- Leap provides a faster data path to remote memory. Latency for 4KB remote page accesses improves by up to 104.04× (24.96×) at the median and 22.06× (17.32×) at the tail in case of Disaggregated VMM (VFS) (§5.1).
- While paging to disk, our prefetcher outperforms its counterparts (Next-K, Stride, and Read-Ahead) by up to 1.62× for cache pollution and up to 10.47× for cache miss. It improves prefetch coverage by up to 37.51% (§5.2).
- Leap improves the end-to-end application completion times of PowerGraph, NumPy, VoltDB, and Memcached by up to 9.84× and their throughput by up to 10.16× over existing memory disaggregation solutions (§5.3).

Methodology We integrate Leap inside the Linux kernel, both in its VMM and VFS data paths. As a result, we evaluate its impact on three primary mediums.

- *Local disks*: Here, Linux swaps to a local HDD and SSD.
- *Disaggregated VMM (D-VMM)*: To evaluate Leap's benefit for disaggregated VMM system, we integrate Leap with the latest commit of Infiniswap on GitHub [4].
- *Disaggregated VFS (D-VFS)*: To evaluate Leap's benefit for a disaggregated VFS system, we add Leap to our implementation of Remote Regions [10], which is not open-source.

For both of the memory disaggregation systems, we use respective load balancing and fault tolerance mechanisms. Unless otherwise specified, we use AccessHistory buffer size $H_{size} = 32$, and maximum prefetch window size $PW_{size_{max}} = 8$.

Each machine in our evaluation has 64 GB of DRAM and 2× Intel Xeon E5-2650v2 with 16 cores (32 hyperthreads).

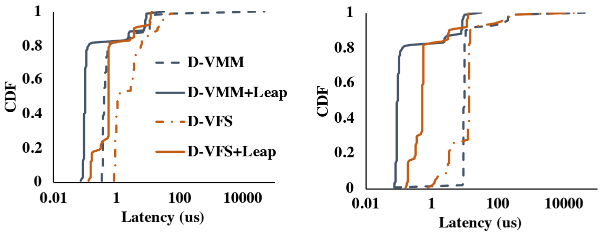
5.1 Microbenchmark

We start by analyzing Leap's latency characteristics with the two simple access patterns described in Section 2.

During sequential access, due to prefetching, 80% of the total page requests hit the cache in the default mechanism. On the other hand, during stride access, all prefetched pages brought in by the Linux prefetcher are unused and every page access request experiences a cache miss.

Due to Leap's faster data path, for **Sequential**, it improves the median by 4.07× and 99^{th} percentile by 5.48× for disaggregated VMM (Figure 7a). For **Stride-10**, as the prefetcher can detect strides efficiently, Leap performs almost as good as it does during the sequential accesses. As a result, in terms of 4KB page access latency, Leap improves disaggregated VMM by 104.04× at the median and 22.06× at the tail (Figure 7b).

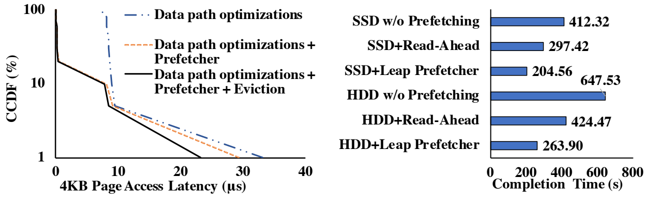
Leap provides similar performance benefits during memory disaggregation through the file abstraction as well. During sequential access, Leap improves 4KB page access latency by 1.99× at the median and 3.42× at the 99^{th} percentile. During



(a) Sequential

(b) Stride-10

Figure 7: Leap provides lower 4KB page access latency for both sequential and stride access patterns.



(a) Benefit Breakdown

(b) Prefetcher with Slow Storage

Figure 8: The prefetcher is effective for different storage systems.

stride access, the median and 99^{th} percentile latency improves by 24.96× and 17.32×, respectively.

Performance Benefit Breakdown For disaggregated VMM (VFS), the prefetcher improves the 99^{th} percentile latency by 25.4% (23.1%) over the optimized data path where Leap's eager cache eviction contributes another 9.7% (8.5%) improvement.

As the idea of using far/remote memory for storing cold data is getting more popular these days [9,32,45], throughout the rest of the evaluation, we focus only on remote paging through a disaggregated VMM system.

5.2 Performance Benefit of the Prefetcher

Here, we focus on the effectiveness of the prefetcher itself. We use four real-world memory-intensive applications and workload combinations (Figure 3) used in prior works [10,32].

- TunkRank [8] on PowerGraph [29] to measure the influence of a Twitter user from the follower graph [44]. This workload has a significant amount of stride, sequential, and random access patterns.
- Matrix multiplication on NumPy [57] over matrices of floating points. This has mostly sequential patterns.
- TPC-C benchmark [7] on VoltDB [70] to simulate an order-entry environment. We set 256 warehouses and 8 sites and run 2 million transactions. This has mostly random with a few amount of sequential patterns.
- Facebook's ETC workload [13] on Memcached [5]. We use 10 million SET operations to populate the Memcached server. Then we perform another 10 million queries (5%SETs, 95%GETs). This has mostly random patterns.

The peak memory usage of these applications varies from 9–38.2 GB. To prompt remote paging, we limit an application's memory usage through `cgroups` [2]. To separate the benefit of the prefetcher, we run all of the applications on disk (with existing block layer-based data path) with 50% memory limit.

5.2.1 Prefetch Utilization

We observe the benefit of Leap's prefetcher over following practical and realtime prefetching techniques:

- *Next-N-Line Prefetcher* [52] aggressively brings N pages sequentially mapped to the page with the cache miss if they are not in the cache.
- *Stride Prefetcher* [14] brings pages following a stride pattern relative to the current page upon a cache miss. The aggressiveness of this prefetcher depends on the accuracy of the past prefetch.
- *Linux Read-Ahead* prefetches an aligned block of pages containing the faulted page [72]. Linux uses prefetch hit count and an access history of size 2 to control the aggressiveness of the prefetcher.

Impact on the Cache As the volume of data fetched into the cache increases, the prefetch hit rate increases as well. However, thrashing begins as soon as the working set exceeds the cache capacity. As a result, useful demand-fetched pages are evicted. Table 2 shows that Leap's prefetcher uses fewer page caches (4.37–62.13%) than the other prefetchers for every workload.

A successful prefetcher reduces the number of cache misses by bringing the most accurate pages into the cache. Leap's prefetcher experiences fewer cache miss events (1.1–10.47×) and enhances the effective usage of the cache space.

Application Performance Due to the improvement in cache pollution and reduction of cache miss, using Leap's prefetcher, all of the applications experience the lowest completion time. Based on the access pattern, Leap's prefetcher improves the application completion time by 7.4–75.3% over Linux's default Read-Ahead prefetching technique (Table 2).

Effectiveness If a prefetcher brings every possible page in the page cache, then it will be 100% accurate. However, in reality, one cannot have an infinite cache space due to large data volumes and/or multiple applications running on the same machine. Besides, optimistically bringing pages may create cache contention, which reduces the overall performance.

Leap's prefetcher trades off cache pollution with comparatively lower accuracy. In comparison to other prefetchers, it shows 0.3–10.8% lower accuracy (Table 2). This accuracy loss is linear to the number of cache adds done by the prefetchers. Because the rest of the prefetchers bring in too many pages, their chances of getting lucky hits increase too. Although Leap has the lowest accuracy, its high coverage (0.7–37.5%) allows it to serve with accurate prefetches with a lower cache pollution cost. At the same time, it has an im-

	PowerGraph				NumPy				VoltDB				Memcached

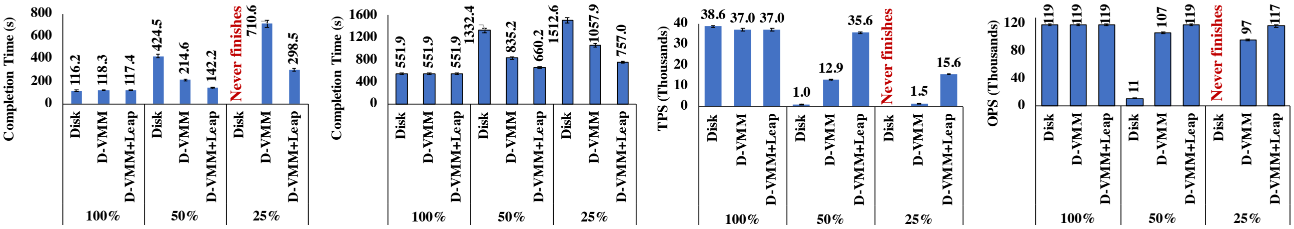
Table 2: Leap's prefetcher reduces cache pollution and cache miss events. With higher coverage, better timeliness and almost similar accuracy, the prefetcher outperforms its counterparts in terms of application level performance. Here, shaded numbers indicate the best performances.



(a) PowerGraph Completion Time **(b)** NumPy Completion Time **(c)** VoltDB Throughput **(d)** Memcached Throughput

Figure 9: Leap provides lower completion times and higher throughput over Infiniswap's default data path for different memory limits. Note that lower is better for completion time, while higher is better for throughput. Disk refers to HDD in this figure.

proved timeliness over Read-Ahead (4–52.6×) at the 95^{th} percentile. Due to the higher coverage, better timeliness, and almost similar accuracy, Leap's prefetcher thus outperforms others in terms of application-level performance. Note that despite having the best timeliness, Stride has the worst coverage and completion time that impedes its overall performance.

5.2.2 Performance Benefit Breakdown

Figure 8a shows the performance benefit breakdown for each of the components of Leap's data path. For PowerGraph at 50% memory limit, due to data path optimizations, Leap provides with single μs latency for 4KB page accesses up to the 95^{th} percentile. Inclusion of the prefetcher ensures sub-μs 4KB page access latency up to the 85^{th} percentile and improves the 99^{th} percentile latency by 11.4% over Leap's optimized data path. The eager eviction policy reduces the page cache allocation time and improves the tail latency by another 22.2%.

5.2.3 Performance Benefit for HDD and SSD

To observe the usefulness of the prefetcher for different slow storage systems, we incorporate it into Linux's default data path while paging to SSD. For PowerGraph, Leap's prefetcher improves the overall application run time by 1.45× (1.61×) for SSD (HDD) over Linux's default prefetcher (Figure 8b).

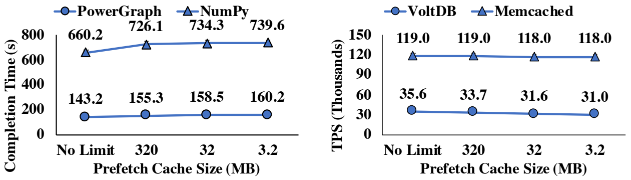
5.3 Leap's Overall Impact on Applications

Finally, we evaluate the overall benefit of Leap (including all of its components) for the applications mentioned in Section 5.2. We limit an application's memory usage to fit 100%, 50%, 25% of its peak memory usage. Here, we considered the extreme memory constrain (e.g., 25%) to validate the applicability of Leap to recent resource (memory) disaggregation frameworks that operate on a minimal amount of local memory [65].

PowerGraph PowerGraph suffers significantly for cache misses in Infiniswap (Figure 9a). In contrast, Leap increases the cache hit rate by detecting 19.03% more remote page access patterns over Read-Ahead. The faster the prefetch cache hit happens, the faster the eager cache eviction mechanism frees up page caches and eventually helps in faster page allocations for a new prefetch. Besides, due to more accurate prefetching, Leap reduces the wastage in both cache space and RDMA bandwidth. This improves 4KB remote page access time by 8.17× and 2.19× at the 99^{th} percentile for 50% and 25% cases, respectively. Overall, the integration of Leap to Infiniswap improves the completion time by 1.56× and 2.38× at 50% and 25% cases, respectively.

NumPy Leap can detect most of the remote page access patterns (10.4% better than Linux's default prefetcher). As a result, similar to PowerGraph, for NumPy, Leap improves the completion time by 1.27× and 1.4× for Infiniswap at 50% and 25% memory limit, respectively (Figure 9b). The 4KB page access time improves by 5.28× and 2.88× at the 99^{th} percentile at 50% and 25% cases, respectively.

VoltDB Latency-sensitive applications like VoltDB suffer significantly due to paging. During paging, due to Linux's slower data path, Infiniswap suffers 65.12% and 95.72% lower throughput than local memory behavior at 50% and 25% cases, respectively. In contrast, Leap's better prefetching (11.6% better than Read-Ahead) and instant cache eviction improves the 4KB page access time – 2.51× and 2.7× better 99^{th} percentile at 50% and 25% cases, respectively. However, while executing short random transactions, VoltDB has irregular page access patterns (69% of the total remote page



(**a**) Completion Time (**b**) Throughput

Figure 10: Leap has minimal performance drop for Infiniswap even in the presence of O(1) MB cache size.

accesses). At that time, our prefetcher's adaptive throttling helps the most by not congesting the RDMA. Overall, Leap faces smaller throughput loss (3.78% and 57.97% lower than local memory behavior at 50% and 25% cases, respectively). Leap improves Infiniswap's throughput by 2.76× and 10.16× at 50% and 25% cases, respectively (Figure 9c).

Memcached This workload has a mostly random remote page access pattern. Leap's prefetcher can detect most of them and avoids prefetching in the presence of randomness. This results in fewer remote requests and less cache pollution. As a result, Leap provides Memcached with almost the local memory level behavior at 50% memory limit while the default data path of Infiniswap faces 10.1% throughput loss (Figure 9d). At 25% memory limit, Leap deviates from the local memory throughput behavior by only 1.7%. Here, the default data path of Infiniswap faces 18.49% throughput loss. In this phase, Leap improves Infiniswap's throughput by 1.11× and 1.21× at 50% and 25% memory limits, respectively. Here, Leap provides with 5.94× and 1.08× better 99th percentile 4KB page access time at 50% and 25% cases, respectively.

Performance Under Constrained Cache Size To observe Leap's performance benefit in the presence of limited cache size, we run the four applications in 50% memory limit configuration at different cache limits (Figure 10).

For Memcached, as most of the accesses are of random patterns, most of the performance benefit comes from Leap's faster slow path. For the rest of the applications, as the prefetcher has better timeliness, most of the prefetched caches get used and evicted before the cache size hits the limit. Hence, during O(1) MB cache size, all of these applications face minimal performance drop (11.87–13.05%) compared to the unlimited cache space scenario. Note that, for NumPy, 3.2 MB cache size is only 0.02% of its total remote memory usage.

Multiple Applications Running Together We run all four applications on a single host machine simultaneously with their 50% memory limit and observe the performance benefit of Leap for Infiniswap when multiple throughput- (PowerGraph, NumPy) and latency-sensitive applications (VoltDB, Memcached) concurrently request for remote memory access (Figure 11). As Leap isolates each application's page access path, its prefetcher can consider individual access patterns while making prefetch decisions. Therefore, it brings more accurate remote pages for each of the applications and reduces the contention over the network. As a result, overall application-level performance improves by 1.1–2.4× over Infiniswap. To enable aggregate performance comparison, here, we present the end-to-end completion time of application-workload combinations defined earlier; application-specific metrics improve as well.

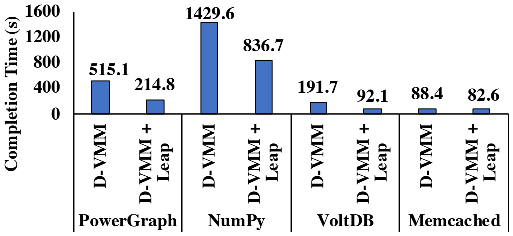


Figure 11: Leap improves application-level performance when all four applications access remote memory concurrently.

6 Discussion and Future Work

Thread-specific Prefetching Linux kernels today manage memory address space at the process level. Thread-specific page access tracking requires a significant change in the whole virtual memory subsystem. However, this would help efficiently identify multiple concurrent streams from different threads. Low-overhead, thread-specific page access tracking and prefetching can be an interesting research direction.

Concurrent Disk and Remote I/O Leap's prefetcher can be used for both disaggregated and existing Linux Kernels. Currently, Leap runs as a single memory management module on the host server where paging is allowed through either existing block layers or Leap's remote memory data path. The current implementation does not allow the concurrent use of both block layer and remote memory. Exploring this direction can lead to further benefits for systems using Leap.

Optimized Remote I/O Interface In this work, we focused on augmenting existing memory disaggregation frameworks with a leaner and efficient data path. This allowed us to keep Leap transparent to the remote I/O interface. We believe that exploring the effects of load balancing, fault-tolerance, data locality, and application-specific isolation in remote memory as well as an optimized remote I/O interface are all potential future research directions.

7 Related Work

Remote Memory Solutions A large number of software systems have been proposed over the years to access remote machine's memory for paging [1, 21, 23, 26, 32, 45, 46, 50, 55, 64, 65], global virtual machine abstraction [6, 25, 43], and distributed data stores and file systems [10, 22, 42, 47, 58]. Hardware-based remote access using PCIe interconnects [48] or extended NUMA memory fabric [56] are also proposed to disaggregate memory. Leap is complementary to these works.

Kernel Data Path Optimizations With the emergence of faster storage devices, several optimization techniques, and design principles have been proposed to fully utilize faster hardware. Considering the overhead of the block layer, different service level optimizations and system re-designs have been proposed – examples include parallelism in batching and queuing mechanism [16, 75], avoiding interrupts and context switching during I/O scheduling [12, 20, 74, 76], better buffer cache management [34], etc. During remote memory access, optimization in data path has been proposed through request batching [37, 38, 71], eliminating page migration bottleneck [73], reducing remote I/O bandwidth through compression [45], and network-level block devices [46]. Leap's data path optimizations are inspired by many of them.

Prefetching Algorithms Many prefetching techniques exist to utilize hardware features [33, 35, 66, 80], compiler-injected instructions [27, 40, 41, 60, 61], and memory-side access pattern [24, 54, 67–69] for cache line prefetching. They are often limited to specific access patterns, application behavior, or require specified hardware design. More importantly, they are designed for a lower level memory stack.

A large number of entirely kernel-based prefetching techniques have also been proposed to hide the latency overhead of file accesses and page faults [19, 24, 31, 39, 72]. Among them, Linux Read-Ahead [72] is the most widely used. However, it does not consider the access history to make prefetch decisions. It was also designed for hiding disk seek time. Therefore, its optimistic looking around approach often results in lower cache utilization for remote memory access.

To the best of our knowledge, Leap is the first to consider a fully software-based, kernel-level prefetching technique for DRAM with remote memory as a backing storage over fast RDMA-capable networks.

8 Conclusion

The paper presents Leap, a remote page prefetching algorithm that relies on majority-based pattern detection instead of strict detection. As a result, Leap is resilient to short-term irregularities in page access patterns of multi-threaded applications. We implement Leap in a leaner and faster data path in the Linux kernel for remote memory access over RDMA without any application or hardware modifications.

Our integrations of Leap with two major memory disaggregation systems (namely, Infiniswap and Remote Regions) show that the median and tail remote page access latencies improves by up to 104.04× and 22.62×, respectively, over the state-of-the-art. This, in turn, leads to application-level performance improvements of 1.27–10.16×. Finally, Leap's benefits extend beyond disaggregated memory – applying it to HDD and SSD leads to considerable performance benefits as well.

go-pmem: Native Support for Programming Persistent Memory in Go

Jerrin Shaji George* *VMware*

Abstract

Persistent memory offers persistence and byte-level addressability at DRAM-like speed. Operating system support and some user-level library support for persistent memory programming has emerged. But we think lack of native programming language support is an impediment to a programmer's productivity.

This paper contributes *go-pmem*, an open-source extension to the Go language compiler and runtime that natively supports programming persistent memory. *go-pmem* extends *Go* to introduce a runtime garbage collected persistent heap. Often persistent data needs to be updated in a transactional (i.e., crash consistent) manner. To express transaction boundaries, *go-pmem* introduces a new *txn* block which can include most *Go* statements and function calls. *go-pmem* compiler uses static type analysis to log persistent updates and avoid logging volatile variable updates whenever possible.

To guide our design and validate our work, we developed a feature-poor Redis server *go-redis-pmem* using *go-pmem*. We show that *go-redis-pmem* offers more than 5x throughput than unmodified Redis using a high-end NVMe SSD on memtier benchmark and can restart up to 20x faster than unmodified Redis after a crash. In addition, using compiler microbenchmarks, we show *go-pmem*'s persistent memory allocator performs up to 40x better and transactions up to 4x faster than commercial libraries like PMDK and previous work like Mnemosyne.

1 Introduction

At present, there is a large gap between the access latency for memory and storage hierarchy. The fastest tier of storage, e.g., SSDs, which provide persistence, can be 100x-1000x slower than DRAM, which are volatile and lose all their data on a power cycle. Applications carefully place their working set data in DRAM where the access latency is between 50-100ns, and every so often, perhaps under the guidance of the user via policies, save the data from DRAM to the storage tier. Over the past three decades, applications and operating systems have evolved to orchestrate this data movement in a highly efficient way.

Persistent memory (*pmem*) is a new type of random-access memory that offers persistence and byte-level addressability at DRAM-like access speed [19]. Intel© Optane™ DC Persistent Memory [12] is an example of a readily available persistent memory product. Persistent memory is now becoming increasingly available in servers [1]. Operating systems such as Linux have had support to use pmem as faster storage disks for some time now [6].

The obvious way to consume pmem is as a faster storage device (block mode access) by running an unchanged application on top of a file system. We demonstrate a significant improvement in the throughput of Redis when it is run on top of Linux ext4 filesystem using persistent memory as the block storage device. But, we were also able to show even further performance improvements with a Redis that was hand modified to use byte-addressable persistent memory for its in-memory database. Unsurprisingly, we were also able to show that a good bit of the application's I/O processing code that store the data from volatile DRAM to storage, can now be retired as data is being immediately persisted all over the application. So, using the byte-addressable mode of pmem delivers more performance than using it in block mode, and also lowers the overall complexity in the application code. We delve deeper into this in §2.

We argue that databases like Redis are fast and popular because they highly optimize the data structures used in volatile memory. However, applications must write these data structures into serial buffers for persistence and these optimizations are lost. With byte-addressable persistent memory, applications can directly persist and retrieve their data structures without serialization. And so, the main focus of this work is that we strive to make manipulating persistent memory similar to manipulating volatile memory.

Towards this, we contribute *go-pmem*, an open source extension to the popular Go programming language. go-pmem provides a familiar Go-esque programming model to the appli-

*Co-first authors ordered alphabetically cation developers to use persistent memory at byte-level granularity. We arrived at our current model by implementing a feature-poor implementation of Redis (*go-redis-pmem*) (§5.3) that directly uses byte-addressable pmem. With go-pmem, we contribute a programming model with the following design goals:

1. Single type system. No separate persistent types as in [18, 32].
2. Pointers remain unchanged, i.e., no fat pointers. A consequence of this is we implement pointer swizzling (§4.3.2).
3. Support two heaps, volatile and persistent: go-pmem extends Go runtime to manage pmem and uses pointers to identify objects in pmem.
4. Allow pointers both across and within the persistent and volatile heap, but make system safe across crash and recovery. To do this, go-pmem extends Go's garbage collector (GC) to work across both the heaps.
5. After restart, allow applications to retrieve back data stored in pmem by associating it with a string name. These are called named-objects (§4.4.1).
6. Allow transactional code blocks by requiring the user to demarcate these with a new Go *txn* keyword.
7. Reuse functions to operate on data in volatile or persistent memory.
8. Allow allocation and update of pmem resident data structures outside a transaction as long as they are not reachable from a *named object*. In case of a crash-and-recovery, go-pmem's GC will garbage collect such objects thus avoiding any persistent memory leaks.

In a set of microbenchmarks, we see that go-pmem performs up to 40x better than other pmem libraries languages. go-redis-pmem offers 5x more throughput than unmodified Redis on an SSD against memtier benchmark and restarts up to 20x faster than unmodified Redis. We explain our evaluation methodologies more in §6. To the best of our knowledge, ours is the first expansive effort to change Go to support persistent memory. In §5, we explain how Go's existing design features helped and challenged us towards our idea of supporting pmem.

go-pmem is developed from the Go 1.11 code base, and is fully open-sourced. Links to the respective repositories can be found at https://vmware.github.io/persistent-memory-projects/.

2 Background

To give more context into our work, we begin by asking why should anyone care about persistent memory?

2.1 Experiments with Redis

Over the years, a lot of work has gone into optimizing data intensive applications. To reduce the latency of data access, these applications keep frequently used data in DRAM, and flush the dirty data from DRAM to disks/SSD at certain well-defined points. For example, Redis [24] allows users to persist their data to disks/SSD in an append-only-file (AOF). But if no persistence mode is used, a crash at any point would cause all the in-memory data to be lost. If the user cannot afford any data loss at all, he has to write to the AOF file after each write request and as such sees significantly reduced throughput.

In all the experiments in this section, we run Redis in the zero data loss mode, as that is the fair way to compare with byte addressable persistent memory which provides zero data loss. To see the benefits of persistent memory, we now conduct the following experiment:

1. Use the memtier benchmark as the load generating input workload [25], configured to issue read-write requests in a 70:30 ratio.
2. Run unmodified Redis-3.2, in the following two modes:
   (a) saving the AOF on an SSD and
   (b) saving the AOF on a persistent memory device.
3. Run Redis-3.2 hand modified for byte-addressability taken from [11].

Figure 1 shows that just by running unchanged Redis on a pmem device as block storage, the throughput increases by up to 4x. This configuration gives a higher throughput owing to the inherent faster access time of persistent memory. Figure 1's *Pmem Block IO* curve confirms this. The third curve (PMDK-Redis) [11] shows the performance of a Redis server modified to write data to persistent memory used in byte-addressable mode. In fact, PMDK-Redis even outperforms Redis running on pmem as block-storage.

To understand this, we perform another experiment. We run unmodified Redis-3.2 once with AOF disabled and once with always-fsync-AOF option on *nullfsvfs* virtual file system [2]. This file system treats all read and write system calls to the storage media as no-ops. So the difference in performance is entirely due to serializing data in the application and the overheads in making system calls. This is the reason why in Fig. 2 Redis with AOF enabled on nullfsvfs is slower than Redis with AOF disabled. Because pmem is faster than SSD, the time spent accessing the device is significantly reduced and the overhead of the software stack become a significant portion of the overall application latency.

These two experiments convince us that using persistent memory can give significant throughput improvements in data intensive applications and that the most efficient way for applications to access persistent memory is through direct CPU load/store instructions bypassing any file-system/PCIe overheads. A more extensive study on persistent memory can be found in [37]. Since memory is accessed in 64-byte cache lines, the CPU reads only what it needs to read, instead of rounding every access up to a block size, like storage. Linux also allows persistent memory to be used in a direct-access (DAX) mode [6, 20, 21]. This mode allows users to mmap files in persistent memory into their virtual address space and access it through loads/stores, bypassing the OS page cache

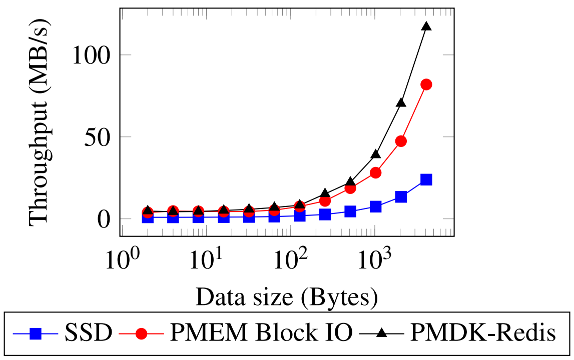

Figure 1: Redis throughput comparison against memtier

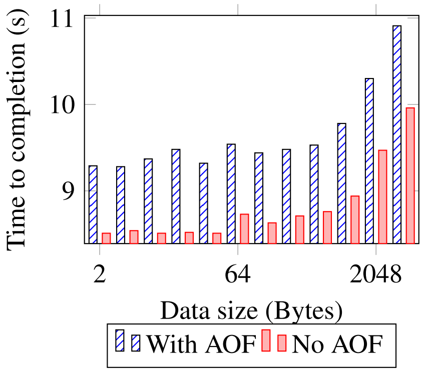

Figure 2: Redis-server runtime on nullfsvfs

and file systems. In the rest of this work, we use pmem in *byte-addressable* mode, unless we specifically mention block storage mode.

2.2 Why Change a Programming Language?

Hand porting applications to use byte-addressable pmem can introduce fragility in the code. Just think of a situation, where the developer misses to guard a single store to persistent memory within a transaction - the bug will be very difficult to discover. So, the next question is: how can the porting process be made easier? Ideally, any acceptable solution should have the following features:

1. Be similar to existing programming models.
2. Work transparently for systems not supporting persistent memory. I.e., we want to be able to write functions that can operate on data in persistent memory or volatile memory.
3. Fast execution time.

One approach is via ad hoc libraries. As we will discuss in §3 and §4, these libraries expose a programming model different than existing programming models for volatile memory. In particular, memory management becomes tricky and these solutions either don't provide a simple and complete programming model, or go through complicated steps to keep it simple. We argue that programming languages already manage volatile memory. So, persistent memory which is a special type of memory and is also byte-addressable, should also be managed by programming languages.

Such a language should at least provide:

1. Persistent memory allocations on heap
2. Garbage collection of persistent heap objects
3. Support modifying persistent memory in a crash-consistent way
4. Support recovery from crashes, i.e., include support for reverting inconsistent updates.
5. Not require offline processing of persistent data regions
6. Similar to existing programming models, for easier adoption.

2.3 Why Go?

We chose Go because it is a high-level managed language with an easily extendable runtime. Moreover, we use some of Go's design to our advantage. For example, we reuse Go's mark-and-sweep garbage collector to garbage collect pmem. Go uses static escape analysis to determine the scope of objects at compile time and intelligently places objects on the stack or the heap. We extend this to track accesses to volatile and persistent heap and prevent unnecessary pmem accesses. Additionally, the potential benefits of high-level languages are well understood. Automatic memory management in HLLs like Go reduce programmer effort and use-after-free bugs. These kinds of bugs are more dangerous with the use of pmem because any memory leak will survive crashes/restarts. Go's type-safety helped us to avoid special data types and invalid memory accesses. Go also has an active developer community with increasing adoption in systems community (e.g. popular software such as Kubernetes, Docker etc. are written in Go) and this fits well with our plan to open-source our changes.

3 Related Work

Most of the previous efforts to program persistent memory fall into two categories:

1. Ad hoc library to support pmem. This library usually allows special objects to be created/updated/destroyed in a crash-consistent way through special APIs [17, 18, 30].
2. Programming language enhancements to manage pmem and instrument user code with transactions [26, 27, 32, 45, 46].

In section 6, we compare go-pmem's performance with works in both categories, PMDK [18] (a library) and Mnemosyne [45], Makalu [26] (language changes).

Previous efforts often provide a new allocator for pmem and require the user to free memory allocated in pmem [7, 18, 26]. Either they don't handle leaks in persistent memory [45] or use special objects and data types to maintain reference counts [26, 30, 32] for garbage collection. Often they provide offline

Library (language)	Model	References	Transactions			Heap	
			Semantics	Implementation	Fn calls	Growth	Reloc.
go-pmem (Go)	Compiler support, Library	Direct pointers	Explicit - user tagged	Undo logs	Yes	Yes	Yes
PMDK [18] (C,C++)	Library	Fat pointers	Explicit - user tagged	Undo logs	Yes	No	Yes
Mnemosyne [45] (C)	Compiler support, Library	Direct pointers	Explicit - user tagged	Redo logs	No	No	No
Makalu [26] (C)	Library	Direct pointers	N/A	N/A	N/A	No	No
Atlas [27] (C)	Compiler support, Library	Direct pointers	Implicit - using locks	Undo logs	No	No	No
Autopersist [43] (Java)	Compiler, JVM support	Direct references	Explicit - user tagged Implicit - durable roots	Undo logs	Yes	No	No
Espresso [46] (Java)	Compiler, JVM support	Direct references	Explicit - user tagged	Persistent objects	Yes	No	No
iDO [38] (C,C++)	Compiler support	Direct pointers	Implicit - using locks	Atomicity via resumption	No	No	No
JUSTDO [36] (C,C++)	Library	Direct pointers	Implicit - using locks	Atomicity via resumption	No	No	No

Table 1: Table comparing features of various pmem libraries

tools to check pmem file for garbage [18, 26]. Some require that users must do pmem memory allocations within transactions [18]. To access data in pmem they usually provide fat pointers [18, 30] or allow direct pointers and ignore pointer swizzling [26, 46]. We did not find any previous work that handled growing persistent heap at runtime. In section 6.4.2 we discuss why this is important.

[31, 45] also provide concurrency through transactions. Of course, transactions for programming languages has been a well-researched topic [34]. However, we don't pursue transactions as a way of solving concurrency, but more from a point of view of crash-consistent/atomic updates while minimally getting in the way of Go's existing concurrency paradigms. In this regard, we are similar to [32, 43] but are more flexible (see section 4.5).

Similar to [27, 32] we use a modular SSA pass to inject undo transaction logging statements to user code. But unlike [32] we do not ask the user to provide special pragmas for faster execution. We believe these optimizations complicate the programming model. We also allow function calls within transactions unlike [45] and want the functions to be reused for persistent and volatile data.

Another design point is how to demarcate the transactional code block. For example, Atlas [27] uses existing locks and constructs a happens-before graph to determine order of logs and updates. Autopersist [43] on the other hand, is quite different. Like go-pmem, they allow users to explicitly demarcate transactional code blocks. But, they also allow users to write normal Java code and when they point to a volatile data from a pmem root, Java runtime moves the transitive closure of the volatile data to pmem transactionally. go-pmem allows updates to pmem-resident objects outside transactions as long as they are not pointed to by a named object.

So far, most of these efforts have been confined to C, C++ with some work in Java [17, 43, 46] and OpenJDK [15]. There have been calls for these programming languages to support persistent memory [4] but we don't know of any concrete changes yet. Table 1 presents a concise summary comparing the features of various pmem libraries. *Fn calls* captures whether the transaction semantics allows function calls inside a transaction. *Heap Growth* indicates whether the library supports a growable heap design and *Heap Reloc.* states if the library supports relocating the pmem heap on an application restart.

4 Design

The design of go-pmem is driven mainly by two considerations:

1. The changes should be accepted to the Go language. This translated to reusing existing Go compiler techniques and keeping our changes to a minimum.
2. Provide a familiar programming model to developers

that has a minimal interface and is congruent with the existing Go infrastructure. This would help in easier acceptance and adoption by the Go community.

4.1 Programming Model

Listing 1 shows how to add a new node to a linkedlist resident in pmem using go-pmem. We have highlighted how this is different than normal Go code adding a node to a linkedlist in volatile memory. Memory in pmem is allocated using *pnew*, similar to Go's *new* and all updates are made transactional using codeblock *txn("undo")*. We argue that this is very similar to how Go code is written today. How we managed to get a programming model like Listing 1 is discussed in the rest of this section.

```
package main
import "pmem"            // <-
import "transaction"     // <-

// add new node to tail; return new tail
func addNode(tail *node) *node {
  n := pnew(node)        // <-
  txn("undo") {          // <-
    mutex.Lock()
    n.prev = tail
    updateTail(tail, n)
    mutex.Unlock()
  }                      // <-
  return n
}

func updateTail(tail, n *node) {
  txn("undo") {          // <-
    tail.next = n
  }                      // <-
}
```

Listing 1: Add node to a linkedlist in pmem

4.2 Language Constructs

We have added two new APIs to Go semantics to support persistent memory allocations:

```
func pnew(Type) *Type
func pmake(t Type, size ...IntType) Type
```

Just like new [8], *pnew* creates a zero-value object of the Type argument in pmem and returns a pointer to this object. The *pmake* API is used to create a slice in pmem. The semantics of pmake is the same as the make API in Go.

4.3 Runtime Design

Go runtime uses datastructures such as mcache, mspan, mcentral, mheap, etc. to store the metadata related to the heap. A span is a contiguous region in memory (one or more pages) from which the allocator allocates similar-sized objects. mspan stores metadata about a span. mcache is used to cache spans at a thread level. If an allocation request can be satisfied using the cached span, then it can be done so without acquiring any locks, making such allocations very fast. If not, a new span is obtained from the mcentral or mheap. mcentral is a central store of small spans (object size <= 32K) and mheap is a central store of freed spans and large spans.

The heap is managed in arenas of size 64MB. Each arena data-structure stores the following metadata:

1. Span table - Span table is an array that holds a reference to the mspan object corresponding to that virtual page index.
2. Heap type bitmap - The heap type bits are used by the GC to identify what regions in memory have pointers in them. The GC uses these bits while walking the heap. The heap type bits corresponding to an object is set by the allocator when it allocates that object.

Linux exposes pmem to applications as a file. Byte-level load/store access to pmem is available once a pmem file has been mmap'd to an application's address space [33]. We do all this in Go runtime and abstract these out through a Go package called *pmem*. We have incorporated a simple approach to enabling pmem support in Go - one with minimal changes to the design of the existing memory allocator and garbage collector (GC). Rather than make all the runtime data-structures crash-consistent, we log additional metadata to keep track of allocated regions. This saves us from extensive code changes that would have been necessary in the runtime and aids in the implementation of a robust design. A novelty of our approach is the minimal amount of additional metadata that we log.

4.3.1 Growable Heap Design

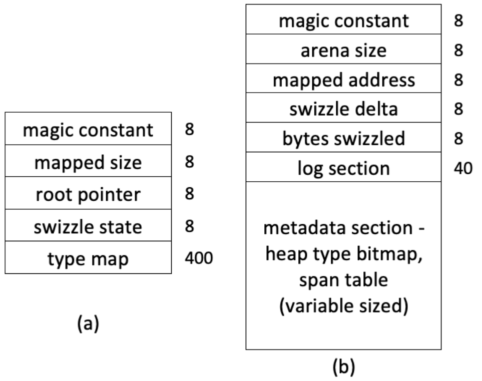

Figure 3: (a) pmem file header (b) arena header layout. Storage space in bytes adjacent to each field.

The runtime maps the pmem file into memory in arenas of sizes that are a multiple of 64MB. Figure 3(a) shows the layout of the global header stored in the beginning of the pmem file. *magic constant* is an 8-byte random number which helps to distinguish between first and subsequent initialization of persistent memory. *mapped size* is the size of the file currently mapped. *root pointer* is used to store the pointer to the application named objects (§4.4.1). *swizzle state* is used for implementing pointer swizzling (§4.3.2). *type map* is used to cache a fixed number of data types which are the most frequently allocated, helping pmem allocations of such types to be completed significantly faster (§5.1.5).

Each arena is divided into two sections - the arena header section and the region managed by the allocator. Figure 3(b) shows the layout of the header section in each arena. *arena size* is the size of the arena and *mapped address* stores the address at which the arena is currently mapped. *swizzle delta* and *bytes swizzled* help to implement the pointer swizzling algorithm. The *log section* helps to implement a minimal undo log in runtime which is used only during swizzling. The *metadata section* stores the runtime metadata for this arena as mentioned in §5.1.3. Whenever runtime runs out of persistent memory space, the persistent memory file is grown to accommodate a new arena. The metadata in the global header is updated in a consistent manner to reflect the addition of this new arena.

4.3.2 Pointer Swizzling

Pointer swizzling is a powerful feature that allows direct pointers to be stored in persistent memory and dereferenced, even after multiple invocations of the application. Since persistent memory is exposed through files mapped into memory, the virtual address of the mapping can change during each invocation. In the common scenario, go-pmem is able to map arenas at the same address, avoiding the need to swizzle pointers. If the mapping address changes, then all pointers stored in the pmem heap becomes garbage. Pointer swizzling is the process of 'fixing' these pointers by re-writing them with their new mapped address. Some libraries such as PMDK work around this problem by using a *base, offset* pair object as a reference to an object in persistent memory. Dereferencing such an object involves a hashmap lookup and offset computation which can get expensive.

Swizzling is done during pmem initialization in a per-arena manner. The algorithm uses the *swizzle delta* field in arena header to store the offset by which pointers that point into this arena should be changed. *bytes swizzled* help track how many pointers have already been swizzled. The *log section* in the arena help update pointers transactionally. The swizzling algorithm is resilient to crashes during swizzling. If a crash occurs, any partially executed swizzling is completed on the next run, before swizzling all pointers to the new mapped address. go-pmem uses a parallelized algorithm to swizzle pmem arenas. As an added advantage, the swizzle algorithm also implements pointer safety. On application restart, any pointer stored in the pmem heap that point outside the pmem heap are garbage. The swizzle algorithm zeroes out any such pointers to ensure applications do not access such rogue pointers. This gives users the freedom to store both pmem and volatile pointers in the pmem heap.

4.4 Restarting After a Crash/Exit

Our design currently handles graceful exits and non-corrupting failures. Listing 2 shows code starting/recovering from a crash. We provide a *pmem* package that handles initializing pmem and restarts.

```
package main
import "pmem"
func init() {
  firstInit := pmem.Init("database")
  var head *node
  if firstInit {
    // Create a named object called root
    head = (*node)(pmem.New("root", head))
  } else {
    // Retrieve the named object "root".
    // One-line restart!
    head = (*node)(pmem.Get("root"), head)
  }
}
```

Listing 2: Code for start/restart of application

4.4.1 Roots/Named Objects: pmem Package

Any data in volatile memory is lost on restart, so volatile pointers pointing to data in pmem will be lost too. This means only pointers residing in pmem pointing to data in pmem can be used to access pmem-resident data after a restart. We allow the applications to retrieve these pointers through string names. These can then be used to navigate other objects stored in pmem. We call these objects *"named objects"* and they can be pointers to native types, structs, or Go slices. Any updates to these named objects must be made through *pmem* package APIs as shown in Listing 2.

4.5 Transactions as a Part of Go: txn Block

To make sure no data is left in an inconsistent state, we use transactions. We change Go compiler to natively support undo transactions. We pursue transactions in Go with the intention of providing crash consistency and durability for updates to data in pmem. We introduce a new keyword to Go called *txn* that automatically intercepts stores to pmem and logs them in an undo log. We add a new SSA (Static Single Assignment) pass to Go compiler's backend that injects statements to Go's intermediate representation of the user code. Our design is derived from a similar technique used in Go compiler to add write barriers for garbage collection to stores in volatile heap [14]. Our new *LogStore* SSA pass comes after most of the existing Go SSA passes, so we don't lose on the existing optimizations. For example, successive stores to a pmem resident location can be eliminated by Go's *deadstore elimination* SSA pass even after our changes.

To demarcate transactions, we require users to contain their code within a *txn("undo")* code block. The *"undo"* indicates we currently support automatic code generation only for undo logging. We briefly discuss how we provide typical transaction properties below.

1. Atomicity: The *pmem.Init()* call (see Listing 2) initializes pmem and reverts any incomplete updates stored in the transaction logs of an application in case of a restart.
2. Consistency: We rely on the user to explicitly demarcate updates to pmem-resident data by using a txn block around the code.
3. Isolation: Simultaneous transactions accessing common data must not see any updates till a transaction is committed. We do not support isolation through software transactional memory but rely on programmers to use Go's mutex locks for critical sections. Our concurrency model is simple:
   (a) All the locks acquired within a transaction must be released within the transaction.
   (b) All the locks acquired outside a transaction must be released outside the transaction.

   Our design then makes sure that all the updates to shared data structures are visible only at the end of a transaction. This is achieved by delaying unlocking any locks acquired within a transaction until the end of the transaction. This is similar to the 2PL locking strategy used in database transactions [40].
4. Durability: All the changes made to data in pmem are made durable at the end of a transaction by flushing relevant data stored in the processor caches or buffers.

```
 1  // txn block of addNode()
 2    tx.Begin()        // <-
 3    mutex.Lock()
 4    tx.Log(&n.prev)  // <-
 5    n.prev = tail
 6    updateTail(tail, n)
 7    tx.End()          // <-
 8    mutex.Unlock()   // <- generated after End()
 9
10  // txn block of updateTail()
11    tx.Begin()        // <-
12    if inPmem(&tail.next) { // <- extra check
13      tx.Log(&tail.next)     // <-
14    }                        // <-
15    tail.next = n
16    tx.End()          // <-
```

Listing 3: Compiler generated code for listing 1.

We point out a couple of limitations that our locking model introduces -

1. Multiple *lock()* and *unlock()* operations on the same lock do not work inside a *txn* block.
2. Holding all locks taken inside a transaction until the end of the transaction can make lock-based critical sections in go-pmem slower than other models such as Atlas [27] that allow dependent transactions to run concurrently (as soon as required locks get unlocked). In order to provide isolation, they capture transaction dependency between multiple threads in their logs.

Listing 3 shows the compiler generated code of the `txn{}` code block in listing 1. Additional code added by the compiler to ensure transactional semantics is highlighted. Line 8 of listing 3 shows how a mutex unlock is delayed until the end of the transaction. go-pmem also allows function calls within a transaction, as explained further in §5.2.2.

4.6 No Persistent Data Types

go-pmem intentionally does not introduce new data types. Previous works have often introduced data types like *pint*, *p<int>* or *persistent int*. They usually do this because they offer a library implementation and overload the assignment operator [18] or they want type-safety, reference counting etc. for pmem resident data [32]. We believe this complicates the programming model and instead rely on Go's in-built typesafety and garbage collection.

5 Implementation

go-pmem adds about 4000 lines of code and removes 300 lines of code from Go runtime, excluding code documentation. This does not include the code in the CPUID package from Intel [10] that is used by runtime to identify CPU features for flushing CPU caches. The two Go packages (pmem and transaction) took close to 2300 lines of Go code. These changes were made on top of Go 1.11 release and don't include the code for testing these changes. Our implementation currently works only for 64-bit Linux 4.15 and above.

5.1 Runtime Details

5.1.1 Data Structure Support

To support persistent memory allocations, runtime datastructures such as the mspan, mcache, mheap, mcentral were extended to store persistent memory metadata. The mspan structure was augmented to identify if this is a pmem span or volatile memory span. Similarly, mcache, mcentral, and mheap were doubled in size to store pmem spans separately. It should be noted that no Go runtime data-structures are stored in pmem. Instead, minimal additional metadata is logged in pmem arena header to capture pmem state.

5.1.2 Memory Allocation

A persistent memory allocation request results in the following workflow - if a cached pmem span is available in the mcache with a free slot, it is used to satisfy the allocation request. Otherwise, a new pmem span is requested from the mcentral/mheap. If no pmem span is available, a new pmem arena is mapped to memory. The required span is then carved out from the pmem arena to satisfy the allocation request. Any required metadata is also logged (§5.1.3). An advantage of the go-pmem allocator is that these steps can be done without invoking transactions. This is because any pmem leaks are plugged by the GC during heap recovery (§5.1.4).

5.1.3 Metadata Logging

The metadata that is logged is the minimum amount of information that the runtime needs to reconstruct the memory allocator and garbage collector state on the subsequent execution of the application. The benefits of keeping the metadata to a minimum are twofold: we do not need to introduce complex transactions in the runtime to maintain consistency and the allocator performance is only slightly affected due to the additional logging.

Two kinds of runtime metadata are logged. The first is the GC heap type bits. Whenever the allocator sets heap type bits for a pmem object, it is also logged in the pmem arena header section. Like its volatile memory representation, heap type bits occupy 2 bits for every 8 bytes of heap data. In §5.1.5 we talk about an optimization that helps avoid heap type bitmap logging for frequently allocated data-types. The second is the span table. The span table captures information such as which spans are in use and the size class of the span. Span table logging happens when a new span is created by the allocator or freed up by the GC. Span table reserves 32 bits for every pmem page in the arena (Go uses a page size of 8KB). For a 64MB pmem arena, the arena header section occupies 2024KB, and 63512KB is available for the allocator. The arena section includes 80 bytes for the header, 31756 bytes for the span table and 1984.75KB for the heap bitmap, making the pmem arena memory overhead as 3.09%.

5.1.4 Reconstruction

All runtime data structures related to memory allocator and garbage collector are stored in volatile memory. So, if an application crashes, all state information is lost. *Reconstruction* is the term used in our project to denote the process of bringing back the state of the memory allocator and garbage collector related to persistent memory as it was before the crash. The additional metadata stored in pmem aids in this *reconstruction* process. No persistent memory data is modified during reconstruction. Hence the reconstruction process is resilient to any crashes that happen while it is ongoing. Briefly, *reconstruction* works as following:

1. GC is disabled until *reconstruction* finishes so that it does not interfere with the *reconstruction* process.
2. Spans are recreated using the logged span metadata table.
3. The logged heap type bitmap is copied as-is to the arena metadata in volatile memory.
4. Pointers are swizzled, if necessary
5. GC is re-enabled

GC walks the *reconstructed* pmem heap starting from the named root objects. It marks all reachable objects as being in-use, and makes any leaked pmem objects available for reuse. This GC walk runs in the background, making the *reconstruction* process execute quickly.

5.1.5 Using Go's Typesystem to Optimize Pmem Allocations

An allocation of an object that has pointers in it results in the allocator setting the heap type bits for it. If this is a pmem object, these type bits are also logged in the pmem arena header. If a datatype is heuristically found to be a frequently allocated type, then that type is promoted to be cached specially in mcache to speed up allocations of such objects. The heuristic used is the following - the number of allocations of such an object has exceeded the number of slots available in a span corresponding to this object sizeclass and its allocation frequency is greater than 100 objects per second. A span specially so cached is used only to allocate objects of one type. This makes it possible that the heap type bits be logged only for the first object allocated, making further allocations from this span very fast. We employ the typemap (§4.3.1) in the global header to store what types have been specially promoted. Our design supports promoting up to 50 types to be specially cached. In our experience, the maximum number of types frequently allocated by various pmem applications were far fewer. Each type is represented in the typemap section in the pmem header using an 8-byte identifier, making typemap occupy a total of 400 bytes.

5.1.6 Undo Log Implementation

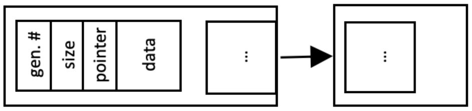

Figure 4: Undo log design

Undo logs are stored within a linked list of Go's byte arrays. Each undo log entry has the layout as shown in figure 4. *gen.#* stores current undo log generation number. On a successful abort/commit, the *generation number* is bumped up to mark all entries as no longer valid. *size* stores the size of the data logged. *pointer* is the address at which this data originally resided. *data* contains the logged copy of the data. Since we do not anticipate a transaction abort in the common case, log entries are populated using *movnt* instructions so that data is directly moved to the pmem device bypassing the processor cache.

We also employ a number of optimizations to make logging fast in go-pmem:

1. Empty transactions do not incur any runtime overhead as no cache flushes or memory fences are issued.
2. Logging the same object multiple times incur minimal overhead. We maintain a map to track what objects have already been logged.
3. As byte arrays are very common in Go, we specially optimize logging 1-byte data. We try to pack consecutive 1-byte data objects in a single log entry rather than create separate entries for each.

5.1.7 Working Around Go's GC to Optimize Undo Logging

Go uses a mark-and-sweep GC. It scans the heap in a breadth-first fashion, traversing the heap through the live pointers it finds. The scan starts from the pointers found in goroutine stacks and global variables. We want objects pointed at from the logged data to be kept alive until the transaction completes. But since data is logged in a byte-array, runtime no longer has the type information of each data item logged. Our initial logging library used Go's reflect package which gave a poor performance, so we decided to use Go's byte arrays. To identify pointers in the byte array, whenever a data is logged, all pointers within this data item is stored separately in an array of pointers residing in volatile memory. This ensures that GC finds these pointers while traversing the heap.

5.1.8 Cache Flushing

Data written to persistent memory can be guaranteed to be persistent only after they are flushed from the processor cache to the persistent memory media. The runtime provides the PersistRange API to flush the processor cache over the address range passed to it.

```
func PersistRange(addr unsafe.Pointer, len int)
```

If the persistent memory device supports direct-access, this function takes care of executing the most optimized cache flush instruction supported on the processor (such as clwb, clflushopt, or clflush) and any necessary memory barriers [42]. If the device does not support direct-access, then *PersistRange* invokes the msync system call to flush data at a page size granularity. Transactions in go-pmem automatically call into the runtime to flush data from the caches, freeing the programmer from having to do it manually.

5.2 LogStore SSA Pass

The LogStore SSA pass can automatically interpose stores to persistent memory and redirect this to an undo transaction. The user can wrap any codeblock with a *txn("undo")* keyword and engage this new SSA pass. In the absence of any txn block, this SSA pass does not do anything. Because we wanted to keep the changes to a minimum, this SSA pass can be plugged into/out of the Go compiler's usual workflow.

5.2.1 Handling Volatile Memory Access Inside Transactions

Go uses escape analysis [28] to figure out life time of variables, and thereby avoids unnecessary memory allocations to volatile heap. We extend this to avoid unnecessary allocations to persistent heap and track pointers in volatile heap. With this static analysis, we know the probable location of an update within the transaction. If this update can be proven to be a location in volatile memory, we do not do anything. Otherwise we store the current value of the data in a persistent log which will be replayed in case of a crash.

5.2.2 Handling Function Calls Inside Transactions

Go compiles each function independently and cannot know if this method will be called from a transaction, or a non-transactional code at compile time. Instead of cloning the function for transactional access, we maintain a per Go-routine handle and ask the user to wrap any potentially transactional code within a txn code block. Based on whether a transaction is already ongoing or not, we intelligently start a new transaction or continue the same transaction at runtime. In case this function is called from a non-transactional code, the function simply operates on volatile data without any side effects. Using the techniques mentioned in §5.2.1 we try to keep the performance overhead to minimum in this case.

5.3 Implementing Go-redis-pmem

We implement a multithreaded feature-poor redis server called *go-redis-pmem* written using go-pmem. *go-redis-pmem* currently supports storing/retrieving string KV pairs in pmem and can run traffic generated from memtier benchmark. It currently has 6800 lines of code across 11 files and 360 functions. As we were implementing go-redis-pmem, we realized that as the applications become complicated it becomes increasingly difficult to keep track of exactly which variables and pointers are in persistent memory. Our desire to support function calls and ability to reuse functions for data in volatile and persistent memory was driven by the implementation of go-redis-pmem and the ease this offered to the programmer.

5.4 Limitations

go-pmem is a work in progress and will continue to evolve as we gain more experience in programming applications for persistent memory. Below, we enumerate the current limitations of go-pmem:

1. No support for shrinking persistent heap file after they have grown. We believe an offline application working like a compacting garbage collector can fix this.
2. No support for allocating/transactionally using Go's maps or channels in pmem. go-pmem currently supports basic Go types, structs, and Go slices.
3. No support for working with multiple persistent heaps
4. No support for operating systems other than 64-bit Linux.
5. No support for redo/custom implementation of transactions with the txn code block.
6. We do not handle the case when there are traditional I/O operations (like network, display, etc.) inside a transaction and then there is a crash. Previous works have handled this by throwing an exception [34] and by providing safe IO [44]. We can do something similar.

6 Evaluation

We use the benchmarks from Computer Language Benchmarks Game (CLBG) [5] as the microbenchmarks to compare the performance of our memory allocator and transactions.

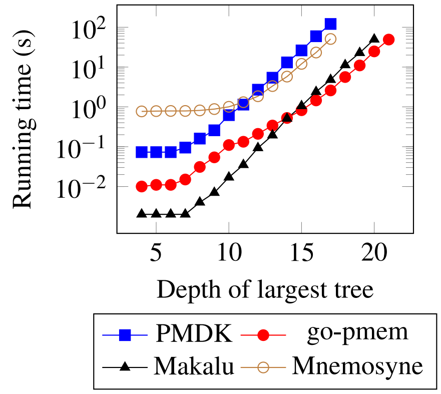

Figure 5: Runtime as depth of largest tree changes

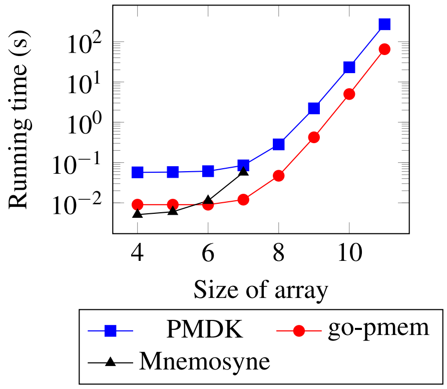

Figure 6: Runtime as num. of permutations in fannkuch-redux changes

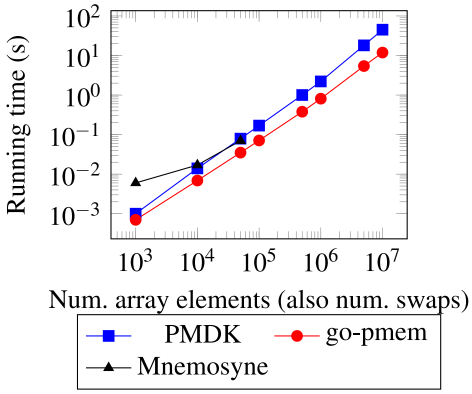

Figure 7: SPS Benchmark: Overhead of transactions

CLBG has gained wide attention for comparing the performance of different programming languages [39]. Go has also used some of these benchmarks to optimize their implementation in the past [23]. We extend some of these benchmarks to test how they perform when run on pmem, and don't focus on others as they test other language features such as arithmetic precision, hashtable performance etc. which is not our focus here. To test multicore scalability of go-pmem, we use the microbenchmarks from the Phoenix suite [41]. The phoenix suite was originally written to evaluate the MapReduce model for multi-core systems. We use the *pthread* version of these benchmarks to port to various pmem libraries. We also compare the performance of *go-redis-pmem* with other Redis implementations. In these evaluations, we ensure there is no remote persistent memory traffic by keeping only one CPU socket on. We compare our work against PMDK stable version (1.7 release commit *bc5e30948*) and we write code in C++ using C++ bindings from PMDK (stable version 1.8 commit *ab4ff69b7*) [22]. The Mnemosyne examples build on implementation code from [7] and Makalu examples run on implementation code from [16].

6.1 Experimental Setup

Our system is a 24-core Intel Cascade Lake machine with hyperthreading disabled and only one socket to avoid remote pmem traffic. It has 4 Intel© Optane™ DC Persistent Memory Module, each of 128GB, and 64GB of DRAM. In all the runs, the deviation observed across runs was <2%. We report the average runtime across 3 runs.

6.2 Change in Compile Time

The compilation time of Go source code increased by 3.4% (from 42.71s to 44.16s) because of all our changes to Go compiler. In the compilation of go-redis-pmem (which has 6800 lines of code and 11 files), we did not see any noticeable difference in the compile time with and without the new ssa pass. The difference was <1% (0.71s vs 0.713s). These numbers were obtained for a fresh compilation with go's build cache cleaned. With the build cache enabled, the observed difference was even smaller (less than 1ms).

6.3 Memory Allocator Performance

The Binary Tree allocator microbenchmark from CLBG stresses the pmem allocator by creating several perfect binary trees. One of these stresses memory to see maximum memory available. One is a long-lived binary tree and there are several short-lived trees which are created and then deallocated. Figure 5 compares the performance of go-pmem's pmem allocator to PMDK, Mnemosyne and Makalu. We note that because go-pmem can garbage collect pmem we did not have to free any tree nodes. Makalu and go-pmem do not write to pmem for each new allocation and so are at least an order of magnitude faster than PMDK and Mnemosyne. PMDK must do all allocations and deallocations within a transaction and performs the worst.

6.4 Performance of Transactions

6.4.1 Long Running Transactions

We use *fannkuch* from CLBG and *sps* to model programs with a long-running transaction. *Fannkuch* takes a byte array of size *n* and shuffles around elements for all *n!* permutations of this array. We model all this to happen inside a single transaction. This lends it the behavior of a long running transaction. We also noticed that both PMDK and go-pmem use undo logs and maintain minimal state in pmem (only the oldest value of the array) whereas Mnemosyne uses redo log and quickly starts to use a lot of pmem. The *sps* microbenchmark has been used previously [30, 31] to report throughput of transactions. *sps* randomly performs swaps between entries of an integer array. The number of these swaps is equal to the number of elements. We change the number of elements in this array from 1k to 10 million and do all the swaps within one single transaction. So unlike *Fannkuch*, the size of data being operated on also increases as the transaction becomes longer. Figures 6 and 7 compare the running time of *Fannkuch*

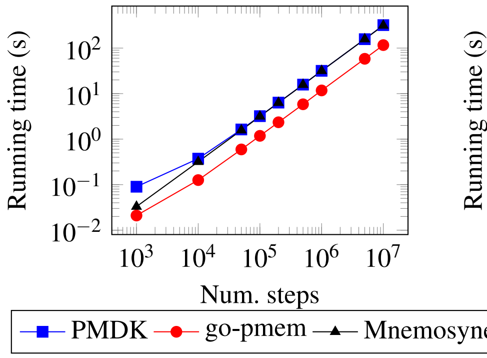

Figure 8: n-body: Runtime as num. of steps a planet moves varies

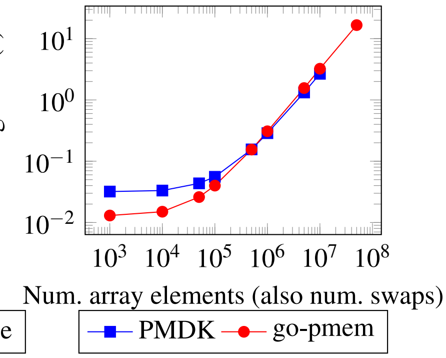

Figure 9: Tx recovery time after abort at the last swap

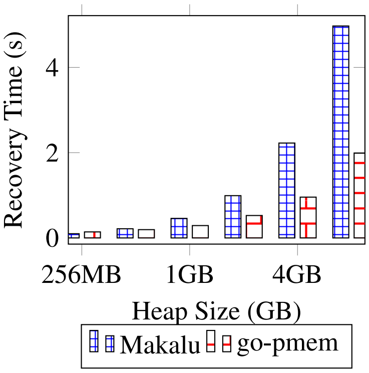

Figure 10: Restart time comparison using fill-heap

and *sps* for PMDK, Mnemosyne and go-pmem. We note that Mnemosyne curves stop early as the public implementation does not support large amounts of data within a transaction. Similar results for Mnemosyne were reported in [31]. The PMDK curves stop early as the default PMDK implementation does not allow creating a pmem file of 2GB or larger. For both these cases, we consistently outperform PMDK by 3-4x as the transactions become larger.

6.4.2 How Much Data do Applications Store to pmem?

We also want to highlight that the existing programming models are inept for long-running applications like the ones we model above. PMDK asks the user to specify the pmem file size at the beginning. It crashes if this size is exceeded. Mnemosyne always creates a pmem file of fixed size. We think it is very difficult to predetermine the pmem capacity that commercial applications will use. With the ability to grow pmem heaps (§4.3.1), our programming model is more flexible.

6.4.3 Several Short Transactions

We use *n-body* microbenchmark from CLBG to model a program with several short transactions. For short transactions, the overhead in setting up the transactions is not amortized, and we try to capture this overhead here. n-body models the orbits of planets using an algorithm. The input is the number of steps that the planets move from a starting point and the output is the new coordinates of the planets. We change one step movement of the planets to be one transaction. Figure 8 shows the running time as we vary the number of small transactions. go-pmem consistently performs 2-3x faster than PMDK and Mnemosyne even as the number of small transactions in the application increase to 10 million.

6.5 Multicore Scalability

We run all 7 benchmarks from the Phoenix 2.0 suite [41] to evaluate how go-pmem scales on multithreaded benchmarks. We modified these benchmarks to keep the data manipulated by each thread in pmem. Figure 13 captures the relative running time of PMDK compared to go-pmem. All benchmarks use 24 threads and run on the largest input configuration provided by Phoenix. Unlike PMDK and go-pmem, Mnemosyne stores more data in its redo logs and we were not able to get it running on any of these benchmarks. go-pmem scales much better than PMDK on all benchmarks other than *linear regression*. *Linear regression* stores very little data on pmem and incurs minimal transactional overheads. The benchmark *kmeans* uses 2D arrays in pmem and is significantly slower for PMDK. PMDK uses fat pointers and accessing 2D arrays requires multiple indirections. Although figure 13 shows results with 24 threads, we ran the benchmarks varying the number of threads from 2 to 24. The results with different thread counts are similar to the results shown in figure 13.

6.6 Restart Time Comparison

6.6.1 Undo Transaction Recovery Time After a Crash

We reuse *sps* benchmark from §6.4.1 to measure time spent by undo transactions in PMDK and go-pmem to revert back to consistent application state. We change the number of integers swapped in *sps* and crash at the last integer swap. Figure 9 shows go-pmem performs at par with PMDK when the amount of data to recover is less but gets slower by 20% as the amount of data to recover increases. We have not optimized the recovery path too much as this is not the common path. One obvious optimization is to store application data in cacheline aligned chunks. This will reduce the number of writes to pmem when we write back the consistent data during restart. Optimizing this path without affecting the performance of common cases remains on our future agenda.

6.6.2 Restart Time of Persistent Heaps

We use *fill-heap* benchmark from Makalu [26] to compare the restart time as the size of the persistent heap changes. *fill-heap* creates 64-byte objects to fill up a specified heap size. It makes half of these objects reachable from the pmem root objects. On restarting the *fill-heap* application, we measure the time taken by go-pmem, PMDK, and Makalu to recover

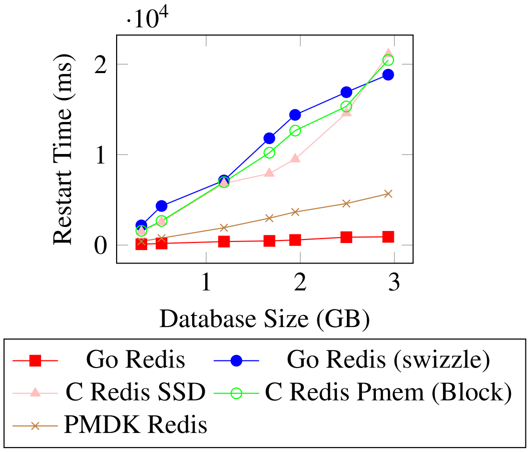

Figure 11: Comparing restart time of various Redis versions

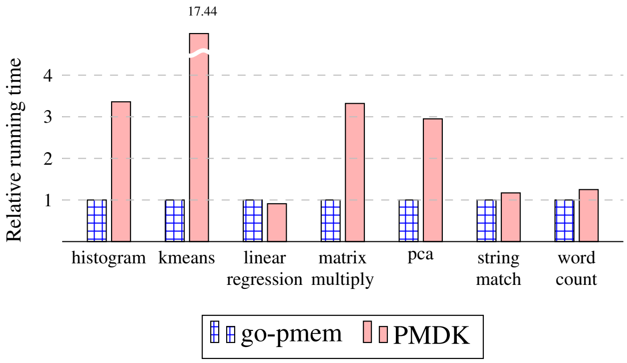

Figure 13: Relative comparison on Phoenix benchmarks

the pmem heap. As seen in figure 10, go-pmem recovers the pmem heap much faster than Makalu as Makalu has to go through an expensive offline GC phase. PMDK recovers almost instantaneously, because their allocator is inherently transactional, and hence incurs minimal startup cost.

6.6.3 Restart Time of Redis Variations

To measure how go-pmem heap's recovery fares on a pmem application, we compared the restart time of go-redis-pmem against various other Redis configurations as shown in figure 11. Go Redis swizzle measures the cost of swizzling pointers by force mapping all arenas at a different address than where it was originally mapped. C Redis SSD persists its data as an AOF file on SSD, whereas C Redis Pmem block persists the AOF file on pmem used in block IO mode.

6.7 Go Benchmarks

We run a set of 4 macro-benchmarks used by Go community to monitor Go performance regressions as new features are added to the compiler [9]. These benchmarks stress the memory allocator, GC, compiler, etc. Table 2 compares performance of go-pmem versus Go-1.11 upon which our changes are based on. Our changes add little to no performance difference in these benchmarks.

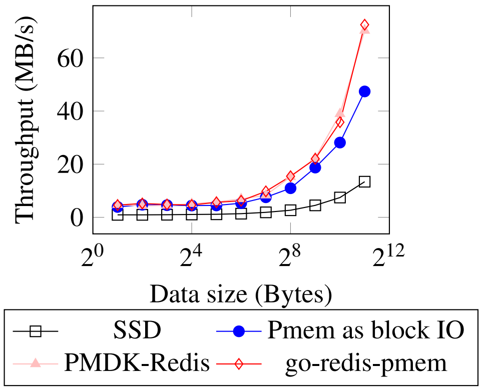

Figure 12: Redis throughput comparison against memtier benchmark

Benchmark	go-1.11	go-pmem	delta
Build-24	23.9s	23.9s	0%
Garbage-64	23.4ms	23.6ms	0.87%
JSON-24	84.0ms	84.3ms	0.44%
HTTP-24	73.9μs	75.5μs	2.15%

Table 2: Go benchmark comparison

6.8 Go-redis-pmem

Figure 12 shows the throughput of go-redis-pmem on the same memtier benchmark used in figure 1. Even though go-redis-pmem is multithreaded this configuration uses one client thread for a fair comparison. We can see that go-redis-pmem matches the performance of pmdk-redis reconfirming our observation that if applications use persistent memory in byte addressable mode, they will perform the best. In data not shown here, we did see that go-redis-pmem performed better than pmdk-redis and redis-3.2 when there are multiple client threads because it is multithreaded.

7 Conclusion

In this work, we presented go-pmem, an opensource extension to the Go language that allows programmers to develop pmem applications in Go. go-pmem is a natural extension of Go for pmem support, following the normal idioms of the Go language. We present a simple programming model and demonstrate its effectiveness by developing a feature-poor Redis equivalent key-value store in Go.

Abstract

To ensure low-latency memory allocation, mobile operating systems kill applications instead of swapping memory to disk. This design choice shifts the burden of managing over-utilized memory to application programmers, requiring them to constantly checkpoint their application state to disk. This paper presents Marvin, a new memory manager for mobile platforms that efficiently supports swapping while meeting the strict performance requirements of mobile apps. Marvin's swap-enabled language runtime is co-designed with OS-level memory management to avoid common pitfalls of traditional swap mechanisms. Its key features are: (1) a new swap mechanism, called *ahead-of-time (AOT) swap*, which pre-writes memory to disk, then harvests it quickly when needed, (2) a modified bookmarking garbage collector that avoids swapping in unused memory, and (3) an object-granularity working set estimator. Our experiments show that Marvin can run more than 2x as many concurrent apps as Android, and that Marvin can reclaim memory over 60x faster than Android with a Linux swap file can allocate memory under memory pressure.

1 Introduction

Over the past decade, mobile apps have become bigger and more complex [28], far outpacing increases in mobile device memory [4]. This trend has increased memory pressure on mobile operating systems as apps compete for limited space. Going forward, mobile OSes must more efficiently share memory across demanding apps, or user experience will suffer.

Unfortunately, while mobile apps have become more sophisticated, mobile memory management remains in its infancy. Today's popular mobile OSes set a fixed upper bound on memory for each running application (e.g., 1.4GB for iOS running on an iPhone X [36] and 512MB for Android running on a Google Pixel XL). They never overcommit memory; instead, they kill running applications and restart them later.

This simplistic approach worked well when mobile apps were small and largely stateless. However, it is unsustainable as mobile OSes replace desktop ones (e.g., Android is now the most used OS in the world) and mobile apps replace desktop counterparts (e.g., Google Docs and Word Online replacing Microsoft Word). Today's apps already do not fit into their memory allocation, so they manually swap objects between memory and local storage or use libraries to meet their needs [11]. Because apps are increasingly likely to be killed due to memory pressure, they must also continuously save execution state to disk and strive to minimize their start-up times to cope with frequent restarts. Despite significant engineering effort [21, 27, 32], it still takes several seconds to kill and restart popular apps.

Improving mobile memory management is difficult. Mobile apps run in high-level language runtimes (e.g., Swift, ART), which limit OS insight (e.g., working set estimation is impossible) and are notoriously difficult for OS-level memory managers to work with [20]. Further, mobile apps often allocate large amounts of memory quickly (e.g., when starting, or for cloud downloads); unless the OS keeps a large pool of free memory, this is easier to accommodate by killing entire applications. Finally, touch-based interfaces impose strict latency requirements, which swapping to disk cannot meet.

In this paper, we improve mobile memory management with a key observation: unlike other operating systems, mobile OSes run all of their apps in a *common* language runtime. For example, all apps running on Android must run in the Android Runtime (ART). This difference lets us co-design the language runtime to assist the mobile OS in optimizing memory management instead of hindering it. Due to its knowledge of memory usage, the language runtime becomes an ideal place for mechanisms that can better manage memory.

This paper demonstrates the value of leveraging the runtime for OS tasks. We present *Marvin*, a new memory manager for Android that efficiently supports memory overcommit. Marvin implements most memory management in the language runtime, which has more insight into an application's memory usage. Marvin relies on the operating system only for cross-application resource allocation.

By integrating with the language runtime, Marvin can offer

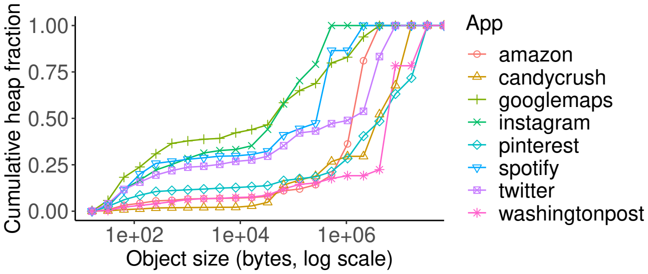

Figure 1: CDF of object size and heap percentage occupied by objects that size or smaller.

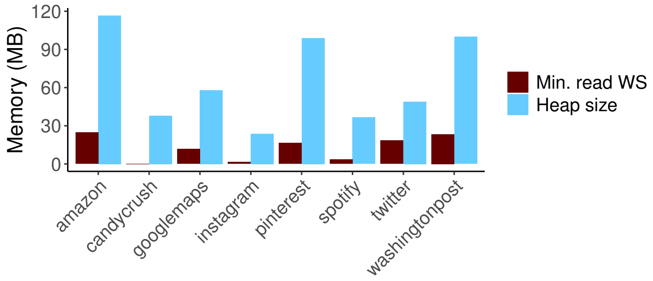

Figure 2: *The cost of fixed allocation.* Each bar shows the total Java heap size of a popular app alongside its minimum Java working set during active use.

three new features that enhance memory management:

- A new swap mechanism, which performs *ahead-of-time* swapping to disk to avoid synchronous disk writes when reclaiming memory, and which leaves checkpointed objects in memory (unlike Linux's kswapd [18]).
- A new object-level working set estimator, which separates garbage collector (GC) and app accesses, and avoids false sharing with object-level access tracking.
- A new bookmarking garbage collector [20], which tracks exact liveness data without accessing swapped-out objects.

We implement a prototype of Marvin by modifying the interpreter and compiler of the Android Runtime (ART). Experiments show that our Marvin prototype is able to run more than 2x as many concurrent apps as Android, and that Marvin can reclaim memory over 60x faster than Android with a Linux swap file can allocate memory under memory pressure.

2 Limitations of Modern Mobile OS Memory Resource Management

Although mobile OSes may be based on traditional OSes (e.g., Android and Linux), they diverge in two important ways: (1) for each app, they bound memory usage to a fraction of physical memory (e.g., 512MB on a 4GB device), rather than letting apps allocate as much memory as they need, and (2) they kill applications when physical memory runs out rather than overcommitting memory through paging or other mechanisms. To motivate our work, we ran experiments with popular apps that show the reasoning and cost for these design decisions. We ran all experiments on a Pixel XL phone with 4GB RAM and a quad-core Qualcomm Snapdragon 821 CPU.

2.1 Fixed Memory Allocation

Mobile OSes have poor insight into app memory usage. The runtime garbage collector regularly touches all objects and moves objects for heap compaction, and the OS cannot distinguish this activity from app accesses. Mobile apps also access language-level objects, which vary in size, while the OS can only track memory accesses at page granularity. To understand the impact of object-level accesses on page-sized access tracking, we measured the size of objects in popular apps. Figure 1 shows a CDF of the size distribution. Most objects are not page-sized (e.g., up to 40% of objects are smaller than 4KB), so the OS cannot accurately track their usage.

Without good insight into app memory usage, today's mobile OSes allocate all apps a fixed memory budget. On Android, this memory limit is the same whether an app is in the foreground or background. Android attempts to minimize the memory footprint of apps using techniques such as forking all apps from a single "zygote" process with copy-on-write pages. These techniques reduce duplication of framework data structures and shared libraries but do not impact application objects in the Java heap. Using Marvin's object-level working set estimator, we measured the working set of popular apps. Figure 2 shows that although the heap footprint of these apps is large, their working sets actually account for a small fraction of their total heap size. This rarely accessed memory would be better utilized keeping other apps alive, rather than wasting space not being used.

Popular apps often have large memory footprints but small working set sizes because they cache as much as possible from the cloud. This caching improves performance, but it leads to poor memory utilization, and choosing the correct cache parameters is difficult [30]. Worse, modern applications frequently exceed their memory budgets. Coping with this problem requires apps to implement manual swap-to-storage, which adds significant programming complexity [10, 11]. While caching libraries like Glide [5] and Fresco [34] are helpful, they do not apply to all memory objects. Therefore, today's apps use a complex combination of libraries and manually shuffling data between memory and disk.

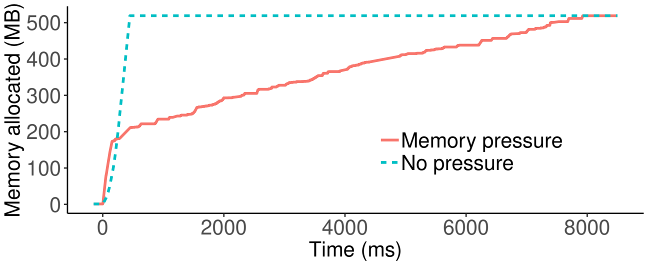

Figure 3: Progress over time of a memory allocation on Android with a swap file and memory pressure vs. no memory pressure.

2.2 No Memory Overcommit

Today's mobile OSes kill applications rather than swapping to disk when physical memory runs out. They take this approach because mobile apps must respond to user input within hundreds of milliseconds, so traditional swap mechanisms, which place synchronous disk writes on the critical path, impose too much latency. To measure the effect of swapping on memory allocation, we enabled a Linux swap file on our Android test device [35], and we measured the amount of time required to allocate 512MB when the Android OS had free memory and when it had a swap file and memory pressure. Figure 3 shows the progress of the memory allocation over time. With memory available, the OS allocated all 512MB in 450ms; however, with a swap file and memory pressure, it took almost 8 seconds for the OS to allocate the same amount. Such high allocation latency would be unacceptable if an app were allocating memory in response to user input.

Unfortunately, killing and restarting apps comes at a cost. As shown in Figure 2, modern apps have large memory footprints, and a restarted app must fetch all of its cached data from the network or disk. We measured the amount of time needed to restart popular apps and compared it to that needed to fetch their entire checkpointed memory image from disk. As shown in Figure 4, restarting apps takes 4-27x longer than fetching the all of the app's memory from disk.

The ability to kill and restart apps at any time also imposes a programming burden on app developers. Modern OSes give apps a limited time budget to perform cleanup before being killed. This limit leads apps to constantly write state to storage; in fact, Android encourages it [9]. Such constant checkpointing in response to app lifecycle events adds programming complexity, a challenge described in prior work [14]. Not only do app developers have to manage the checkpointing process, they have to correctly use a variety of mechanisms to do so with good performance [12]. The programming effort required to prepare for unexpected app deaths is an additional cost that app developers must pay.

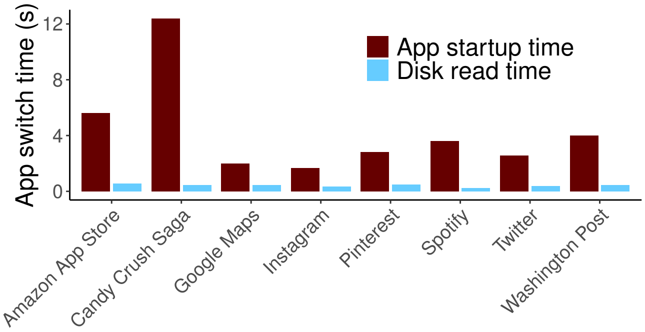

Figure 4: The cost of re-starting apps compared to reading their memory image from disk.

3 Our Approach

The primary barrier to improving memory resource management in mobile operating systems is the OS's lack of insight into the language runtime. To overcome this barrier, we *co-designed* the language runtime and the mobile OS. Mobile operating systems are uniquely suited to such co-design because, unlike their desktop counterparts (e.g., Linux), they force all applications to use the same language runtime.

Marvin's design focuses on Android (and the Android Runtime (ART)), which is now the most popular OS in the world [25]. Using the language runtime, Marvin manages memory entirely at object granularity, tracking, reclaiming and faulting in entire objects. This section describes in more detail the barriers to better memory resource management in a mobile OS and how Marvin addresses those challenges.

3.1 Object-Level Working Set Estimation

The first step to better memory resource management is a better understanding of each application's working set. Thus, Marvin implements language-aware working set estimation in the language runtime, which tracks app reads and writes at object granularity. Marvin uses this mechanism to identify candidates for ahead-of-time swap (Section 3.2) and separate garbage collector accesses from app accesses (Section 3.3). Lacking hardware access bits to help with this tracking, Marvin implements software access tracking in both the ART interpreter and compiler, as modern mobile language runtimes run both interpreted and compiled code.

3.2 Ahead-of-time Swap

As noted, swapping to disk when the OS needs memory is not feasible for mobile OSes and their touch-based apps. Marvin takes a different approach. While traditional swapping mechanisms write to disk when memory is needed, Marvin uses a new *ahead-of-time* swap technique. This technique saves memory to disk *before* it is needed and then reclaims those pages under memory pressure. Ahead-of-time swap separates swapping to disk from reclaiming memory; thus, we distinguish between *saved* objects, which have been copied to disk but still reside in memory, and *reclaimed* objects, which no longer reside in memory but are only on disk.

Swapping objects before they are needed leaves a large pool of clean memory that the OS can quickly reclaim and reallocate. While this technique lets apps continue using memory until the OS reclaims it, whenever the app dirties a page, the swap mechanism must update the on-disk copy before the OS can reclaim it. Due to this trade-off, Marvin prioritizes swapping objects that are infrequently or never written.

3.3 Bookmarking Garbage Collector

Like traditional swapping, ahead-of-time swapping is affected by friction with the language-level garbage collector. As noted by Hertz et al. [20], the garbage collector can inadvertently page in memory when walking the object heap to look for unused objects. With ahead-of-time swapping, the garbage collector can also inadvertently dirty pages when updating references, causing unnecessary writes to disk. Marvin solves this problem by integrating a modified bookmarking garbage collector [20] into the Android Runtime.

Marvin's swap mechanism leaves *stubs* – analogous to bookmarks – for each reclaimed object that detail the objects' references to other objects. Using these stubs, its garbage collector can process a reclaimed object during a mark-and-sweep run without faulting in the entire swapped object. Marvin's swap mechanism can further optimize swapping from disk by dropping dead objects without faulting them in.

4 Marvin Overview

Marvin is a new mobile memory manager that supports flexible memory allocation between apps and memory overcommit through swapping. Marvin includes components in the language runtime and OS, which are co-designed to provide better memory management. This section overviews both.

4.1 Design Goals

Marvin's design meets the following goals:

1. **Fast memory allocation.** Marvin must allocate memory quickly on-demand, avoiding disk accesses on the critical path for memory allocation.

2. **High memory utilization.** Marvin must provide the illusion of unlimited memory, provided working sets do not exceed the size of physical memory.

3. **Minimal overhead.** Marvin must impose low runtime overhead and require no app code changes.

While the last two goals are common to all memory management systems, existing mobile platforms sacrifice high memory utilization for fast memory allocation. Marvin aims to achieve all of these goals.

4.2 Marvin System Model

Marvin assumes a systems environment that meets three requirements: (1) all apps are written in a single managed language (e.g., Java), (2) all apps run in a single managed language runtime (e.g., ART), and (3) the runtime performs garbage collection or some form of automatic memory management. Marvin's design targets Android, which meets all of these requirements. Android also runs some libraries using native code; however, Marvin is not needed to manage their memory because they do not have the same issues with OS-level memory management as managed languages.

Marvin's optimizations could apply to other operating systems as well (e.g., iOS). For example, Swift uses automatic reference counting as an alternative to garbage collection, so it would require a bookmarking reference counter that can track references without faulting in the entire object.

Marvin runs unmodified Android apps on ARM64-based devices. Android distributes apps in a bytecode format called DEX. ART runs DEX bytecode directly in an interpreter and also compiles DEX to native ARM64 instructions both at install time (ahead-of-time, or AOT, compilation) and at runtime (just-in-time, or JIT, compilation). Marvin modifies both the interpreter and compiler.

4.3 Marvin Architecture

Marvin has two key components: (1) the *Marvin Kernel* (MK), a modified Android/Linux kernel, and (2) the *Marvin Runtime* (MRT), a modified ART. Most memory management occurs in MRT; it performs working set estimation, ahead-of-time swapping, and bookmarking garbage collection. MK's sole responsibility is to balance memory allocation among apps by deciding when and from which app to reclaim memory.

Marvin performs working set estimation and swapping at object granularity; however, there is no CPU support for object-level access bits and memory faults. As a result, Marvin implements software object access tracking and faulting in the MRT interpreter and compiler. The interpreter marks access bits and checks for swapped-out objects as it runs DEX bytecode; the compiler inserts that functionality as additional ARM64 instructions. Marvin reserves four bytes in each object header and uses them to store swapping metadata and access bits. Implementing these features in software imposes overhead, which we quantify in Section 8. Hardware improvements in future mobile devices could reduce this overhead.

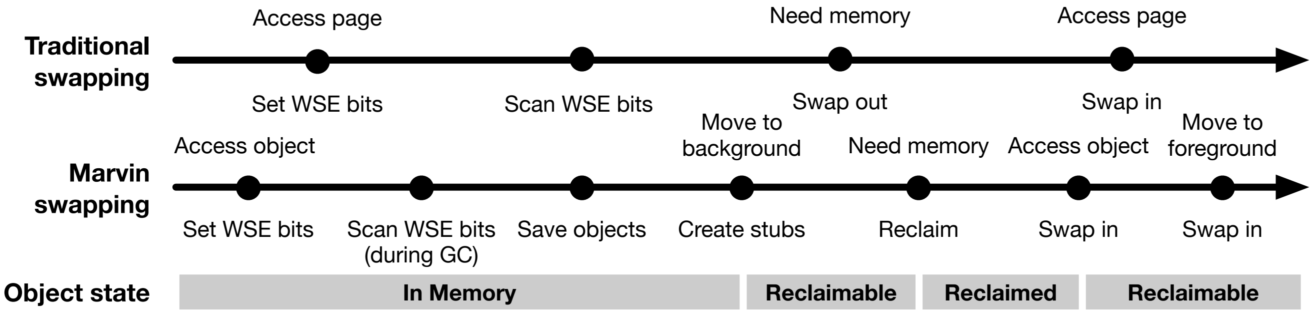

Figure 5: A timeline of actions performed by Marvin's swap mechanism as compared to traditional (e.g., Linux) swap mechanisms. Events are listed above the timeline while Marvin's actions in response are listed below.

4.4 Marvin Memory Management Timeline

Objects managed by Marvin move through several states over time, driven by app behavior and app lifecycle events. Figure 5 illustrates these events and states and compares Marvin's swapping to a traditional swap mechanism. When an app first starts, MRT begins tracking its working set. It identifies objects that are suited for swapping by examining whether they are cold (have not been read or written recently by the app). MRT begins saving checkpoints of those objects to disk in the background. We refer to an object with a saved checkpoint as a *saved* object.

When the app moves from foreground to background, MRT pauses app threads and creates stubs, small proxy objects that add a layer of indirection over swap candidate objects. Stubs ensure that Marvin can intercept accesses to objects and fault them back in, if necessary. Once MRT creates a stub for an object, that object becomes *reclaimable*; the object is still memory-resident, but MK can reclaim its memory at any time. When MK reclaims an object, it enters the *reclaimed* state; only the object's stub remains in memory, and the object's checkpoint will need to be faulted back into memory before the object can be accessed again. The garbage collector uses only the stub and need not fault the object back into memory.

5 Marvin Core Mechanisms

As noted in Section 3, Marvin's key features are ahead-of-time swap, language-aware working set estimation, and bookmarking garbage collection. Designing these features required addressing three challenges: adding a layer of indirection for object references, coordinating between the OS and runtime, and interposing on object accesses. This section describes Marvin's mechanisms for addressing these challenges.

5.1 Stubs for Object Reference Indirection

According to the Java language specification, object references are opaque. However, in practice, object references in the Android Runtime are direct pointers to the heap memory holding the referenced object. This design requires Marvin to inject a layer of indirection to implement features like software object faulting and the bookmarking garbage collector. Marvin creates this layer of indirection using special objects, called *stubs*. Each stub contains a pointer to its underlying object along with a copy of each reference held by the object. All references to an object point instead to its stub, and only the stub holds a pointer to its underlying object. Accessing an object through a stub adds overhead, so Marvin creates stubs only for objects that are cold and at least 2KB in size.

When creating a stub for an object, Marvin moves the object to a separate page-aligned region of memory and then redirects all references to the object to point to its stub instead. These tasks require that all app threads be paused. Therefore, they can be performed more efficiently if Marvin can create stubs for many objects at once, using a single scan of the heap to redirect all affected references. As a result, Marvin periodically executes a heap task that pauses all app threads and creates stubs, and it executes this heap task only when the app is in the background and its threads can be safely paused. Stubs are only created once for each object, so the cost is low, especially because Marvin does not restart apps frequently.

5.2 Reclamation Table for OS-Runtime Coordination

Modern mobile platforms have multicore processors that let system services run concurrently with apps. In this environment, the OS should be able to reclaim memory quickly from a running app without scheduling the app's threads for execution. However, the OS cannot simply seize memory from an app whose threads are not scheduled—a pointer to the memory in question may be present in an app thread's stack or registers, waiting to be used as soon as the thread is scheduled once again. As a result, the OS and runtime need a way to coordinate concurrent accesses to objects so the OS does not try to reclaim one that the runtime is accessing.

Marvin uses a shared-memory *reclamation table* to provide this coordination. MRT populates the table with reclaimable objects, and MK uses it to identify memory to reclaim. Each reclamation table entry is a small, fixed-size data structure that holds the address of an object, its size, a set of flags indicating whether the object is memory-resident and the entry is valid, and a set of bits used for locking by the runtime and OS. To reclaim an object, MK first acquires an exclusive lock on the object's reclamation table entry. Similarly, whenever an app thread prepares to access an object, MRT acquires a shared lock on the reclamation table entry.

The reclamation table is necessary because it provides an agreed-upon location that MK can quickly scan to identify reclaimable objects. If the metadata in the reclamation table were instead stored inside the stubs themselves, then MK would need to scan MRT's entire Java heap to identify reclaimable objects, and stub headers would need to contain a magic number or provide some other way for the kernel to recognize them.

5.3 Object Access Interposition

All of Marvin's features require the runtime to interpose and perform specific tasks whenever an app accesses an object. On every object access, MRT must set read and write bits for working set estimation; check for the presence of a stub and redirect the object access through the stub if necessary; and fault in the object if it has been reclaimed. It must also set a dirty bit whenever an object is modified so the ahead-of-time swap mechanism knows which objects need to be saved, and it must update stubs whenever reference member variables in their corresponding objects change to support the bookmarking garbage collector.

Android apps execute both as DEX bytecode running in an interpreter and as compiled native code running directly on the hardware, and Marvin must interpose on all object accesses in both kinds of code. As a result, Marvin features a set of paired interpreter and compiler modifications that add the required object access interposition. For each additional task performed by the interpreter when it accesses an object, there is a corresponding change to the compiler, adding assembly instructions performing the same task to compiled code.

6 Marvin Memory Management

This section describes how we use Marvin's mechanisms (stubs, the reclamation table, and object access interposition) to design the features that make up Marvin's memory management system.

6.1 Working Set Estimation

MRT performs object-granularity working set estimation by maintaining two access bits in each object header, a read bit and a write bit, and scanning those access bits.

Setting access bits. MRT uses object access interposition to set an object's read and write bits whenever that object is read or written from either interpreted or compiled code. It avoids including garbage collector reads in its working set estimation by setting a flag in the object header when the garbage collector is visiting an object and leaving the read bit untouched if that flag is set.

Access tracking in MRT is performed on a best-effort basis to minimize its overhead: MRT uses non-atomic operations with relaxed memory ordering semantics when setting read and write bits. As a result, concurrent reads and writes to the same object could result in a lost update to one of the access bits. An update to the read bit could also be lost if an app thread reads an object that the garbage collector is processing. These optimizations may decrease swapping performance if the estimated and actual working sets differ significantly, but they do not affect correctness.

Scanning access bits. MRT periodically walks the heap and uses the Clock algorithm [8] to track each object's long-term usage. Each object header holds two four-bit *shift registers*, one for reads and the other for writes. The time between heap walks constitutes an access-tracking "round," and each shift register tracks whether the object was read or written in the last four rounds. During a heap walk, MRT updates an object's shift registers and then clears the object's access bits.

MRT piggybacks off of garbage collection to scan access bits, since GC requires walking the heap anyways. Some of ART's GCs only walk subsets of the heap, so MRT limits its access bit scanning to full-heap collections. It also periodically invokes GC to ensure up-to-date working set estimates in the absence of app activity.

Producing the working set. As MRT walks the heap and scans access bits, it tabulates the app's working set. Our current MRT implementation considers an object part of the working set if it has been written within the last four access-tracking rounds. The precise policy is an implementation detail that can be easily changed.

6.2 Ahead-of-Time Swapping

In Marvin's ahead-of-time swap mechanism, MK reclaims objects and decides which apps to target for reclamation. MRT performs all other functions, including saving object checkpoints to disk, restoring reclaimed objects, and preventing the operating system from reclaiming objects in use by app code.

Saving objects to disk. MRT identifies suitable objects for swapping (i.e., cold objects) using its working set estimation feature, and it proactively saves checkpoints of them to a swap file on disk so they can be reclaimed quickly under memory pressure. MRT saves objects to disk in a periodic heap task that runs on a background thread concurrently with app code.

After app code modifies an object, MRT must save an updated copy of that object to disk. It does not need to save the updated copy immediately as long as it prevents the kernel from reclaiming the object while it is "dirty." To do so, MRT maintains a *dirty bit* in the object header. It uses object access interposition to set this dirty bit whenever app code writes to an object, and its object-saving heap task clears this dirty bit when saving the object to disk. MK checks dirty bits when looking for objects to reclaim and avoids reclaiming dirty objects. MRT and MK use strong memory-ordering semantics when reading and writing the dirty bit to ensure that no modifications to objects are lost.

MRT begins saving swap candidate objects to disk even before those objects have had stubs created for them. Once MRT creates a batch of stubs, those objects become immediately reclaimable without requiring further disk I/O.

Reclaiming objects. MK selects apps to target for reclamation and reclaims objects from the MRT instances corresponding to those apps. It never targets the foreground app, in order to avoid any swapping delays on the foreground app's user interface (UI) thread. After selecting an MRT instance to target, MK scans the MRT instance's reclamation table until it finds an entry for an object that is neither dirty nor locked by the runtime. MK then locks that entry and reclaims the object's pages. It continues scanning the reclamation table and reclaiming objects until it has harvested the desired amount of memory from the MRT instance.

Each MRT instance ensures that MK does not reclaim an object currently being accessed by its app code. To do so, it uses object access interposition to detect whenever a reclaimable object is being read or written, and it locks the object's reclamation table entry before the access and unlocks its entry after the access.

Restoring objects. MRT restores reclaimed objects either eagerly or on-demand. Either way, whenever MRT restores an object, it locks the object's reclamation table entry, copies the saved checkpoint data of the object into memory, and copies any modified references from the object's stub into the object itself. This last step is necessary because references in the stub may have been modified by the garbage collector while the object was not memory-resident.

Marvin's eager object restoration uses app lifecycle information to restore objects before app code needs them. We implemented a simple eager restoration policy, where an MRT instance restores all reclaimed objects when it transitions to the foreground. This policy increases the transition delay in exchange for a guarantee that no swapping delays will block the foreground app's UI thread. Our design is flexible and could support more advanced policies; for instance, the runtime could predict which objects are likely to be touched immediately after a foreground transition and restore those objects first, trading off a shorter pause time in exchange for the risk of user-perceptible stuttering.

If an object has not been eagerly restored, MRT restores it on-demand when app code accesses it, a process that we call *software object faulting*. Whenever app code accesses a reclaimable object, MRT uses object access interposition to check if the object is memory-resident by inspecting a bit in its reclamation table entry. If not, MRT executes an object fault handler that calls into its C++ object restoration function.

6.3 Bookmarking Garbage Collector

A tracing garbage collector touches every object in the heap (or a subset of the heap), causing live objects to be swapped back into memory even if app code is not using them. Marvin's garbage collector avoids touching reclaimed objects by storing an object's references inside its stub and using the stub during the mark phase of garbage collection. Stubs play a similar role as bookmarks in the bookmarking collector [20].

During the mark phase, the garbage collector maintains a *mark stack* and repeatedly pops an object from the mark stack, marks all its references, and pushes those references onto the mark stack. Marvin's garbage collector checks whether an object is a stub when it pops the object from the mark stack; if so, it reads the references off the stub instead of accessing the underlying object.

For the garbage collector to use stubs in place of their objects, MRT must ensure that the stub of a memory-resident object has up-to-date copies of the object's references. It uses object access interposition to update the stub of a reclaimable object whenever Java code modifies one of the object's reference member variables.

MRT must also properly clean up after any saved objects that are freed by the garbage collector. MRT records when saved objects have been freed by the garbage collector, and when the fraction of the swap file consisting of freed objects passes a set threshold (25% in our implementation), it compacts the swap file in a heap task. MRT also cleans up after reclaimable and reclaimed objects by checking whether an object being freed is a stub; if so, it deletes the reclamation table entry corresponding to the stub. If an object is reclaimable, MRT deletes the memory-resident copy of the underlying object; if the object is reclaimed, MRT simply marks its copy in the swap file for deletion without needing to fault it in.

6.4 Design Tradeoffs and Alternatives

By tracking working sets and faulting in objects in software at the runtime level, Marvin achieves a clean design, albeit with some drawbacks. First, Marvin cannot reclaim objects accessed by native libraries: native libraries have no way to detect stubs and no recourse for faulting in reclaimed objects. Second, software working set estimation and object faulting add overhead, particularly to compiled code. We evaluate this overhead in Section 8.

Marvin moves almost all memory management into the runtime because we believe that the runtime's better access to information about app behavior makes it better suited for managing memory. The functionality remaining in the kernel is the minimum required by existing Linux kernel design; if Marvin was built on top of an exokernel [13, 23], it could move even more functionality into the runtime. A variety of other designs are possible that split functionality between the runtime and kernel in different ways.

Kernel-level working set estimation would reduce the overhead of accessing objects, but it would suffer from false sharing if an app's working set is mixed with unused objects across 4KB pages. Faulting in memory at the kernel level would similarly reduce object access overhead but would require more extensive re-design of the runtime garbage collector to avoid unnecessary swapping activity. By tying the granularity of memory management to the size of pages, kernel-level memory management will also become inflexible as large pages become more common and the disparity between object sizes and page sizes widens. In any case, kernel-level memory management would require some sort of ahead-of-time swap mechanism to satisfy the latency requirements of modern mobile platforms (Figure 3), and even adding ahead-of-time swap to the Linux kernel would require significant effort.

Marvin's garbage collector is different from the original bookmarking collector [20] in that it maintains exact reachability information with stubs rather than conservatively storing approximate reachability information. The latter approach requires the garbage collector to perform less work when evicting pages and scanning the heap, but it can result in the heap being needlessly occupied with dead objects.

7 Marvin Prototype

We implemented a prototype of MRT by modifying ART on Android 7.1.1 (which includes Linux 3.18.31). Our implementation includes a modified version of ART's ARM64 compiler, allowing our prototype to support Android devices with 64-bit ARM processors. Our changes to the ART codebase resulted in 3475 additional lines of code [38].

In addition to modifying ART, we made a small modification to the version of OpenJDK included with Android 7.1.1, namely, we added fields to the Object class definition to mirror the bytes added to the object header in ART. We also changed a source file in the Android framework (`ProcessList.java`) to increase a hard-coded limit on the number of concurrently running apps since Marvin is able to run more.

Our experiments require us to manually trigger reclamation, so we did not implement automated reclamation in the MK. However, our MRT implementation includes the reclamation table and performs all operations required to support kernel memory reclamation.

7.1 Object Access Interposition

We implemented MRT's object access interposition by adding specialized functionality to the ART interpreter and compiler. This lets MRT interpose on object accesses from both DEX bytecode running in the interpreter and compiled OAT code running natively. The following section describes in detail how we modified each component.

MRT interpreter. The ART interpreter internally represents each Java object as a C++ *mirror object*, which it manipulates when executing DEX bytecode instructions that read or write an object. The mirror object's type definition includes methods to read or write the data at a given offset within the object's memory footprint, and the interpreter code calls these methods when executing DEX instructions. To add object access interposition to the interpreter, we modified the mirror object methods to implement Marvin's features.

For example, to redirect object accesses through stubs and perform on-demand object faulting, we added a preamble macro to each mirror object method. The preamble first checks if the object is actually a stub. If so, it casts the `this` pointer to a stub, calls a method that locks the stub's reclamation table entry (RTE), checks the RTE's resident bit, and if the resident bit is cleared, calls a method to fault in the object from disk. The preamble then gets the address of the underlying object from the RTE and invokes the mirror object method on the underlying object. Finally, the preamble unlocks the RTE and returns the result of the mirror object method, if any.

ART contains multiple interpreter implementations, and the default is the "mterp interpreter," an interpreter written in assembly. When the mterp interpreter executes DEX instructions that read or write an array, it directly accesses the array's memory, bypassing the mirror object methods. To allow Marvin to interpose on array accesses, we instead use the "switch interpreter," an interpreter written in C++ that calls the mirror object methods when executing array accesses.

MRT compiler. Java code in Android framework libraries and portions of app Java code execute as native code, which is compiled by the ART compiler either statically after installation or dynamically with just-in-time (JIT) compilation. We added object access interposition to this compiled code by modifying the compiler's assembler to generate additional assembly instructions that implement Marvin's features when it performs code generation for object accesses. We used ARM64 devices for testing and evaluation, so we added support for object access interposition to the ARM64 assembler.

Each operation described above for the interpreter's implementation of stub redirection and object faulting has a corresponding block of ARM64 instructions in compiled code. The main difference is that when a stub is detected, the compiled code must explicitly overwrite the register holding the stub's address with the address of the underlying "real object;" it then loads the stub's address back into that register when it is done with the object. In the common case, when an object is not a stub (or when it is, but its underlying "real object" is memory-resident), execution branches past many of the added object-faulting instructions.

7.2 Limitations and Potential Optimizations

Our MRT implementation is a research prototype and has some limitations as a result. One is instability when reclaiming objects from black-box commercial apps. When running apps that we create in Android Studio, MRT reliably and consistently reclaims and restores objects, but when running commercial apps with stub creation and reclamation enabled, it tends to crash. MRT's object access interposition works correctly with commercial apps, so by disabling stub creation and reclamation, we can test its overhead and collect working set data. Our MRT prototype also does not support reclaiming objects with live JNI global references or directly accessing a reclaimable array's memory through JNI.

Our implementation of object access interposition in the MRT compiler is unoptimized, and the per-object-access overhead of compiled code could be reduced with deeper compiler integration. We modified the ARM64 assembler, which translates intermediate representation (IR) instructions to ARM64 binary code. Our implementation generates ARM64 instructions performing object access interposition for every IR instruction that reads or writes an object, even though many of those instructions only need to execute when the object's register allocation begins or ends. An optimized version of the compiler, with modifications at the IR level, could decrease both the execution and size overhead of compiled code.

The MRT compiler has other areas for optimization. For instance, we noticed situations where ARM64 parameter registers (`x0`–`x7` and `d0`–`d7`) appear to be live but are not reported as such by the ART compiler's `LocationSummary` class; therefore, we conservatively save all parameter registers to the stack when performing a procedure call. Saving only live parameter registers would further reduce code size overhead. In addition, the ARM64 assembler makes a maximum of two scratch registers available at any time, which required us to save backpointers and add more instructions to juggle required state among the limited available registers.

8 Evaluation

Our evaluation demonstrated that Marvin successfully met its design goals. It could: (1) quickly reclaim memory on-demand; (2) maintain high memory utilization by sharing memory among apps rather than killing them; and (3) achieve the previous two goals with low overhead and no app changes.

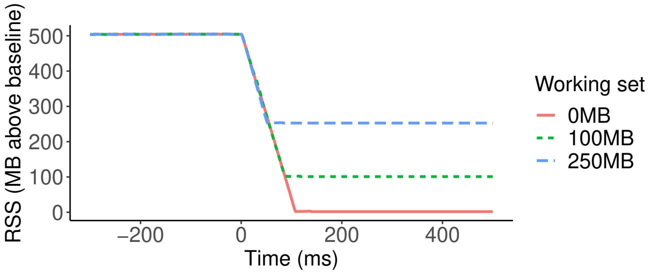

Figure 6: Memory usage as Marvin reclaims memory from a benchmark app with different working set sizes.

8.1 Evaluation Setup

We ran our experiments on a Google Pixel XL smartphone with 4GB RAM and a quad-core Qualcomm Snapdragon 821 CPU. The smartphone ran either the open-source release of Android 7.1.1 (AOSP tag android-7.1.1_r57) or our Marvin implementation based on that release. Both our Marvin implementation and our baseline Android build included a change to the Android framework to increase a hard-coded cap on the number of concurrently running apps.

Our experiments used a mix of synthetic apps for benchmarking and real-world apps. We built several synthetic workloads that simulate various memory footprints and working set sizes to measure their effect on Marvin compared to Android. We also used PCMark for Android, a commercial benchmark app based on real-world apps, to measure Marvin's overhead on real apps [3]. We chose two benchmarks from the test suite (Writing 2.0 and Data Manipulation) since the remaining three test the performance of native libraries.

8.2 Memory Reclamation

Marvin must be able to quickly reclaim memory from running apps when a new or existing app needs to allocate large amounts of memory. Its ahead-of-time swap mechanism ensures that each MRT instance has a pool of clean memory that can be quickly reclaimed without swapping to disk. In this section, we measure the latency of reclaiming memory for apps with different working set sizes. Reclamation latency depends on the app's working set size since Marvin can reclaim more memory from apps with smaller working set sizes.

For our prototype, we use `madvise` to return memory from MRT to the kernel. This design lets us trigger reclamation rather than waiting for memory pressure. Our MRT prototype reclaims memory when an app transitions to the background and then periodically while it is in the background.

Figure 6 shows memory usage over time for apps with a 500MB heap and differing working set sizes. RSS values shown are relative to the RSS reported for a minimal Android app with a single empty Activity (approx. 80MB). At time 0ms, MRT begins to return memory from the app to the OS.

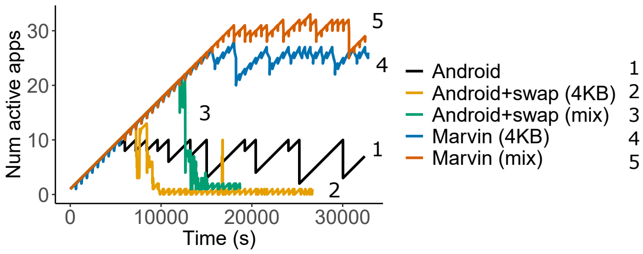

Figure 7: Count of active benchmark app instances over time. Marvin runs more than twice as many apps as regular Android before needing to kill any apps; on Android with a swap file, most apps are alive but inactive due to constant swapping activity.

Marvin returned 250MB of memory in 52ms and 500MB of memory in 108ms. In comparison, as shown in Figure 3, Android with a Linux swap file took nearly 8 seconds to free and allocate 500MB of memory under memory pressure. Using ahead-of-time swap let Marvin reclaim memory over 60x faster than Android with Linux swap could allocate the same amount of memory, allowing Marvin to meet the strict latency requirements of mobile apps.

8.3 Memory Utilization

To demonstrate Marvin's more efficient memory manager, we ran multiple instances of an app with a large memory footprint and a limited working set, and we counted the number of *active* apps that were alive and making progress on their workloads. Each app had a 220MB heap filled with arrays, and it deleted and reallocated 20MB of those arrays every 5 seconds. We used two different heap compositions: one where the apps had heaps filled with 4KB arrays, and one where they had an even mix of 4KB and 1MB arrays (similar to the bimodal distribution of real apps in Figure 1). We consider an app "inactive" if it fails to perform a round of its workload for 20 seconds after the previous round; we consider it "active" once again if it succeeds in performing a round of its workload within 7 seconds of the previous round. We started a new app instance every 10 minutes to give Marvin time to perform background work. For unmodified Android, only the data for the apps with 4KB arrays is shown, because its behavior was nearly identical for the 4KB/1MB mix.

As shown in Figure 7, Marvin ran over 2x as many active apps concurrently as unmodified Android and over 1.5x-2x as Android with a Linux swap file enabled, where swapping left almost all apps unusable as the experiment went on. While baseline Android begins killing apps when physical memory runs out, Android with swap keeps more apps alive. However, without a bookmarking garbage collector, the system experienced constant swapping activity, which prevented most apps from making progress on their workloads. Our experimental runs of Android with a swap file consistently ended early due to the device crashing.

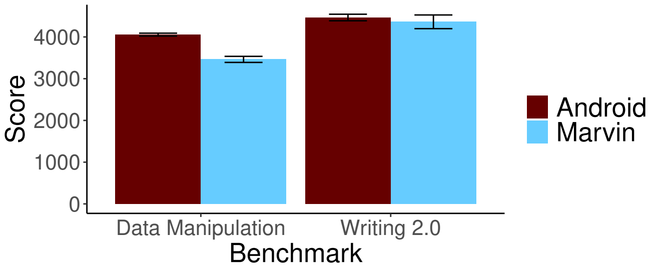

Figure 8: PCMark for Android benchmark results.

Marvin made better use of device memory because it reclaimed unused memory from apps and used its bookmarking garbage collector to avoid touching that unused memory when running garbage collection. While Android only ran 10 apps concurrently, and Android with a swap file only briefly reached a maximum of 13 concurrent apps (4KB arrays) or 20 apps (4KB/1MB mix), Marvin ran 27 apps (4KB arrays) or 30 apps (4KB/1MB mix) concurrently. Marvin's memory reclamation and bookmarking garbage collector let it execute 1.5-2x as many apps concurrently while neither killing apps nor suffering performance degradation.

8.4 Runtime Overhead

While Marvin provides better memory management, it comes with a set of trade-offs. This section quantifies Marvin's four sources of overhead: (1) *execution time overhead* caused by Marvin's object access interposition in compiled OAT code; (2) *increased compiled code size* due to object access interposition; (3) *CPU utilization overhead* caused by Marvin's heap walks for working set estimation; and (4) *faulting overhead* when an app accesses a reclaimed object.

Execution time overhead of object access interposition. Native code produced by the MRT compiler has additional ARM64 instructions to support object access interposition. Some instructions (stub checks, dirty bit updates, and access-tracking bit updates) execute on every object access. Other instructions (indirecting object accesses through stubs and locking RTEs) execute only on accesses to reclaimable objects. We measured the overhead of the added instructions that apply to all object accesses using PCMark for Android, and we used a synthetic benchmark to illustrate the dependence of that overhead on the makeup of application code.

Figure 8 compares the performance of Marvin and unmodified Android on the PCMark benchmarks in our test set. Each bar shows the mean and standard deviation of five runs. We turned off stub creation and swapping when running PCMark, using the benchmarks to measure the overhead of the instructions added to every object access for stub checks and working

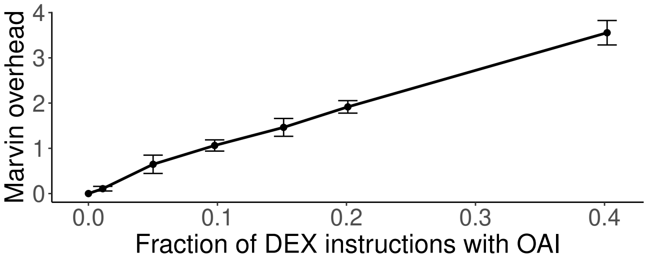

Figure 9: Overhead of Marvin for a synthetic workload with different proportions of object access interposition (OAI). The point (0,0) represents the theoretical scenario of running without any OAI, while other points show experimental results.

set estimation. Marvin's score on the Writing 2.0 benchmark was nearly identical to Android's, and its score on the Data Manipulation benchmark was only 15% lower. These scores show that Marvin's overhead for accessing regular (i.e., non-reclaimable) objects is low for real-world apps.

Figure 9 explores the dependence of Marvin's overhead on the DEX instruction mix of application code. The graph shows Marvin's overhead executing a synthetic workload that performed a tunable proportion of object accesses (array reads and writes) and integer operations (addition and multiplication). Each point represents the mean and standard deviation of Marvin's execution time overhead relative to Android for 40 iterations of the workload. For large proportions of object accesses, Marvin had relatively high overhead (e.g., 350% overhead for 40% object accesses), while for low proportions of object accesses, Marvin's overhead was minimal (e.g., 10% overhead for 1% object accesses). PCMark's 15% overhead indicates that the real app workloads represented by PCMark have low proportions of object accesses.

Although these overheads are already reasonable, they could be improved with optimizations. As noted in Section 7, deeper compiler integration would let Marvin reduce overhead by performing object access interposition less frequently.

Code size overhead of object access interposition. The ARM64 instructions added by Marvin's object access interposition also increase the size of compiled native code. To measure the increase in code size, we compared the compiled Android framework libraries generated by Marvin to the framework libraries on unmodified Android. Marvin increased the total size of the ARM64 framework libraries (in the `/system/framework/arm64` and `/system/framework/oat/arm64` directories on the Android filesystem) from 117 MB to 292 MB. This code size overhead, while relatively high, could be reduced significantly with deeper compiler integration (Section 7).

CPU utilization overhead of heap walks. Our Marvin prototype performs the heap walks required for working set estimation by invoking the concurrent garbage collector and piggybacking off its heap walk. Our prototype performs a heap walk every 5 seconds when an app is in the foreground and every 30 seconds for an app in the background. In theory, this periodic invocation of the garbage collector across multiple MRT instances could add CPU utilization overhead. In practice, when running multiple apps in the background, we found that the difference between Marvin's and unmodified Android's CPU utilization was negligible, likely because GC invocations were so infrequent for background apps.

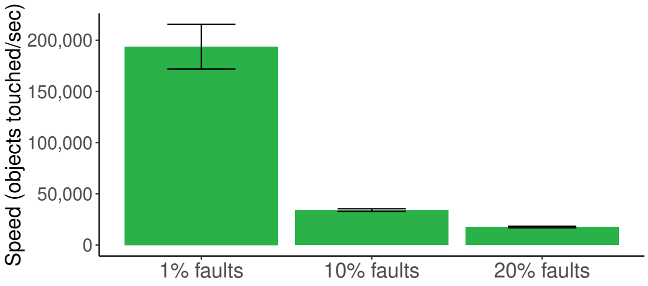

Figure 10: Speed of a benchmark app as it touches objects in its heap with different fractions of reclaimed objects.

Overhead of faulting in objects. When an app first accesses a reclaimed object, Marvin must fault it in from disk, adding significant latency to that initial access. Marvin's default policy eagerly restores all objects when an app moves to the foreground, trading off a longer transition delay for a guarantee that object-faulting latencies will never block the app's UI thread once it is in the foreground. The added transition delay is proportional to the amount of reclaimed memory and the restoration rate. Anecdotally, our prototype restored memory at about 100 MB/s, but we believe that rate could improve to around 260 MB/s with optimization. (The slower rate is the disk read speed of the C++ standard library implementation used by ART, while the faster rate is the speed of the standard library implementation linked by the Android standalone toolchain.) Object faults may occur for background apps, but the Java working sets of apps in the background are generally quite small (less than 4MB for all commercial apps in our test set), so we expect object faulting to happen infrequently in practice.

We nonetheless studied the effect of object faulting on performance, to understand how Marvin would perform in situations where different policies or workloads result in more object faulting. Figure 10 shows the effect of object faulting on a heap-walking benchmark app as it touches different fractions of reclaimed objects. The app looped over a set of 4KB arrays, reading five member variables of each array, and measured the speed of traversing the objects. Each bar shows the mean and standard deviation of five measurements, and the device's disk cache was cleared before each run. As expected, there was an inverse relationship between heap-walking speed and fraction of faults; for instance, speed dropped by 49% as the fraction of faults increased from 10% to 20%.

9 Related Work

Several recent systems provide swapping for mobile platforms but focus on page-granularity rather than object-granularity swapping. SmartSwap [43] predicts which apps are unlikely to be used and swaps out pages from those apps ahead-of-time. A2S [22] takes the opposite approach; it avoids swapping out pages from unused apps, since their pages will be freed anyways when they are terminated. MARS [19] optimizes Linux swapping to improve performance on flash storage devices. It disables garbage collection in background apps and reclaims memory from those apps. DR. Swap [42] uses NVRAM rather than flash storage to store swapped-out pages and satisfies reads by reading directly from NVRAM. Choi et al. [6] improve the performance of an in-memory file system by co-designing the swap mechanism to minimize I/O.

The Linux kernel includes a daemon, *kswapd*, which frees unused pages in the background to maintain a reserve pool of unallocated memory [18]. Like Marvin, kswapd proactively checkpoints unused memory, but unlike Marvin, kswapd reclaims pages when it checkpoints them. As a result, kswapd is limited in how much memory it can checkpoint ahead-of-time—keeping a large proportion of memory checkpointed and reclaimed would make that memory unusable and shrink the device's effective memory footprint.

Liang et al. [24] present FAST, an Android memory management system that modifies kswapd to improve its suitability for Android. FAST changes kswapd to prioritize reclaiming pages from apps in the background. It also identifies a mismatch between the large reclamation sizes of kswapd and the small sizes of typical Android allocations, and it includes a predictor to determine the reclamation size based on workload patterns. Like FAST, Marvin avoids reclaiming memory from the foreground app, but Marvin differs in its runtime-level memory management and its decoupling of checkpointing and reclamation.

A significant body of work examines the issue of providing persistent memory for object-oriented languages [1, 7, 26, 31, 33, 40]. These systems checkpoint objects to disk or non-volatile memory, but they do so to ensure safety in the face of failures rather than swapping out unused memory. As a result, they focus on supporting transactional programming models that provide strong guarantees under failure [7, 31] and on implementing crash-safe garbage collection [7, 40] rather than on maximizing the number of apps that can run concurrently.

SSDAlloc [2] is a persistent memory system that, like Marvin, is motivated by the goal of helping apps with large memory footprints avoid memory pressure. Unlike Marvin's runtime-level object faulting and working set estimation, SSDAlloc allocates objects in separate virtual pages and uses the existing virtual memory system to estimate the working set and trigger its object fault handler.

Like Marvin, the bookmarking collector [20] aims to improve the performance of Java apps in memory-constrained environments. It assumes that the OS uses a traditional page-level swapping mechanism and focuses on letting the garbage collector run without unnecessary swapping. It conservatively stores approximate reachability information (bookmarks) that is used during garbage collection, whereas Marvin stores exact reachability information (stubs). The BMX garbage collector [15] also uses stubs to avoid expensive object accesses, but in the context of a distributed persistent object store.

Other recent work on garbage collection focuses on co-designing the GC and runtime to manage software caches more efficiently [30], co-designing the GC and virtual memory manager to improve performance [41], measuring the effect of GC on scalability [16], and designing GCs or memory managers for domains such as big data systems [17, 29].

With multiple runtimes managing their own memory on top of a single operating system, Android's architecture resembles that of a virtual machine manager, where multiple guest operating systems run on top of a hypervisor. Marvin's runtime–OS cooperation is analogous to that between guest OS and hypervisor in the VMware ESX server [37], which uses a balloon driver to induce guest OSes to reclaim memory.

Wright et al. [39] present a system in which the architecture and Java runtime are co-designed for improved memory access performance. It features hardware modifications that allow an object-addressed CPU cache and an in-cache GC.

10 Conclusion

Users of mobile devices expect to use apps and switch between apps with low latency. As mobile apps have become more memory-hungry, device RAM capacities have not kept pace, and traditional swapping mechanisms cannot meet user latency expectations. Marvin overcomes this challenge with a novel runtime-level swapping mechanism that accurately estimates working sets, moves disk I/O off the allocation critical path, and avoids unnecessary swapping during garbage collection. As our experiments demonstrate, Marvin lets more apps run simultaneously and reclaims memory faster than unmodified Android while adding reasonable overhead. The source code for our Marvin prototype and experiments is available at https://github.com/UWSysLab.

Abstract

Radio frequency identification has been gaining popularity in a variety of applications from shipping and transportation to retail industry and logistics management. With a limited reader-tag communication range, multiple readers (or reader antennas) must be used to provide full coverage to any deployment area beyond a few meters across. However, reader contention can seriously degrade the performance of the system or even block out some tags from being read. Most prior work on this problem requires hardware and protocol support that is incompatible with the EPC Gen2 standard. Moreover, they assume the knowledge of a reader network that precisely describes the contention relationship among all readers, but the efficient acquisition of the reader network in a practical system with commercial-off-the-shelf (COTS) tags is an open problem. This study fills the gap by proposing a novel protocol *Retwork*, which works under the limitations imposed by commercial Gen2-compatible tags and identifies all possible reader contentions efficiently through careful protocol design that exploits the flag-setting capability of these tags. We have implemented a prototype with 8,000 commercial tags. Extensive experiments demonstrate that *Retwork* can reduce communication overhead by an order of magnitude, in comparison to an alternative solution.

1 Introduction

Radio frequency identification (RFID) has been gaining popularity in a variety of pervasive applications, including library inventory [7,13,16,25,26], warehouse control [6,17,21,22,24,38–41], supply chain management [12,15,19,20,23], and object tracking [9,18,29,31–34,36]. Given that tags use backscattering to communicate with readers, the communication distance between a reader and a tag is limited to a few meters. In a deployment (e.g., a retail store or a warehouse) that goes beyond the communication range of a single reader antenna, multiple reader antennas (referred to simply as *readers* for convenience) must be used to cover the whole area. If the readers take turn to communicate with the tags in their respective interrogation zones, then this condition will not be time efficient for inventory operations. On the contrary, if they operate simultaneously, a complex situation of collisions, where tags in overlapped areas will be left unread, may be created. To solve this dilemma, research has been trying to find solutions to properly schedule readers so that only those that do not collide will be active at any time.

This reader scheduling is built upon the knowledge of *reader network*, which is a graph that depicts the contention relationship among the readers and underlies many multi-reader protocols [5,8,10,14,27,28,30,35,37,42]. However, in practice, a reader can hardly know the size of its own interrogation zone, which takes an irregular shape that is difficult to determine due to directivity of reader antenna and environment reflection. More difficulty is to determine whether any two readers contend, which happens when their interrogation zones overlap and at least one tag in the overlapped area exists. To make reader scheduling practical, in this paper, we work under the limitations of commercial Gen2-compatible RFID systems and propose a solution to determine their reader network, without any modification to tags or reader-tag communication protocols, and without any assumption of pre-knowledge about the shape and size of any reader's interrogation zone. One naive solution is to activate the readers in sequence, one at a time, to collect tag IDs in its zone, and then compare the tag sets of any two readers to see if the intersection is empty. If it is, then no contention exists between the two readers; if not, there is a contention link between them in the network. However, this serialized approach is inefficient and already collects all tag IDs, which makes deriving the reader network unnecessary.

This paper proposes a new protocol called *Retwork* that efficiently determines the reader network of a large RFID system, with two key advantages. First, it avoids the need to perform inventory over the entire tag set by the native solution that activates one reader at a time (which reads its tags, one at a time). Second, it is completely compatible with the worldwide standard of EPC Gen2 [4], allowing the new protocol to be deployed in commercial systems. The idea behind *Retwork* is not to read all tags and compare the readers' tag sets, but to make each reader broadcast certain information to tags in its zone. The Gen2 standard does not allow us to write a reader's ID to all tags in its zone at once. Had this been supported, after all readers did that, tags would know whether they are in the overlapped areas of multiple readers and would then report that to their readers. Fortunately, according to the Gen2 standard, a reader's transmission can flip certain flags in the memory of all tags that receive the transmission. With a careful design, we show that these flags can be exploited to fully support identification of all contention relationship among the readers. Our protocol only requires each reader to transmit a few Gen2 commands that trick its tags to flip their flags in a certain way. Thus, after all readers transmit, tags in overlapped areas will have their flags set differently from other tags. Tags will signal the readers for contention relationship without having to deliver their IDs to the readers. The execution time of *Retwork* is a function of the number of readers, instead of the number of tags, which is much larger in practical systems. The major contributions of this study are listed below.

- We propose an efficient solution *Retwork* to the practically important problem of identifying the contention relationship among multiple readers in a large RFID system, which underlies a majority of multi-reader protocols.
- Our protocol exploits the flag-setting capability in Gen2. With a carefully-designed series of flag-flipping operations, our protocol can classify tags into groups: those under reader contention and those free of contention.
- We implement a prototype of *Retwork* with 8,000 commodity RFID tags. Extensive experiments show that it boosts the read throughput of the system and thus cuts the inventory time by an order of magnitude.

2 Problem Formulation

An RFID system generally consists of a large number of tags and multiple readers. Each tag is attached to an object to exclusively indicate the associated object. The tag set is denoted by $\Gamma = \{t_1, t_2, ..., t_n\}$. A reader is surrounded by a finite space within which it can communicate with tags. This space is referred to as the *interrogation zone* (or *read zone*) of that reader. In a multi-reader RFID system, the layout of readers constitutes a *reader network*, which is represented by a graph $\mathcal{G} = (V, E)$, where $V = \{v_1, v_2, ..., v_m\}$ is the set of vertices (readers) and E is the set of edges (contention links). An edge $(v_i, v_j) \in E$ exists between the reader v_i and the reader v_j if and only if at least one tag $t_k \in \Gamma$ is located at the overlapped interrogation zone covered by both readers. At this point, these two readers are called *neighbors* or *adjacent nodes*, which may incur collision if they communicate concurrently. The tags within the overlapped zone are referred to as *contentious tags*. Notably, forming an edge requires two necessary conditions: overlapped read zone and contentious tags. Two readers with the same read zone are still treated as collision-free if no tags reside in such a zone. This is reasonable because no contention will happen even if the two readers run in parallel. Note that, various factors, such as the reader planning, multi-path effects, and material of tagged objects, greatly affect a reader's signals and thus make the shape of its interrogation zone irregular. Our protocol design is robust to any kinds of RFID systems, regardless of the shape of the interrogation zone.

3 Tag Inventory

Exploring the reader network is essentially to check whether a contention link exists between any pair of readers. An intuitive solution is to conduct tag inventory reader by reader over the whole tag set. In particular, each reader individually queries the tag subpopulation in the field of view. Upon receiving a query request, all tags report their tag IDs to the reader by running the Gen2 protocol. To avoid reader collision, all readers need to execute the tag inventory sequentially rather than concurrently. That is because these readers do not have any prior knowledge on the reader network; a collision is very likely to take place when concurrent inventory is conducted. This blocks out some tags in the overlapped zone from being read. After one-round inventory by all readers, each reader can learn its neighbors by comparing its own tag list with others'. If two readers share a common tag subset, an edge must exist between them; otherwise, they are conflict-free. By checking all pairs of readers, the reader network $\mathcal{G} = (V, E)$ is formed finally. This solution is foolproof but suffers from high latency. The reason is that all tags have to transmit their long tag IDs to readers, resulting in at least $n \times t_{id}$ time overhead, where n is the number of tags and t_{id} is the time delay for transmitting a tag ID. This process is extremely time consuming, especially in a large RFID system.

4 Retwork

4.1 Basic Idea

The basic idea of *Retwork* is piggybacking some payload in a reader's instruction via one-to-many broadcasting over the air and taking a few tag replies instead of all as the indicator to obtain the link information between readers. By this means, most tag inventories are avoided and the identification time of reader network is determined by only the small number m of readers rather than the number n of tags ($m \ll n$), greatly improving the protocol efficiency. Following this idea, we propose *Retwork* in embryo, which gives us a clue to the protocol design and reveals the key hurdle that limits the implementation of *Retwork* on Gen2. It consists of two phases: *over-the-air writing* and *selective reading*. The former is to tell each tag in which readers' interrogation zones the tag resides via one-to-many broadcast. The latter chooses a specific tag subset to reply. By checking the tag responses, the reader is able to learn whether two readers conflict.

Over-the-air Writing. This phase is composed of m time slots, where m is the number of readers. Each reader is assigned an exclusive slot and scheduled to transmit its reader index in that slot. Without loss of generality, we suppose that the reader v_i is assigned to the i-th slot. The reader v_i broadcasts its index i to all tags in its vicinity during the i-th slot. Clearly, only the tags within the reader's interrogation zone can hear this broadcast. By recording reader indices, a tag knows at which readers' interrogation zones it is located. More specifically, each tag holds an m-bit indicator vector in its memory, which is denoted by I and initializes to zeros at first. Once a tag receives an index of value i, it sets the i-th bit of the vector to '1', that is, $I[i] = 1$, which indicates that this tag is under v_i's coverage. A contention link between v_i and v_j is formed if two bits $I[i]$ and $I[j]$ meet $I[i] = 1$ and $I[j] = 1$, where $1 \leq i < j \leq m$. By checking all indicator vectors and converging these pieces of information together, we can obtain the reader network $\mathcal{G}(V,E)$. However, although tags know all of this, the readers do not. We next introduce the second phase that aims to extract the contention information from tags and shed light on the reader network.

Selective Reading. Directly collecting each tag's indicator vector can obtain the reader network but suffers from long time delay as tag inventory. To improve time efficiency, the reader chooses only a few tags to reply each time and removes most of dispensable memory accesses. In particular, each reader in turn checks whether it conflicts with others. Consider any one reader v_i, $1 \leq i \leq m$. To obtain the link status between v_i and v_j $(j > i)$, the reader v_i first selects a specific subset of tags with indicator vectors that satisfy $I[j] = 1$. If the reader v_i detects any tags in the field of view, then v_i and v_j are neighbors for sure. Otherwise, no response from tags means no tags hold $I[j] = 1$, which further indicates that v_i and v_j are conflict-free.

Given the use of over-the-air writing and selective reading, the execution time relates to only the number m of readers, regardless of the number n of tags. Since m is much smaller than n in practice, the proposed solution greatly improves the time efficiency compared with tag inventory (in §3) that needs more than n tag collections.

4.2 Challenge in Implementation

Consider the above two phases. The selective reading can be well supported by the *Select* command specified in Gen2 (see §4.3). Over-the-air writing, however, needs the reader to write a group of tags in its vicinity via one instruction. We refer to this one-to-many write operation as *BlastWrite*, which is however out of the scope of Gen2 that specifies the reader has to perform memory access on one tag at a time. This condition makes building indicator vectors roll back to one-to-one transmission again.

4.3 EPCglobal Gen2 Protocol

The EPCglobal Gen2 protocol [4] defines the physical interactions and logical operating procedures between readers and tags. We highlight two functions that we will use on *Retwork* shortly later.

Select Command. *Select* is a mandatory command that can assert or deassert a tag's selected (SL) flag, or set a tag's inventoried flag to either A or B. These flags are used to determine whether a tag may respond to a reader, which is the key to identify the reader network (details are given in §4.4). *Select* comprises six mandatory fields.

- *Target.* It indicates the object that *Select* will operate, which is either a tag's SL flag or an inventoried flag in any one of four sessions. Sessions are specified by Gen2 to fit the case of exclusive reading amongst multiple readers.
- *Action.* This field elicits the action to be taken by a tag. Eight actions are available, where matching and not-matching tags assert or dessert their SL flags, or set their inventoried flags to A or B. By combining *Target* and *Action*, the reader is able to modify a specific flag. For example, a matching tag's inventoried flag in session 2 will be set to A when *Target*$= 010_2$ and *Action*$= 000_2$.
- *MemBank*, *Pointer*, *Length*, *Mask*. The four fields jointly determine which tags are matched for *Action*. *MemBank* specifies the memory bank. *Pointer* indicates the starting position. *Length* determines the length of *Mask*, which is a customized bit string according to upper application requirements. If *Mask* is the same as the string that begins at *Pointer* and ends *length* bits later in the memory of *MemBank*, then the corresponding tag is matched.

Query Command. After *Select*, *Query* initiates and specifies a new inventory round over the tag subpopulation chosen by *Select*. In the inventory round, the reader will play out a frame that consists of a group of time slots. Each selected tag randomly picks one of these time slots and transmits its tag ID to the reader in that slot. A tag inventory may need to execute several inventory rounds and is finished after all selected tags successfully reply to the reader. *Query* command includes three fields that we concern.

- *Sel.* This field consists of two bits that determine which tags respond to *Query*: 00_2 and 01_2 indicate all matching tags in the previous *Select* command; 10_2 indicates tags with deasserted SL flag; 11_2 indicates tags with asserted SL flag.
- *Session.* It selects a session for the subsequent inventory round. Gen2 requires readers and tags to provide four sessions (denoted as S0, S1, S2, and S3). Tags in one of these sessions shall neither use nor modify an inventoried flag for a different session. This way allows two or more readers to

use different sessions to independently inventory a common tag population (in different time slots).

• *Target.* This field chooses whether tags with inventoried flag of A or B participate in the upcoming inventory round, where 0 indicates A and 1 indicates B. Tags may invert their inventoried flags from A to B (or vice versa) after being successfully queried.

4.4 Design of Retwork

Although *BlastWrite* is not supported by Gen2, a reader's command (e.g., *Select* and *Query*) can be transmitted to all tags simultaneously through one-to-many broadcast. If we can piggyback some useful information in a reader's command such that all tags' memories are updated in the meanwhile, then an equivalent mimic of *BlastWrite* might be implemented on Gen2. An indicator flag (inventoried flag or SL flag) can make this condition possible because all tags' indicator flags can be set by a single reader command. Below, we detail the use of reader commands together with the Gen2-compatible indicator flag to obtain the reader network. For ease of presentation, we choose the inventoried flag in session 2 (S2) as the vehicle to show how *Retwork* works; other indicator flags can also be adopted similarly.

4.4.1 Detection of Contention Link

Consider any two readers v_i and v_j, $1 \leq i < j \leq m$. The contention link between v_i and v_j can be determined by the following three steps: (i) the reader v_i broadcasts a *Select* command to set all inventoried flags of the tag set in its vicinity to A; (ii) the reader v_j performs the similar operation that sets the inventoried flags to B; (iii) the reader v_i issues a *Query* command and executes the tag inventory on the subset of tags with inventoried flags of B. If v_i and v_j are neighbors, the tags in the overlapped zone must be set to B and v_i can get replies from these tags. Otherwise, none of tags in the field of view of v_i is set to B and nothing will be received. Accordingly, by checking tag replies, v_i can learn whether it conflicts with v_j. Next, we elaborate the way to achieve the above function with Gen2-compatible *Select* and *Query*. A *Select* command is denoted by:

$$\mathcal{S}(\underbrace{t}_{Target},\overbrace{a}^{Action},\underbrace{b}_{MemBank},\overbrace{p}^{Pointer},\underbrace{l}_{Length},\overbrace{k}^{Mask}), \tag{1}$$

with the fields of *Target* (t), *Action* (a), *MemBank* (b), *Pointer* (p), *Length* (l), and *Mask* (k). To set all tags' inventoried flags (in S2) to A, the reader needs to broadcast:

$$Flag = A : \mathcal{S}(2,0,1,0,0,0),$$

where $t = 2$ (010_2) means the operating object is set to the inventoried flag in session 2 (S2), $a = 0$ indicates that the inventoried flags of matching tags will be set to A while those of not-matching will be set to B, and $(b, p, l, k) = (1,0,0,0)$ means all tags within the coverage are selected (matching). Similarly, to set the inventoried flag to B, the reader only needs to carry out the same *Select* except that the value of *Action* field is altered to 100_2 ($a = 4$). Thus, we have:

$$Flag = B : \mathcal{S}(2,4,1,0,0,0).$$

After *Select*, a *Query* is needed for inventory:

$$Q(\underbrace{e}_{Sel},\overbrace{s}^{Session},\underbrace{g}_{Target}). \tag{2}$$

To inventory all tags with inventoried flags in S2 of B, the query command shall be $Q(0,2,1)$, where *Sel* (e), *Session* (s), and *Target* (g) are 00_2, 10_2, and 1, respectively. By combining the *Select* and *Query* together, we obtain the instructions for detecting the contention link between v_i and v_j.

$$\begin{aligned} &\textcircled{1}\ v_i:\ \mathcal{S}(2,0,1,0,0,0)\\ &\textcircled{2}\ v_j:\ \mathcal{S}(2,4,1,0,0,0)\\ &\textcircled{3}\ v_i:\ Q(0,2,1). \end{aligned} \tag{3}$$

With these commands, the contentious tags (if appropriate) in the overlapped zone between v_i and v_j are isolated from others; the reader v_i can check the existence or absence of these tags by executing a short inventory round. Compared with the basic tag inventory over the entire tag set, this way avoids a great number of tag memory accesses, regardless of the number of tags.

4.4.2 Identification of Reader Network

The findings above indicate that an intuitive solution to identifying the reader network is to detect each pair of readers with the instructions of (3) and later draw the reader graph with the identified contention relationships. This method is far superior to the inventory-based solution as most tag inventories can be avoided. However, this one-pair-at-a-time scheme suffers from repetitive transmissions for setting inventoried flags, increasing the communication overhead. Take the reader v_1 for example. To get the contention relationships between v_1 and other readers, the reader v_1 needs to execute the operation of setting A (① in (3)) $m-1$ times. If this repetition can be avoided, then a great deal of communication overhead will be saved, which improves the protocol performance. To this end, we propose a scheduling policy that tries to reduce the number of broadcasts of instructions and improve the global time efficiency for obtaining the reader network.

The basic idea is that, instead of solely checking each pair of readers, we identify a group of contention relationships by simultaneously taking multiple readers into account. To identify the entire reader network, $m-1$ identification rounds are needed (m is the number of readers). In each round, we select a reader and identify the contention relationships between this reader and others. More specifically, all readers except for v_1 initially set the inventoried flags to A. Thereafter, the identification starts, round by round. In the i-th round ($1 \leq i < m$), we select the reader v_i and check whether it conflicts with other readers v_j ($j > i$) via three steps. (i) The reader v_i solely updates the flag to B. (ii) Each reader v_j in turn queries the tags with the flag equal to B. If any v_j conflicts with v_i, then the tags in the overlapped zone must be set to B in the first step and v_j can obtain the reply from these tags. Otherwise, no tags in the field of view of v_j reply. By this means, all the contention relationships between v_i and v_j are identified. Compared with the one-pair-at-a-time scheme, the reader v_i executes the flag setting only once rather than $m-1$ times, greatly saving the communication overhead. (iii) In the last step, we reset all flags under v_j's coverage to A again, which would be the input of the next round. For this purpose, one broadcast of $\mathit{Flag} = A$ by v_i is sufficient; no need for all readers v_j to do so. That is because the flags that transform from A to B are due to the flag setting by v_i, that is, the tags with flag B must be under v_i's coverage. After the three steps, the current round terminates and we move to the next one. This process repeats round by round until the global reader network is identified.

4.5 Time Efficiency & Improvement

Now, we discuss the execution time of *Retwork*. As aforementioned, $m-1$ identification rounds need to be run to obtain the reader network. Consider the i-th round, $1 \leq i < m$. It consists of two *Select* commands (sent by v_i) and $m-i$ *Query* commands (issued by each reader v_j, $j > i$). Therefore, the execution time of the i-th round is $2t_s + (m-i)(t_q + t_v)$, where t_s, t_q, and t_v are the time intervals of a *Select* command, a *Query* command, and an inventory round that checks whether requested tags exist, respectively. By considering $m-1$ rounds together with initial $m-1$ flag settings, we have the execution time T of *Retwork*:

$$T = \frac{m(m-1)}{2}(t_q + t_v) + 3(m-1)t_s. \qquad (4)$$

This execution time is determined by only the number of readers once the transmission rate of reader-tag communication is fixed, regardless of the large number n of tags. This way is a great performance boost compared with tag inventory given that m is much smaller than n. For example, in a practical scenario (e.g., warehouse or library), a reader usually covers more than 1000 passive tags, i.e., $m \leq 0.001n$. Below, we propose two schemes that further improve the time efficiency of *Retwork*. First, Gen2 allows a tag to send a truncated reply (i.e., a portion of EPC) by enabling *Truncate* field of the *Select* command. This way will help a tag reduce the transmission of the 96-bit EPC to only a single bit, which reduces the communication delay of tag replies. Second, if the range limit of RFID readers is considered, we do not need to check two readers beyond the communication range, which sharply reduces the number of contention detection.

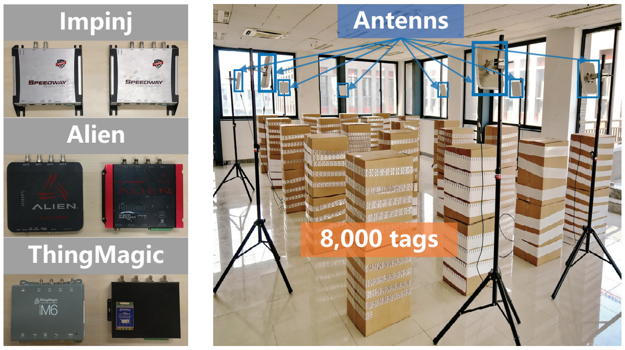

Figure 1: Experimental setup.

5 Evaluation

We evaluate *Retwork* using COTS RFID readers and tags. Six models of UHF RFID readers from three experienced suppliers of RFID products are used in our experiments: ALR-F800 and 9900+ from Alien Inc. [1], R220 and R420 from Impinj [2], Mercury6 and M6e from ThingMagic [3]. Each reader is connected to a directional antenna Larid S9028PCR [11] that is with 8.5 dBic gain and operates at around 900 MHz. To better mimic a real RFID system and extensively study the performance of *Retwork* in practice, we use a total of 8,000 commodity tags in our experiments. As shown in Fig. 1, these tags are densely attached to 40 cartons, each of which contains approximately 200 tags. The readers are deployed with three kinds of densities, namely, sparse (four readers), moderate (six readers), dense (eight readers), to cover a desired area of 12m×8m. The sparse fits for the scenarios of dock door or conveyor belt; the moderate is used for the case of laboratories or office; the dense is suitable for the case of libraries or shopping malls.

5.1 Identification Accuracy

Retwork examines each contention link between two readers by broadcasting *Select* and *Query* commands. Due to the manner of one-to-many transmission, *Retwork* might incur some false positives or false negatives. A false positive is a result that indicates a contention link exists, when it does not indeed. On the contrary, a false negative indicates that two readers do not conflict, while in fact they do. We next study the identification accuracy of *Retwork*, which is measured by false positive ratio (FPR) and false negative ratio (FNR). The ground truth is obtained by executing the inventory-based solution: each reader conducts the tag inventory in sequence and later compares its own tag list with others'; if two readers share a common tag subset, then they conflict. Fig. 2 shows FPR and FNR in three scenarios of different reader densities.

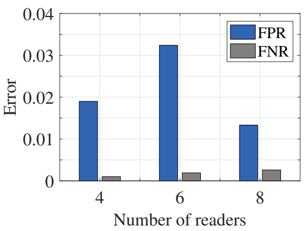

Figure 2: Accuracy.

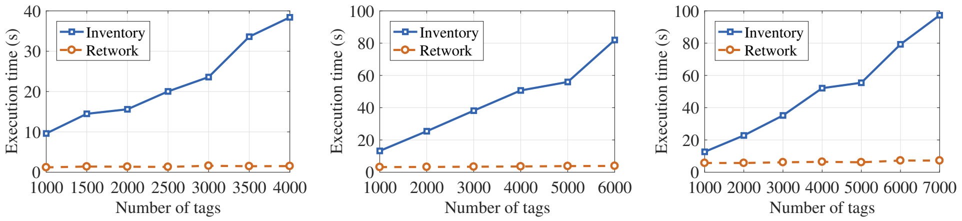

(a) Sparse.

(b) Moderate.

(c) Dense.

Figure 3: Time comparison between *Retwork* and tag inventory.

As observed, FPR and FNR are bounded within a low level of errors. Although FPR is relatively larger than FNR, false positives slightly negatively affect the functions of multi-reader protocols. Instead, false negatives might incur some errors: two neighbor readers work concurrently. However, the FNR is 0.3%, which is very small for most applications. We can further decrease FNR by running *Retwork* multiple times if desired.

5.2 Time Efficiency

The usage of inventoried flags and reader commands avoids most tag inventories and thus lowers the identification latency of the reader network. This is where *Retwork* shines. Now, we study the time efficiency of *Retwork* over the three reader scenarios, where tag inventory in §3 is taken as the baseline for comparison. Fig. 3 plots the execution time of *Retwork* and tag inventory with respect to the number of unique tags that have been read. As observed, *Retwork* is far superior to tag inventory under difference cases. For example, in the moderate case (six readers) with 5,000 tags (Fig. 3(b)), *Retwork* reduces the execution time from 55.9s to only 3.9s, producing a 14.7× performance gain. Given a reader deployment, the execution time nearly remains stable, regardless of the number of tags. This result is consistent with our previous belief in the protocol design. With the increase in the number of readers, the number of detection units required by *Retwork* increases, as well as the execution time. Notably, the execution time here is the worst case of *Retwork*. If the truncated reply and range limit are taken into account (see §4.5), then the performance of *Retwork* will be further improved. The execution time of tag inventory does not see a linear rise over the number of tags because the number of tags in the overlapped read zones increases correspondingly.

6 Related Work

In a multi-reader RFID system, reader collisions occur frequently and inevitably, which impairs the read throughout and leads to misreads. Research has been trying to find solutions to properly schedule readers to ensure that only those that do not collide will be active at any time. Colorwave [30] is one of the first work to address reader collision. It randomly colors readers such that each pair of interfering readers have different colors. In AcoRAS [8], readers are assigned colors by a central server following the build of a minimum independent set. Season [37] proposes a scheme of reader collaboration to improve the time efficiency of tag inventory by using two steps: shelving the collisions and identifying the tags that do not involve reader collisions; performing a joint identification, in which adjacent readers collaboratively identify the contentious tags. Liu et. al [14] propose a maximum-weight-independent-set-based approximation algorithm to address the problem of reader-coverage collision avoidance: activating readers and adjusting their interrogation ranges to cover maximum tags without collisions subject to the limited number of tags read by a reader. In spite of the advancement, the reader scheduling largely depends on the knowledge of reader network, which is a graph that depicts the contention relationship among the readers and underlies many prior multi-reader protocols. Obtaining the reader network, however, is no picnic in practice.

7 Conclusion

In this work, we investigate the fundamental problem of exploring reader network, which is vital to reader scheduling and underlies many anti-collision protocols in a multi-reader RFID system. A Gen2-compatible protocol *Retwork* is proposed to identify reader network on COTS devices. By exploiting flag-setting capability of commercial tags, *Retwork* avoids most tag inventories and improves time efficiency. Extensive experiments show that *Retwork* can reduce the execution time by an order of magnitude.

Abstract

While the Linux memory reclaim scheme is designed to deliver high throughput in server workloads, the scheme becomes inefficient on mobile device workloads. Through carefully designed experiments, this paper shows that the current memory reclaim scheme cannot deliver its desired performance due to two key reasons: page re-fault, which occurs when an evicted page is demanded again soon after, and direct reclaim, which occurs when the system needs to free up pages upon request time. Unlike the server workload where the direct reclaim happens infrequently, multiple direct reclaims can happen in many common Android use cases. We provide further analysis that identifies the major sources of the high number of page re-faults and direct reclaims and propose Acclaim, a foreground aware and size-sensitive reclaim scheme. Acclaim consists of two parts: foreground aware eviction (FAE) and lightweight prediction-based reclaim scheme (LWP). FAE is used to relocate free pages from background applications to foreground applications. While LWP dynamically tunes the size and the amount of background reclaims according to the predicted allocation workloads. Experimental results show Acclaim can significantly reduce the number of page re-faults and direct reclaims with low overheads and delivers better user experiences for mobile devices.

1 Introduction

With many optimizations to Linux's memory reclaim scheme, the existing Linux memory reclaim scheme can efficiently manage pages inside the main memory in desktops and servers [6, 11, 14, 17]. Android mobile devices, which have seen remarkable growth, inherit the same Linux kernel designed for desktops and servers. As a result, these mobile devices utilize the same memory reclaim scheme inherited from Linux desktop and server distributions.

In this work, we show that the nature of mobile devices workloads is fundamentally different from those of desktop and server workloads. Hence, policies designed to improve the efficiency of the memory reclaim scheme in desktops and servers fail to deliver similar efficiency on mobile devices. Specifically, we observe that a slow page reclaim procedure and severe page thrashing can severely degrade the performance of Android applications. One of the key reason behind this performance degradation is page re-fault, which is a page fault that happens on a previously evicted page. This page re-fault can become a bottleneck and lower workloads' read performance because the system now needs to read the page from the storage instead of the much faster main memory, leading to 100x or more increase in page read latency. Another key reason behind performance degradation is direct reclaim. Direct reclaim can negatively impact performance because any page allocations *must wait* for the direct reclaim process to finish. During a direct reclaim operation, many dirty pages may need to be flushed and thus greatly prolong the allocation procedure. To avoid costly direct reclaim operation, an alternative reclaim scheme using the lightweight background reclaim (***kswapd***), is used by the Linux system. ***Kswapd*** is a kernel thread that is wakened up periodically or by page allocation to reclaim free pages. However, in the current Android kernel, we observe that ***kswapd*** takes too long to free up the necessary number of pages and thus direct reclaim has to be triggered.

Through experiments using popular mobile applications, we show that the current Android memory reclaim scheme does not adapt to the characteristics of Android applications. Experiments show that even when launching one small-size application, page re-faults could happen regularly. Under a set of common use cases, 31% of all the evicted pages are page re-faults. This high ratio of page re-faults to normal page evictions means that page thrashing is very severe in modern Android mobile devices. Aside from the high rate of page re-faults, our experiments also show that the percentage of direct reclaims in all reclaims is 0.8% on average under common use cases. Once direct reclaim happens, up to 1024 dirty pages will be flushed to flash storage, which dramatically extends the latency of the page allocation. Thus, direct reclaim should be avoided.

Prior researches focused on reducing the number of page faults by optimizing page eviction algorithms on mobile devices [32, 40]. These previously-proposed eviction algorithms treat the pages of background and foreground applications with the same priority and choose victim pages according to their access time and the frequency of accesses. The optimized LRU is known as a good eviction algorithm and is applied in Android [2]. To avoid direct reclaim, the Android operating system reserves some free pages by setting watermarks for free memory. This additional free pages can prevent direct reclaim from being triggered if there is a sudden and urgent heavy allocation. However, our experimental results show that the number of direct reclaims is still surprisingly high (could be triggered 96 times in five minutes in one common use case) on Android mobile devices. To reduce the long latency of memory allocation caused by poor insight of mobile OSes, Marvin [28] implements most memory managements in the language runtime, which has more insight into an app's memory usage. However, Marvin misses the opportunities at the OS level, e.g. taking into account the foreground/background states of applications to predict applications' allocation.

In this paper, we observe that under certain user behaviors, page re-fault depends on the amount of available memory, while the direct reclaim depends on both the amount of available memory *and* the latency of background reclaims. Based on these observations, we uncover two main causes that lead to a high rate of page re-faults and direct reclaims on mobile devices. First, background applications are not truly inactive but their reduced activities and unevicted pages still create high memory pressure, penalizing the foreground application in an unfair way. Furthermore, low memory killer (LMK) [1] does not help much. Second, we found that the large-size reclaim, which is suitable for desktop and servers as the large-size reclaim amortizes the long latency of each direct reclaim process, is overly aggressive and coarse-grained for Android because 1) it prolongs the latency of the background reclaim and negatively impacts the user experience and 2) Android workloads typically issue page allocation requests that are much smaller compared to desktop and server requests.

Based on these two main causes, we propose Acclaim, a foreground aware and size-sensitive reclaim scheme. Acclaim consists of two major runtime components: foreground aware eviction (FAE) and a lightweight, prediction-based reclaim scheme (LWP). FAE relocates free pages from background applications to foreground applications; it does so by lowering the priorities of the pages belonging to background applications during page eviction. LWP tunes the sizes and amounts of background reclaims based on its prediction of allocation workloads. Evaluation results show that Acclaim benefits I/O-intensive phases in application execution, notably application launch and application installation, which are known crucial to mobile user experience [8].

The contribution of this paper is listed as follows.

- This work reveals that the current memory reclaim scheme fails to deliver a good page re-fault ratio (of up to 31%) and frequency of direct reclaims (of up to 96 times when using only one foreground application for five minutes) on Android mobile devices.
- We analyze the root causes of the inefficient memory reclaim scheme on mobile devices and propose Acclaim, a foreground aware and size-sensitive reclaim scheme, to improve the performance.
- We conduct a survey to collect the usage information of applications through deploying our monitoring application on fifty-two real mobile devices. We evaluate Acclaim according to our survey. The experimental results on a real mobile device show that the performance improves in most use cases.

2 Background

To analyze the latency bottleneck of Android mobile devices, we first look at how Android read a page of data.

2.1 Android I/O Latency

Android is a Linux-based lightweight operating system designed for mobile devices. Figure 1 shows the architecture of Android I/O stack that including the userspace, the Linux kernel, and the I/O devices.

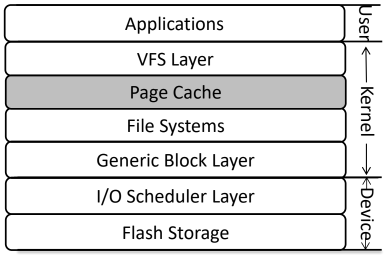

Figure 1: An overview of the Android I/O stack.

We use a read operation as an example to show the latency bottleneck. When an application reads a page in the I/O stack, the application sends a read request to the kernel. The kernel then searches the page cache to see whether the requested page is in the page cache or not. If the requested page is in the page cache, the page cache returns the page to the application. Because the page cache resides in the main memory, the access latency of accessing the page cache takes about one hundred nanoseconds to complete [39]. If the requested page is not in the page cache, a page fault is generated. In this case, the page allocation operation will be triggered to allocate a new page. When the memory is full, the Linux's reclaim scheme is triggered to free pages within the main memory. There are mainly two reclaim schemes: asynchronous background reclaim and synchronous direct reclaim. Background reclaim frees unmapped pages while direct reclaim frees mapped pages or dirty pages, and thus direct reclaim has a heavy cost, especially when writing back dirty pages. After page allocation, the request is delivered to the file system layer, which finds the logical address of the requested page. Then, a read request goes through generic block and I/O scheduler to access the requested page from flash storage through I/O operations. Going through each of these layers contributes to additional microsecond scale latencies to this read request, which can include addressing latency of the file system, queuing latency of the I/O operation, and reading latency of the flash storage. After these operations, the fetched page is finally stored in the main memory and future accesses can be fetched directly from the page cache. Due to these reasons, a page fault can take microseconds to finish, leading to much longer read latency especially when a direct reclaim is triggered.

To quantitatively show the influence of page fault on Android mobile devices, Yu et al. [21] measure the latency of launching Twitter and Facebook applications in three different situations. Figure 2 shows the three scenarios across two setups based on F2FS [19] and EXT4 [23] file systems, which are commonly used in Android. "Cached" refers to the case where most requested pages can be found in the page cache. This case is implemented by re-launching the application right after it is closed, and thus its data is still in memory. "Read" is a case when there are some page faults but there are enough free pages, [1] and thus the reclaim procedure will not be triggered. This case is implemented by launching the application after cleaning the page cache. "Reclaim-first" is the case where there are some page faults and there are not enough free pages, triggering the reclaim procedure. This case is implemented by launching the applications after sequentially launching twenty other applications (to ensure that the page cache is full prior to the launch of Twitter or Facebook.)

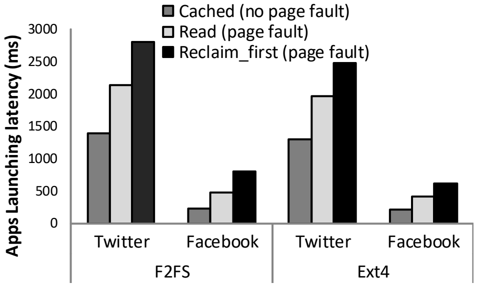

Figure 2: Influence of page fault and reclaim on application launch latency on Android mobile devices.

The results in Figure 2 show that the latency of launching an application is the shortest in the "Cached" case. Compared to the "Cached" case, the "Read" and the "Reclaim_first" cases take longer to launch for both applications. The extended latency is caused by page faults. The launch latency is the longest in "Reclaim_first" case because the reclaim procedure is triggered. Especially, when direct reclaim is triggered, the latency increases significantly.

2.2 Key Factors that Affect Performance

Page Re-fault. Page fault can happen in three scenarios. First, a page fault occurs because physical memory has not yet been allocated for the requested page. This occurs, for example, when the page is read for the first time. Second, a page fault occurs because the application wants to read an already evicted page. We define this case as a page re-fault. Third, a page fault occurs because a process wants to illegally access invalid memory. In this case, the operating system will kill the process. Out of these three cases, the system can be designed to minimize page re-fault because the requested page had been in memory but was evicted by system's page reclaim scheme. Page re-fault can be used to measure the page thrashing and thus evaluate the efficiency of the memory reclaim scheme.

Direct Reclaim. Direct reclaim is a heavy-weight synchronous reclaim scheme that is triggered during the page allocation procedure when there is not enough free space for the system's demands. Once direct reclaim is triggered, Android system needs to pause the allocation process, resulting in additional performance degradation. An alternative solution is to use background reclaim. When the number of free pages is lower than a threshold ($watermark_{low}$), background reclaim threads are woken up to reclaim and free unmapped pages asynchronously. During the background reclaim, the Android system does not pause the allocation process. Hence, background reclaim is lightweight. However, if the background reclaim is unable to reclaim enough free pages in time and there are not enough free pages for the current page allocation, direct reclaim is triggered to reclaim the mapped pages or dirty pages. When the memory is extremely scarce, direct reclaim cannot help and some background applications will be killed by the Android low memory killer (LMK) [1] to reclaim memory. Because the overhead of LMK is larger than direct reclaim [28], LMK cannot be used to replace direct reclaim. Thus, LMK complements direct claim and only handles extreme cases.

3 Analysis of Android Memory Reclaim

In this section, we measure the Android memory reclaim scheme by counting page re-faults and direct reclaims while running popular applications.

3.1 Survey of Application Usage Patterns

We survey the distribution of the numbers of background applications from real phones, then using that numbers to conduct controlled experiments and study launch latencies. We develop a monitoring application [2] and deploy it on the phones of sixty Android users. Out of the 60 users, we verified the data invalidation and selected 52 users (90% 18-35 years old and 10% 35-50 years old) for our analysis. Our

[1] Cache status is checked by the command **dumpsys meminfo**.

[2] https://github.com/MIoTLab/Accliam.

monitoring application collected data on more than twenty mobile device models over a two-month period. During this time, the monitoring application generates an hourly report on other applications' activity, RAM usage, and device information. Our monitoring application runs without root permission. Hence, the application only checks the applications' activity conducted by users but not by systems. With this data, we can estimate the distribution of background applications' usage information as shown in Table 1.

Table 1: Collected data from 52 real phones.

# of phones	# of background applications	Workloads
0	$N < 2$	light
8	$2 \le N < 5$	light
39	$5 \le N < 10$	moderate
5	$N \ge 10$	heavy

Based on the survey, we reproduce different realistic usage scenarios by running several popular Android applications. These applications include Facebook, Twitter, Instagram, WhatsApp, Pinterest, Wish, Chrome, Firefox, Google Earth, Google Map, Uber, Angrybird, CnadyCrush, NewsBreak Youtube, and Spotity. We evaluate both launching and execution of applications with a different number of background applications as shown in Table 2.

Table 2: Application combinations used in experiments. A represents a foreground application and B represents a background application. 3B+A means launching a foreground application when there are three background applications.

Applications	Operations	Memory	Workloads
A	Launch and use an application for 5 minutes	Avail.	Light
3B+A	3 background applications	Avail.	Moderate
8B+A	8 background applications	Full	Moderate
15B+A	15 background applications	Full	Heavy

All our following experiments are performed on a Huawei P9 smartphone with an ARM's Cortex-A72 CPU, 32GB internal memory and 3GB RAM, running Android 7.0 on Linux kernel version 4.1.18. We also conduct experiments on 2.5GB RAM by using **memtester** [34] to occupy memory. There is no external SD card in order to force all the I/O requests to the internal eMMC flash storage (/data partition) of Android. We instrument the Android kernel source code and use the **adb** (Android Debug Bridge) tool [37] to obtain information on memory allocations and the reclaim process of our evaluated smartphone. Our instrumentation framework includes information on the number of re-fault pages, the number of evicted pages, the size of each allocation, the size of each reclaim, the number of direct reclaims, and the number of all reclaim operations. To reproduce the real usage scenarios, after system start, background applications will be launched and wait for a while. And then we start to collect the information while we launch and use the foreground application for five minutes. To avoid bias, each experiment is conducted ten times with the same subset of background applications and the average is shown. In Sections 3.2 and 3.3, we show that page re-fault and direct reclaim happen on Android mobile devices unexpectedly frequently even when a small-size foreground application running.

3.2 Page Re-fault on Mobile Devices

The ratio and the number of page re-faults when launching and running popular applications are shown in Figure 3. We define the page re-fault ratio as the proportion of re-faulted pages on all evicted pages. It can be used to evaluate page thrashing. The results show that the page re-fault ratio could be up to 31% when running popular applications. This means the Android memory reclaim scheme often reclaims pages that will be used soon. Although the ratio of page re-fault depends on users' behaviors, when using only one application in a system with 3GB of memory, page re-faults should not occur because the working set of one application does not exceed 3GB [3]. The existence of page re-faults in Figure 3 indicates that the pre-loaded data and processes' data occupy the memory space causing many page re-faults.

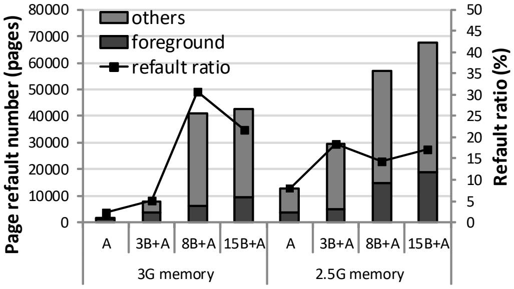

Figure 3: Ratio and number of page re-faults when using one foreground application for five minutes. For each case, there are different number of background applications. "Others" includes background applications and system services.

Moreover, we find that the increase in the number of background applications has a great impact on the number of page re-faults. The ratio of page re-faults is up to 31% when there are eight background applications with 3GB memory. This means almost one-third of the evicted pages will be reused. We further find that a major fraction (37% on average) of page re-faults happens on the foreground app. Because foreground applications directly interact with users, it is important to minimize the number of page re-faults of foreground applications.

3.3 Direct Reclaim on Mobile Devices

Compared to page re-fault, direct reclaim can cause more severe performance degradation and fluctuations because it could flush many dirty pages during a page allocation routine. We show the ratio and number of direct reclaims when running

[3] It is checked by the command **dumpsys meminfo**.

popular applications in Figure 4. We define the direct reclaim ratio as the proportion of the number of direct reclaims on total of reclaims. Even if the direct reclaim ratio is small (up to 2%), it could induce a large latency because page allocations need to wait for the direct reclaim to finish. The latency taken by the direct reclaim can be thousands of times the latency of the background reclaim. Thus, the direct reclaim is supposed to be triggered in memory of emergency cases.

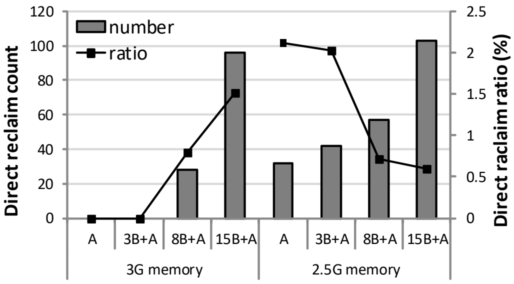

Figure 4: Ratio and number of direct reclaims when using one foreground application for five minutes. For each case, there is different number of background applications.

We find that the increase in the number of background applications and the reduction of physical memory have major effect on the number of direct reclaims. However, the direct reclaim ratio trend is different between on 3GB (default) and on 2.5GB (using **memtester** to occupy memory). When memory is relatively large (3GB), direct reclaim triggers only when there are some background applications and increases as the number of background applications increases. However, when memory is extremely scarce and direct reclaim become ineffective, OS will kill some applications to reclaim memory space. Thus, direct reclaim ratio is decreasing with a larger number of background applications on 2.5 GB of memory. The number of direct reclaims could be up to 96 in five minutes when there are fifteen background applications with the default 3 GB memory. An efficient memory reclaim scheme should minimize the number of direct reclaims.

4 The Cause of Page Re-fault and Direct Reclaim on Mobile Devices

Substantial re-fault rates were also seen on servers, e.g. as high as 14% reported by Google engineers [9]. Compared to servers, mobile devices have vastly different characteristics: much smaller page allocation request size, limited memory, and highly-interactive foreground applications [10, 13]. According to these characteristics, we conduct another set of experiments to analyze the Android memory reclaim scheme to find the main causes of a high number of page re-faults and direct reclaims.

Observation 1: Page re-fault depends on the available memory. Figure 5 shows that the number of page re-fault and evict pages under different available memory. To further eliminate the impact of user behavior, in this experiment, we used different usage scenarios from that in Figure 3. “A” means to launch one foreground app. “A4A” means to launch one foreground application and then launch four background applications, and finally re-launch the foreground application. Relaunching a foreground application is a typical scenario to produce page re-faults.

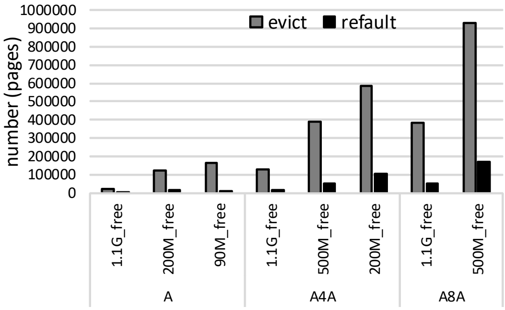

Figure 5: Number of page re-faults and evicted pages under different available memory.

The results show that the number of background applications has a major impact on the number of re-fault and evict pages. Moreover, reducing physical memory can increase number of both re-fault and evict pages. In a word, the number of page re-faults depends on the available memory.

Observation 2: Direct reclaim depends on both available memory and the latency of the background reclaim. The factors which affect the frequency of the direct reclaim can be found in its flow chart which is shown in Figure 6.

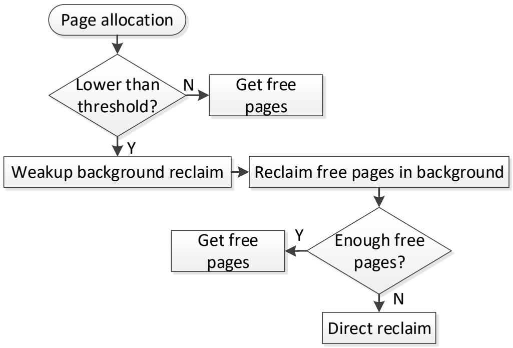

Figure 6: The flow chart of reclaim scheme.

During page allocation, if the number of free pages is lower than a threshold, the background reclaim starts asynchronously. If there are not enough free pages for this allocation or the launched background reclaim does not reclaim enough pages in time, direct reclaim will kick in synchronously. The flow chart shows that direct reclaim depends not only on available memory but also on the latency of the background reclaim. Notably, a larger reclaim size also significantly increases the latency of the background reclaim.

Based on the above two observations and the specific characteristics of mobile devices, we found that there are two additional factors that can increase the number of page re-faults and direct reclaims.

Observation 3: Background applications keep consuming free pages even though they do not have the same impact on user experience compared to the foreground applications. For mobile devices or other highly-interactive systems, foreground applications have significant impact on user experience. However, we found that background applications keep consuming free space under the current memory reclaim scheme due to two main reasons.

First, we find that anonymous pages from background applications thrash pages from the foreground application. In the android system, all the pages are in one of five LRU lists: *Active_anonymous*, *inactive_anonymous*, *active_file*, *inactive_file*, and *unevictable*. The pages in the *unevictable* list will not be evicted. Since anonymous pages contain the heap information associated with a process, these anonymous pages are considered to be more important than file pages to the process. In most cases, the pages in *active_anonymous* list will not be evicted, even if they belong to a background app. Thus, many anonymous pages of background applications stay in memory, while the file pages from the *foreground application* are evicted. These evicted file pages from foreground applications may be accessed again soon, leading to a high number of page re-faults. Moreover, the anonymous pages of background applications occupy free space and thus affect the frequency of the direct reclaim.

Second, we found that background applications are still active even after they are in the background for thirty minutes. The details are shown in Table 3. The results are collected when there are seven user background applications and one foreground application. Notice that system services are treated as applications here.

Table 3: Applications are still active in the background.

Time	Evict apps	Refault apps	Foreground	Background	System
5 mins	53	31	6.2%	34.4%	59.4%
30 mins	52	19	18.3%	33.3%	48.4%

"Evict apps" represents the number of applications that have pages being evicted while "Refault apps" represents the number of applications that have page re-faults. "System" includes system services and private applications that are installed on the mobile device at the factory. The percentages in the Table 3 means the percentage of re-faults. The results show that background applications still request free pages and thus induce page re-faults. Moreover, background applications still consume free space and thus affect direct reclaim frequency.

In summary, the reclaim scheme keeps the pages of background applications in memory and could induce a high number of page re-faults and direct reclaims. For servers, the foreground and background applications usually have the same priority. However, for mobile devices, only the foreground application has a major impact on the user experience.

Observation 4: Large-size reclaim prolongs the latency of the background reclaim. In the buddy system, every memory block has an order, where the order is an integer ranging from 0 to 11. The size of a block of order n is 2^n. The distribution of allocation order when running popular applications is shown in Figure 7. These results are collected from the allocation function *_alloc_pages_nodemask()*. The results show that on the Android mobile device, 99% of allocation orders are 0 (1 page), and more than 99.9% of orders are smaller than 4 (16 pages). This is because the requests on Android mobile devices are mostly in small size. One of the main reasons is that most Android applications use SQLite as the database. SQLite and its temporary files are mostly accessed in 4KB (1 page) units [20, 29].

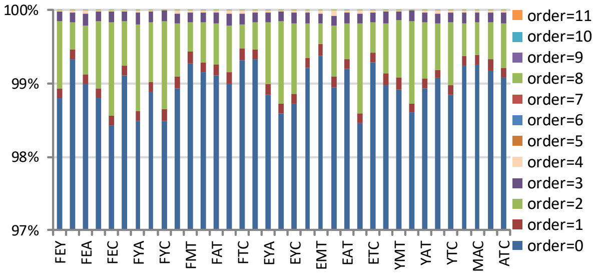

Figure 7: The distribution of allocation orders. The corresponding allocation size equals to 2^{order} [21].

The distribution of reclaim sizes is shown in Figure 8. The results show 80% of reclaim sizes are larger than 32 pages (order=5). Android inherits much of the reclaim scheme from its server counterpart. The latter often reclaims memory as much as possible to fulfill large allocations and avoid expensive direct reclaim or killing processes under memory pressure. As Android applications tend to allocate multiple small blocks of data (shown in Figure 7), the reclaim process becomes overly aggressive and ends up reclaiming excessive pages for each of these small allocations.

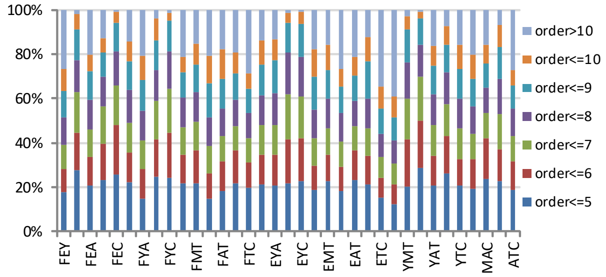

Figure 8: The distribution of reclaim sizes. These results show the reclaims from LRU lists, and they are collected in the functions *shrik_lruvec()* [21].

Large reclaim size prolongs the latency of the background reclaim. According to observation 2, the latency of the background reclaim will affect the frequency of the direct reclaim. Moreover, a large-size reclaim scheme could induce more page re-faults than necessary [21].

Based on our data in Section 3, Android does not efficiently manage its memory. This observation is in-line with multiple technical news: Google Pixel 3 has memory management issues, such as killing background applications [35] and is unable to shuffle between a few applications at a time [33]. Moreover, its memory management issue seemingly gets worse when users use the camera [16]. Hardware vendors tend to address the issue by putting a large-capacity DRAM on devices, which alleviates the problem in a short term but leaves the issue in the future. Moreover, the brute-force solution has many problems, such as cost efficiency, power consumption, the growing trend of application size, etc. and these problems cannot be addressed solely by dropping in more DRAM. Instead, our work aims to improve the efficiency of Android's memory management.

5 Our Solution: Acclaim

With the understanding of the four observations leading to a high number of page re-faults and direct reclaims, we proposed Acclaim, foreground aware and size-sensitive reclaim scheme, which includes two parts. The first part, foreground aware eviction (FAE), is used to solve the problem that background applications keep consuming free pages. FAE takes space from background applications and allocates it to the foreground application. The second part, a lightweight prediction-based reclaim scheme (LWP), is used to reduce the reclaim size of the background reclaim and thus minimize its latency. LWP tunes the size and amount of the background reclaims according to the predicted allocation workloads. In summary, FAE decides from where to reclaim, while LWP decides how much to reclaim.

5.1 Foreground Aware Eviction (FAE)

The memory is always not large enough to eliminate all page re-faults and direct reclaims. Both the number and size of applications increase with memory capacity [38]. Moreover, when the memory capacity increases, mobile device manufacturers often make optimizations, such as locking commonly-used files [3] and pre-loading predicted applications [31] in the memory. All these optimizations consume free memory.

Since the memory size is limited, the total page re-faults can be hardly reduced. The reduction of page re-faults of the foreground application can have a major impact on the user experience of mobile devices or other highly-interactive systems. Thus, we propose to reduce the page re-faults of foreground applications by sacrificing space from background applications. Foreground aware eviction (FAE) is proposed to lower the priority of background pages in LRU lists, causing them to be evicted faster and thus freeing more memory space.

5.1.1 Framework of FAE

The framework of FAE is shown in Figure 9. FAE needs to know whether a page belongs to background applications. Each application has a unique ID (UID). Once an application is installed, its UID is fixed. The UIDs of user applications are added to Page Table Entry (PTE). PTE is only accessible during the page walk process through the page walker. User applications will not be able to access these UID bits as this is handled by OS or hardware. The page's UID is used by FAE during the eviction procedure. Currently, only 8 unused bits of each PTE (the 56th to the 63rd) can be used to store UIDs. Thus, Acclaim only supports 256 unique UIDs at a time, which is an implementation limitation.

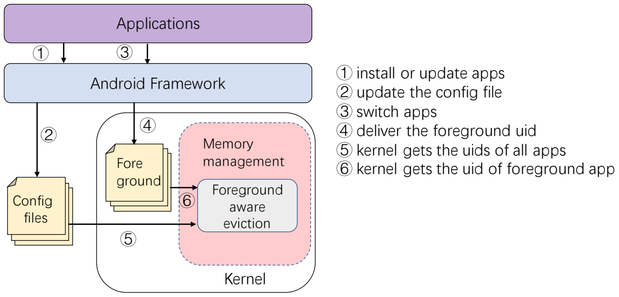

Figure 9: Framework of foreground aware evict scheme.

There is only one foreground application at a moment but there could be several background applications. This list of all background applications can be obtained by subtracting the foreground application from an application list. The main task of FAE is to create a list of background applications and lower their priority compare to the foreground task. To do this, FAE stores the UIDs of applications in the application list in a configuration file. This file will be updated when installing or deleting applications. To identify the current foreground application. FAE notifies the UID of the foreground application to the kernel when users switch applications. Based on the UIDs of applications in the application list and the UID of the foreground application, the system can then lower the priorities of all other applications' pages in LRU lists.

By default, Acclaim deprioritizes all background user applications by assigning them lower priorities in page eviction. To accommodate a small number of applications that keep serving the users in the background, e.g. music or video players, Acclaim can treat them as exceptions without degrading their priorities by excluding them in the application list.

5.1.2 Lower Priority of Background Applications

Initially, we tried to raise the priorities of foreground applications' pages or system's pages. However, this method maintains too many useless pages of foreground applications and the system in memory because of their higher priorities. These useless pages may lead to OS crashes when free memory is used up. Thus, FAE chooses to lower the priority of pages of background applications. Under this scheme, the priority of foreground applications' pages and the system's pages will not be changed. Their useless pages will be evicted from memory and thus free memory will not be used up to crush OS. The details are shown in Figure 10.

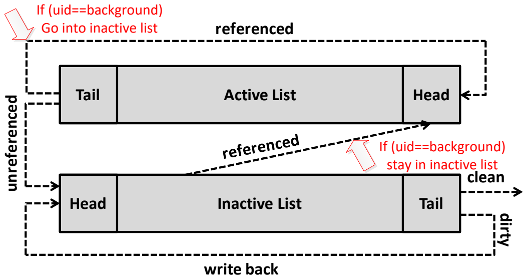

Figure 10: Foreground aware evict scheme of LRU lists.

Page movement between the "active" and the "inactive" LRU lists is driven by memory pressure. Unused pages in the active list go to the inactive list. Pages are taken from the tail of the inactive list to be freed. If the page has the reference bit set, it is moved to the head of the active list and the reference bit is cleared. If the page is dirty, writeback is commenced and the page is moved to the head of the inactive list. FAE lowers the priorities of background pages (See Figure 10) and moves them out of LRU lists quickly. Thus FAE can extract space from background applications for foreground applications and thus to reduce the foreground page re-faults.

Sharing pages have the same priority as their creators. To reduce dynamic-conversion overhead, a sharing page maintains the UID of the application that created it. Thus, the sharing page gets the priority according to the status of its creator. For example, let us assume page A is shared by application D and E. D creates page A first and D is in background while E is in foreground. If page A is not used for a long time, it will be likely to be evicted because its owner is in the background list and thus has low priority. However, if page A is used frequently, A will remains in the memory. Acclaim does not move the application's pages when it is changed from background to foreground and vice versa. Acclaim only checks page's UID and moves a page when it needs to be moved under the default eviction scheme (See Figure 10).

With FAE, the re-launch time of background applications can increase because their pages are out of LRU lists. However, this penalty is much smaller compared to the baseline scenario where these background applications are killed by the Android low memory killer (LMK) [1, 28]. Moreover, the penalty of FAE can be minimized by combining it with application prediction [8, 27, 31]. If the system predicts a background application will be used soon, FAE removes these applications from the background list, and thus does not decrease the priorities of its pages in the LRU lists.

Additionally, FAE is compatible with LMK. For example, FAE can further categorize background applications. Background applications that may be used in the near future can donate some of their memory space with Acclaim while background applications may not be used again can be killed by LMK when memory is getting full.

We expect FAE to benefit impromptu, short interactions (checking and replying instant messages, or switching among applications within a short time span). FAE recognizes them as foreground applications and optimizes them accordingly.

5.2 Lightweight Prediction-Based Reclaim Scheme (LWP)

The original reclaim size of each background reclaim is the maximum number of requested pages until the time of the reclaim. From Section 4, we find that the current reclaim size is too large for the allocation requests of mobile devices. Large-size reclaim induces a high number of page re-faults and direct reclaims. However, there is a trade-off between the reclaim size and performance. If the reclaim size of the background reclaim is too small while the application workloads are heavy, the free pages will be consumed quickly and the heavy-weight direct reclaim will be triggered, lowering performance. On the other hand, if the reclaim size of the background reclaim commands is too large, page re-faults and direct reclaim will happen frequently and, again, degrades overall performance. Thus, we incorporate a workload-prediction based reclaim scheme into our design by incorporating the historical information obtained through a lightweight predictor (See Section 5.2.1). Based on the predicted results, the system can tune the reclaim size of the background reclaim. Another challenge can occur if we reduce the reclaim size according to each workload. In this case, the number of reclaim operations can increase while the amount of reclaimed pages remain unchanged, and thus reducing reclaim size will waste CPU time. To solve this problem, we incorporate the amount of reclaiming pages to dynamically tune the size according to the predicted workloads.

5.2.1 Framework of LWP

LWP consists of two parts, a lightweight predictor and a moderator. Its framework is shown in Figure 11. The lightweight predictor is run during the page allocation procedure. To reduce memory overhead, the sampled allocation requests as inputs are stored in the lightweight predictor. The outputs of the lightweight predictor are the predicted reclaim size and the trend of reclaim amount. The moderator modifies the reclaim size and the amount of the background reclaim according to the predicted reclaim size and the amount trend.

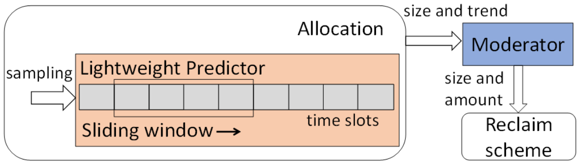

Figure 11: The framework of LWP reclaim scheme.

5.2.2 Lightweight Predictors (LWP)

Using recent information processed by a sliding window to predict the future workloads is commonly applied for prediction [24] [8] [25]. The challenge is how to implement a lightweight predictor. Recent information-based prediction should make sure the correctness of stored information. Page allocation procedure supports concurrency, thus the sliding window needs to guarantee correctness by using locks which will greatly degrade the performance. To predict allocation workloads including size and frequency, the system needs to store the size and time of historical allocation requests. However, storing all historical information precisely will occupy significant space and CPU time and thus degrade the overall performance. To reduce the overhead, the proposed predictor is designed as a lock-free sliding window, and it only stores limited historical information.

Limited historical information. To reduce the stored information, the sliding window is carefully designed in two aspects. First, the sliding window is designed based on time slots to avoid storing the time information. Second, the sliding window stores sampled historical information to reduce the amount of stored information. Each element of the sliding window is the allocation size of a sampling allocation request. For example, when the sampling period equals 10 *ms*, the predictor will pick one of allocation requests that happened in this 10 *ms* and add its allocation size to the sliding window.

Lock-free sliding window. We first analyze the impact of being lock-free on the sliding window. When the window is lock-free, the following three things could happen. (1) Data disorder and data missing could occur; (2) When the predictor samples the historical information, the penalty of being lock-free reduces as there are fewer access to locks; (3) Being lock-free does not affect the system consistency as we only use it to store the memory historical information. We further evaluate the accuracy of the lock-free and sampling predictor. Let sampling = 10 *ms*, sliding = 10 *ms*, and window = 1000 *ms*, to get the sum of the reclaim sizes in a window. To compare three cases, the log of sum value is shown in Figure 12 as the sum in the sampling and lock-free cases are much smaller than that in the lock-free only case and original cases. Three usage behaviors, launching Chrome, launching YouTube, and launching and using five applications, are evaluated. The x-axis is the index of the sliding window. The y-axis is the log of the sum of the reclaim sizes in a window. We use vertical red lines to show the trend changes in the first figure. The results show that the lock-free and sampling case captures the same trend as the original case. (For using the ACFYT case, too much data makes the trend of the sampling case not obvious. It's trend also same as the original case.) Thus, the lightweight predictor can predict the trend of the amount of allocation requests in the next window correctly. In this way, prediction can be achieved with a low overhead in both storage and latency.

5.2.3 LWP-Based Moderator

The moderator is used to tune the reclaim size and amount of the background reclaim according to the predicted results.

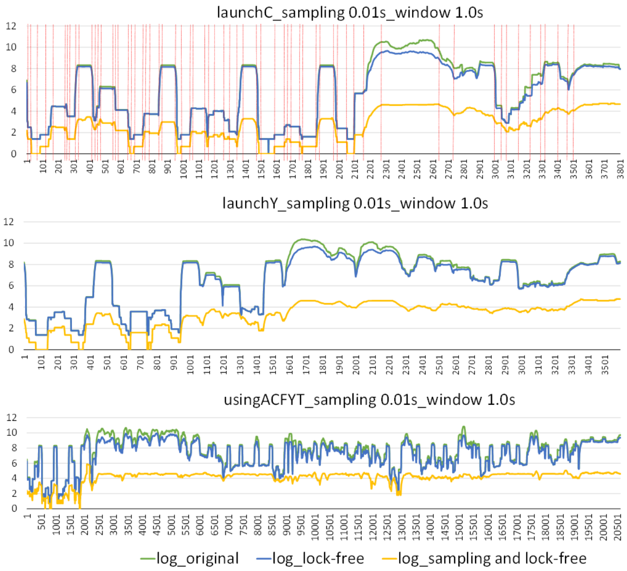

Figure 12: Predicted sum trend of reclaim sizes in the lock-free and sampling sliding window.

The reclaim amount of the background reclaim could be tuned by modifying its stop setting ($watermark_{high}$). The original background reclaim will stop when the number of free pages is above the $watermark_{high}$, which is a fixed value (a proportion of the total number of pages). The original reclaim size of each background reclaim is the maximum number of requested pages until the time of the reclaim. To exploit the trade-off between reclaim size and performance, the LWP base moderator tries to make the background reclaim reclaims just enough free pages just in time. The main idea is to tune the reclaim size of each background reclaim according to the predicted allocation size and tune the $watermark_{high}$ according to the predicted sum trend. "sum trend" is defined as sum/lastsum, where "sum" is the sum of the reclaim sizes in the current window and "lastsum" is the sum of the reclaim sizes in the last window. For the reclaim size, if the trend is larger than a threshold T_1, that means the amount of allocation in the future will be much increased. Thus, the reclaim size should be increased.

- Reclaim size = $P_1 * predicted\ size$ when $trend \geq T_1$
- Reclaim size = $P_2 * predicted\ size$ in other cases, $(P_2 < P_1)$

For the reclaim amount, the moderator tunes the amount of reclaim based on the default value that is set by the mobile device manufacture.

- Reclaim amount = $min(watermark_{high} * (1 + trend), watermark_{high} + T_2)$ when $trend > 1$
- Reclaim amount = $max(watermark_{high} * (1 - trend), watermark_{low})$ in other cases

Reclaim amount is limited. If it is smaller than the default $watermark_{low}$, the performance will be degraded because direct reclaim will be triggered often.

Table 4: Summary of parameters used in LWP.

Symbols	Semantics	Default values
P_1	Amplification factor of reclaim size when I/O is intensive.	4
P_2	Amplification factor of reclaim size when I/O is sparse.	2
T_1	Defines “sudden change” and thus decides the reclaim size.	2
T_2	A threshold to stop background reclaim.	$watermark_{high} - watermark_{low}$

6 Evaluation

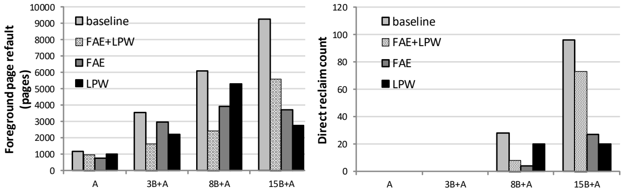
To evaluate Acclaim, we set sampling duration to 10 *ms*, window duration to 100 *ms*, sliding duration to 100 *ms* for sliding window of LWP. Both memory overhead and the predict accuracy of LWP are sensitive to these three parameters.

Moreover, we set the parameters for LWP-based moderator in Table 4. Reclaim size should be larger than the predicted allocation size to avoid memory once heavy workloads are arriving. However, according to the analysis in Section 4, reclaim scheme should not be over aggressive on mobile devices. Thus, we choose small values (4 and 2) as amplification factors (P_1 and P_2) under different workloads.

Furthermore, T_1 determines the sensitivity to the increment in workloads. We configure Acclaim to be sensitive to changes in workloads and responds in time, thus we choose a relatively small value (2). T_2 is the threshold that ensures that the reclaim amount is not too large. Like the default $watermark_{high}$, it is an empirical value. We evaluate Acclaim on three aspects: impact on foreground applications, impact on background applications, and overhead.

6.1 Impact on Foreground Applications

Reduction in page re-fault for foreground applications and direct reclaim of OS. Page re-fault and direct reclaim are closely related to user behaviors. To compare the solution and baseline, we need to choose an application with little change in user behaviors. Thus, a single game, AngryBird, is used as a foreground application for five minutes in this evaluation. The page re-fault and direct reclaim results under the kernel with the original reclaim scheme and the kernel with our solution are shown in Figure 13.



(a) Page re-fault.

(b) Direct reclaim.

Figure 13: The page re-faults in a foreground application (AngryBird) and direct reclaims in the whole OS, showing the benefit of each solution is different in various scenarios.

The results demonstrate the efficacy of Acclaim. For the benchmark (AngryBird), Acclaim reduces page re-faults by 16.3% – 60.2%; it reduces direct reclaims of the whole OS by from 23.9% – 70%. In the experiments, the proposed two techniques play vital, complementary roles. FAE shows higher benefits as the number of background applications increases, as it seizes free pages from background applications to relieve memory pressure. LPW's benefit depends on the accuracy of its prediction, based on which it dynamically tunes the background reclaims. Notably, in case of sudden changes in application workloads, LPW may suffer from accuracy loss and thus underperforms.

Benefit to read/write performance. Reduction in page re-faults and direct reclaims could improve read and write performance. To quantify the impact on read and write operations, we show the read and write performance by using read and write micro benchmarks, [4] and the results are shown in Figure 14. Since most page allocation request sizes on mobile devices are in the size of 4KB [10], we write or read 512MB or 1GB of data in size of 4KB.

This may not be a typical write access pattern, it could happen in some cases. For example, when installing games and applications, more than 1GB of an apk file could be downloaded and written back to flash storage. Moreover, this is a stress test to show Acclaim's benefit under intensive I/O requests. Thus, these evaluation results show the performance impact under intensive I/O requests.

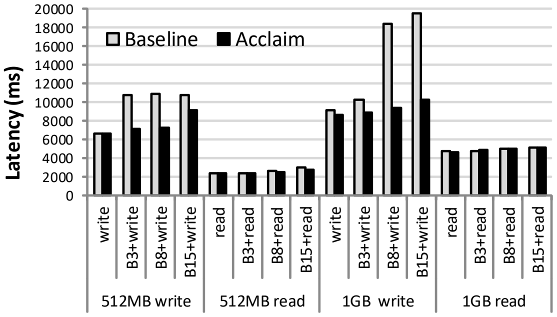


Figure 14: Read and write performance.

The results show that Acclaim improves write performance by up to 49.3% (when writing 1GB of data). This is because page allocation, which Acclaim optimizes, constitutes a significant portion of the delay in writes because of the write-back operations of dirty pages. The read performance is only improved slightly as the latency of page allocation is only a small part of read latency in this set of test cases as no dirty pages are generated and written back during reads.

[4] https://github.com/MIoTLab/Accliam

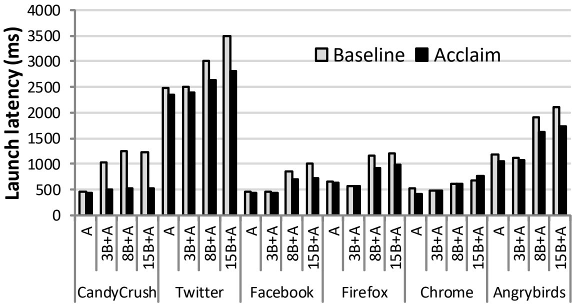

Figure 15: The launch latency of foreground applications.

Benefit to user experience in application launch. To quantify the impact on user experience, the launch time of various foreground applications are evaluated. The evaluation results are shown in Figure 15. The results show that the launch latency improvement varies for different applications. The benefit of Acclaim is more pronounced when an application is launched with multiple memory-hungry applications in background. For example, the launch latencies of CandyCrush and Facebook are reduced by up to 58.8% and 28.8%, respectively. Acclaim can have negative impact when foreground and background applications share common files. For example, the launch latency of Chrome could be prolonged up to 12.3% by Acclaim when there are many background applications. This may because Acclaim evicts common files between background applications and Chrome [3]. However, this penalty can be eliminated by combining with mlocking common files [3]. In summary, Acclaim outperforms the baseline in most test cases. Of all the 24 test cases, it reduces latencies in most of them (20, with median reduction of 19.1% and max reduction of 58.8%) while incurring additional latencies in 4 (with median increase of 3.1% and max increase of 12.3%).

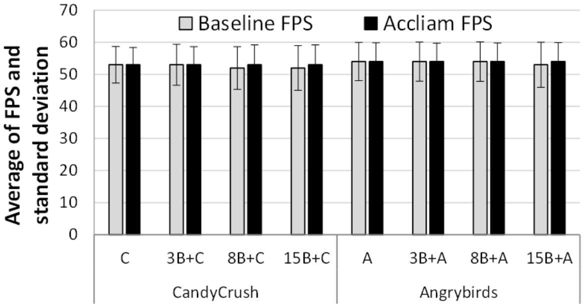

Figure 16: Average FPS and the standard deviation of FPS of foreground applications.

Impact on FPS during active user interactions. Acclaim reduces the launch latency by employing policies on how application uses the memory to cache files. This policy might impact user experience negatively after application launch, as launched applications will have a different amount of data in page cache. Thus, we measure the possible loss in user experience as FPS in KFMARK, a popular gaming benchmark. [12]. The average FPS and the standard deviation of FPS of foreground applications are shown in Figure 16. For the average FPS, the larger the value, the better. While the smaller the value, the better for the standard deviation of FPS. The results in Figure 16 suggest no noticeable impact: the difference between the mean values of the baselines and Acclaim are smaller than their standard deviations.

6.2 Impact on Background Applications

Because Acclaim evicts more pages from background applications, it can negative these applications' re-launch time. We evaluate the re-launch time for the first-launched background application to show the upper bound of the penalty. In this evaluation, we use Facebook as the first launched background application is evaluated when it is launched for one or ten minutes, and the results are shown in Figure 17.

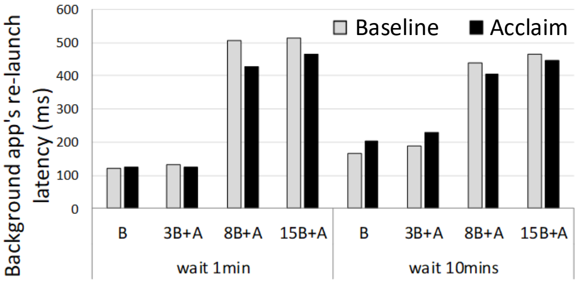

Figure 17: Re-launch time of the first-launched background application (Facebook).

Based on Figure 17, we observe that re-launch penalty only occurs when there are a few background applications after ten minutes. In most cases, the benefit is larger than the penalty. When there are many background applications, Acclaim effectively seizes free pages from background applications, which can be used to aid background applications' re-launch process. Moreover, Acclaim also reduces the number of direct reclaims, benefiting all applications. When the time during which the application is used after it is launched is too short (one minute), Acclaim may not have enough time to move out of the evaluated background application's pages. After system starts, many applications are partially run in the background even if the user does not use them. To this end, their pages will be firstly evicted from LRU lists by Acclaim.

Additionally, notice that the penalty of Acclaim can be eliminated by using it in combination with application prediction [8, 27, 31]. If a background application is predicted as the next used application, Acclaim removes it from the background application list in FAE, and thus the priority of its pages will not be degraded in LRU lists when it is in background. Thus, the penalty will be eliminated.

6.3 Overhead Analysis

Additional memory overhead. FAE adds a uid to PTE, incurring a space overhead of an integer space (4 Bytes). For a device with 3GB of memory, the maximum memory overhead is 3MB. Moreover, FAE needs to store the uids of applications in the application list. If a user installs 100 applications, the total memory cost is only 0.4 KB.

LWP needs to store the sampling historical allocation size (4 Bytes per entry). When the sampling duration is 10 *ms* and the window is 100 *ms*, only 10 values need to be stored. Even if there are 100 values in the window, the LWP only takes up 400B storage overhead. In summary, the total memory overhead is about 3MB (0.1% of memory capacity).

Performance overhead. FAE's performance overhead can be broken down into three parts. First, after system starts, it needs to check the configure file to get the UIDs of the applications. It only happens when the system starts. Second, when the user switches applications, the new foreground UID needs to be delivered to FAE from the framework layer. Third, FAE needs to check if the UID equals to one of the background applications during each page eviction. Only a few comparisons are conducted, thus the performance overhead is negligible.

The performance overhead of LWP includes two parts. First, prediction has a small cost because of the lock-free sliding window. Second, reducing the reclaim size could prolong the wake up time of the background reclaim . However, LWP dynamically tunes the amount of background reclaim according to the allocation workloads to reduce the CPU time consumption. In summary, the performance overhead of Acclaim is trivial.

7 Related Work

Application launch. Existing studies on context-awareness led to the development of application pre-loading algorithms [8, 27, 31]. These algorithms greatly reduce the application launch latency by preparing required resources before they are requested.

Application foreground/background behaviors. Many mobile applications are designed to run in background to enable a model of always-on connectivity and to provide fast response time. This means that once installed and initiated by the user, applications can register themselves with the services provided by the OS framework for background activities, regardless of the user's actual usage of the app. This is true of both iOS and Android OS [4, 7, 26].

Memory management. Many previous works were focusing on the design of the buddy system for managing memory. Burton [6] proposed a generalized buddy system. By using the Fibonacci numbers as block size, Knuth [17] proposed the Fibonacci buddy system. Moreover, this idea was complemented by Hirschberg [15], and was optimized by Hinds [14], Cranston and Thomas [11] to locate buddies in time similar to the binary buddy system. Shen and Peterson [36] proposed the weighted buddy system. Page and Hagins [30] proposed the dual buddy system, an improvement to the weighted buddy system, to reduce the amount of fragmentation to that of the binary buddy system. A buddy system designed for disk-file layout with high storage utilization was proposed by Koch [18]. Brodal et al. [5] improved the memory management for accelerating allocation and deallocation. Marotta et al. [22] proposed a non-blocking buddy system for scalable memory allocation on multi-core machines. Yu et al. [21] show that the existing reclaim scheme is not working well for Android mobile devices. Consequently, this paper proposes a new smart reclaim scheme for Android mobile devices.

Mobile device-specific memory management. Due to mobile OSes have poor insight into application memory usage, the memory allocation may take a long latency, especially under memory pressure. Marvin [28] implements most memory managements in the language runtime, which has more insight into an app's memory usage. They target the same problem at a different layer. By predicting allocation workloads and with foreground and background information, Acclaim improves memory management efficiency at the system level.

8 Conclusion

Existing Linux memory reclaim scheme is designed for servers and PCs. Android inherits Linux kernel and thus the memory reclaim scheme is transplanted to mobile devices. The experimental results show that these algorithms become less effective for the characteristics of applications running on Android mobile devices due to two main reasons. First, background applications has less impact on the user experience than foreground applications. However, they continually consume free pages that increase the frequency of page re-fault and direct reclaim. Second, the large-size reclaim aggravates this problem on mobile devices which involve with almost exclusively small allocation requests. In this work, we propose Acclaim. Acclaim consists of the Foreground aware eviction (FAE), which is designed to relocate free pages from background applications for foreground applications, and the lightweight prediction-based reclaim scheme (LWP), which is used to dynamically tune the size and amount of the background reclaim according to the predicted allocation workloads. Evaluation results show that Acclaim improves the performance in general with a trivial overhead.

Abstract

The Bluetooth Low Energy (BLE) is a promising short-range communication technology for Internet-of-Things (IoT) with reduced energy consumption. Vendors implement BLE protocols in their manufactured devices compliant to Bluetooth Core Specification. Recently, several vulnerabilities were discovered in the BLE protocol implementations of a few specific products via a manual approach. Considering the diversity and usage of BLE devices as well as the complexity of BLE protocols, we have developed a systematic and comprehensive testing framework, which, as an automated and general-purpose approach, can effectively fuzz any BLE protocol implementation. Our framework runs in a central device and tests a BLE device when the latter gets connected to the central as a peripheral. Our framework incorporates a state machine model of the suite of BLE protocols and monitors the peripheral's state through its responses. With the state machine and current state of the central, our framework either sends malformed packets or normal packets at a wrong time, or both, to the peripheral and awaits an expected response. Anomalous behaviours of the peripheral, e.g., a non-compliant response or unresponsiveness, indicate potential vulnerabilities in its BLE protocol implementation. To maximally expose such anomalies for a BLE device, our framework employs an optimization function to direct the fuzzing process. As of today, we have tested 12 devices from eight vendors and four IoT products, with a total of 11 new vulnerabilities discovered and 13 new Common Vulnerability Exposure (CVE) IDs assigned. We call such a bunch of vulnerabilities as SWEYNTOOTH, which highlights the efficacy of our framework.

1 Introduction

The Bluetooth Low Energy (BLE) is one of the key wireless communication technologies behind the massive progress of internet-of-things (IoT). Hence, vulnerabilities in the BLE protocol implementation may lead to concrete and serious aftermath. For instance, through reverse engineering on Broadcom's BLE System-on-Chip (SoC) devices, Mantz et al. [24] performed remote code execution in the device's functions with a malformed over-the-air packet. Similarly, BleedingBit [15], discovered in Texas Instruments BLE SoCs, allows adversaries to install a shellcode, which thereafter permits remote execution and authentication bypass upon receiving specific sequences of manipulated advertisement packets.

The preceding examples indicate that faulty BLE protocol implementations may exist in various IoT devices and potentially bring about chaotic consequences. In this paper, we propose a systematic and automated fuzzing framework that is able to discover vulnerabilities in the BLE protocol implementation of any device. Our framework neither requires access to the source code of an implementation nor changes a single line of code in a device's OS or firmware. In a nutshell, it runs in the user space of a customized BLE dongle (i.e., central) to test a BLE device (i.e., peripheral) during the process of establishing a connection between the two.

The essence of our framework is a fuzzer that systematically subjects the BLE implementation to adversarial conditions. However, it is non-trivial to develop a fuzzer to generate such adversarial conditions. Firstly, we construct a BLE state machine model from the Bluetooth Core Specification [36–38] to make valid BLE packets. This is essential, as a randomly generated, meaningless packet is likely to be rejected by any BLE implementation. Secondly, testing a BLE implementation with valid BLE packets is improbable to reveal flaws, because such compliant cases should have been covered in manufacturing tests [22, 41] as well as in Bluetooth stack certification [39]. Thus, our framework either sends malformed packets based on mutation, or normal packets at a wrong time or inappropriate state, or both, to a BLE peripheral. Through manipulating packets, our framework intends to bring on adverse *corner cases*. Thirdly, the complex structure of BLE packets (cf. Figure 1) and the versatile communication regulations necessitate a comprehensive and directed strategy for generating test cases of packets and

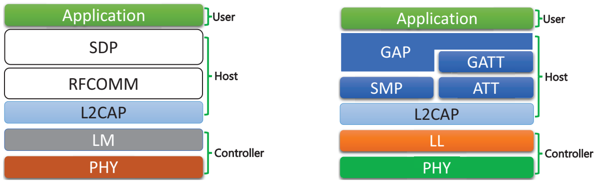
[*] This work was partly done when C. Wang worked at SUTD.

their timings. This aims to drive and stress non-compliant behaviours at the peripheral. To this end, our fuzzer mutates fields of a layer in the BLE stack and employs a particle swarm optimization (PSO) to heuristically refine the mutation probability distribution at both dimensions of each protocol's layers and each layer's fields. Finally, our framework validates any response from a peripheral on-the-fly according to a set of expected packets in each protocol state. This enables it to detect security issues beyond crashes, e.g., security bypass.

Our framework distinguishes itself from existing works [6, 15, 24] in view of being automated and comprehensive. Existing works require manual and tedious efforts, such as reverse engineering and attentive inspection of source code, to discover potential security flaws in the BLE implementation of specific devices [34]. By contrast, our framework is fully automated and embraces the capability to uncover more security issues than a manual approach. Concurrently, although a few scattered approaches have been presented in fuzzing Bluetooth devices [3, 9, 11, 18], they only cover a fraction of the Bluetooth stack. To the best of our knowledge, we compose the first comprehensive approach for BLE fuzzing that is not limited to one or several particular layers, e.g., L2CAP or ATT [3, 11], but fully controls the communication at the Link Layer (LL) as well as the interaction with the Secure Manager Protocol (SMP) for encrypted message exchanging. This, in turn, establishes the efficacy and viability of our framework in fuzzing arbitrary BLE protocol implementations.

The remainder of this paper is organized as follows. In particular, we present the following contributions.

- We present our fuzzing framework to discover implementation flaws for BLE protocols (Section 2).
- We present the optimization process embodied in our fuzzing framework to discover critical security vulnerabilities. We also discuss the systematic process of validating responses from BLE peripheral (Section 3).
- We discuss the implementation specific challenges in our approach and evaluate our fuzzing framework on several commodity BLE SoCs, including SoCs from NXP, Dialog, Texas Instruments, Microchip, ST Microelectronics and Cypress, among others. Our evaluation has revealed 11 unknown security vulnerabilities (nicknamed SWEYNTOOTH) and seven non-compliant behaviours. 13 new common vulnerability exposure (CVE) IDs are assigned and they potentially affect a few hundred types of IoT products. As all the vulnerable SoCs have passed the Bluetooth stack certification, our evaluation also clearly highlights the incompleteness of the certification process (Section 4).
- We evaluate the impact of new vulnerabilities, as discovered by our framework, on four IoT products (Section 4).
- We compare our framework with three other fuzzers and show that our framework is significantly more effective, in terms of finding security vulnerabilities in BLE implementations (Section 4).



(a) Classic (b) BLE

Figure 1: The Stacks of Bluetooth Classic and BLE

After discussing related work (Section 5), we conclude the paper and provide future directions (Section 6).

2 Overview of Our Framework

BLE is the successor of Bluetooth Classic to build a short-range wireless network with reduced energy consumption and improved usage capability. In this section, we first describe the BLE model used in our fuzzing and illustrate the challenges in developing a systematic fuzzing framework for BLE protocols with an example. Then we present an overview of our framework with its main components and workflow.

2.1 The Model of BLE Protocols

We aim to detect *implementation* flaws in BLE protocols defined in the Bluetooth Core Specification [36–38]. Particularly, we study the interactions on Attribute Protocol (ATT), Logical Link Control and Adaptation Protocol (L2CAP), Secure Manager Protocol (SMP), and Link Layer (LL), as shown in Figure 1. L2CAP and ATT are common to both Bluetooth Classic and BLE, while LL and SMP are exclusive to BLE.

Figure 2 illustrates the process of establishing the BLE connection between a central and a peripheral. Our fuzzer works during this process and it is guided by a BLE protocol model we have developed. A simplified representation of the model is presented in Figure 3. Initially, the peripheral periodically broadcasts `advertisements` to nearby devices and the central starts in the `scanning` state. The central scans for such `advertisements` and gets further information from the peripheral such as its name by sending a `scan request` (① in Figure 2). After receiving a `scan response` (② in Figure 2) from the peripheral, the central can choose to start a connection by sending a `connection request` (③ in Figure 2) and proceeds to the `connection` state. On receiving an acknowledgment from the peripheral (④ in Figure 2), the central proceeds to the `initial_setup` state (see Figure 3). As the `connection request` contains connection parameters relevant to the synchronization and communication timing between central and peripheral, after transiting to `initial_setup` state, the central requests information from the peripheral by sending `version request`, `feature request`, `length request` and `MTU length request` (⑤ to ⑧ in Figure 2) with the intention to know the peripheral's

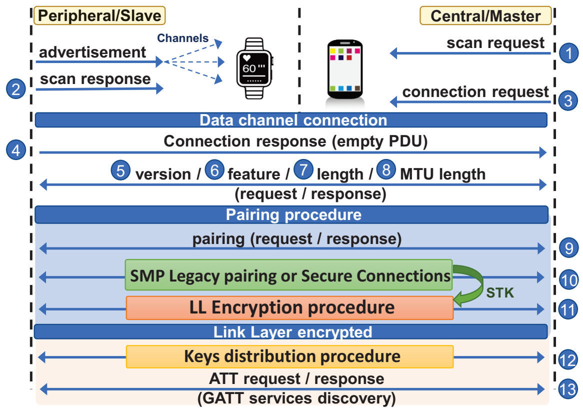


Figure 2: Message exchanges during BLE connection process

supported LL features and capabilities such as the maximum length of the packet it can send or receive. Likewise, the peripheral also gets the central's LL information during the same exchanges. Note that the preceding messages are not necessarily sequentially exchanged, because vendors are free to implement how the peripheral handles such messages. For instance, a peripheral may reply to `version` before `feature`. Similarly, the peripheral may choose to directly read some ATT atributes from the central and go to the `gatt_server` state or skip the state `length` before proceeding. To ensure compatibility with different implementations, we employ several transitions in the state `initial_setup` for the flexible message ordering, as shown at the upper-left of Figure 3.

After the initial setup is done, the central proceeds to the `list_pri_services` state. Here it scans for peripheral's main services via the Generic Attribute Profile (GATT) Service Discovery procedure and stores their attributes in a local array. The central then proceeds to the state `pairing_req` and starts to establish an encrypted communication with the peripheral. The central sends a `pairing request` packet to the peripheral (⑨ in Figure 2), indicating the preferred pairing mode to be used in the next state. If the peripheral accepts the pairing mode proposed by the central, it replies to the central and both proceed to the `smp_pairing` state. As there are two pairing modes for them to choose, i.e., the Legacy pairing or Secure Connection (SC) pairing via SMP exchanges, they go through the pairing procedure from either the `legacy_pairing` or `sc_pairing` state, as shown at the middle-right of Figure 3. Once the pairing procedure is successful, the central derives a `sessionKey` from a Short Term Key (STK) received from `smp_pairing`, transits to the `ll_encryption` state and starts the challenge with the peripheral by sending an `encryption_req` (⑩ in Figure 2). With the peripheral's response, the central sends an encrypted `encryption_res` packet by using the obtained `sessionKey`. If the peripheral is able to correctly authenticate and decrypt the `encryption_res` from the central, it sends another encrypted `encryption_res` to the central, indicating that the connection is successfully encrypted.

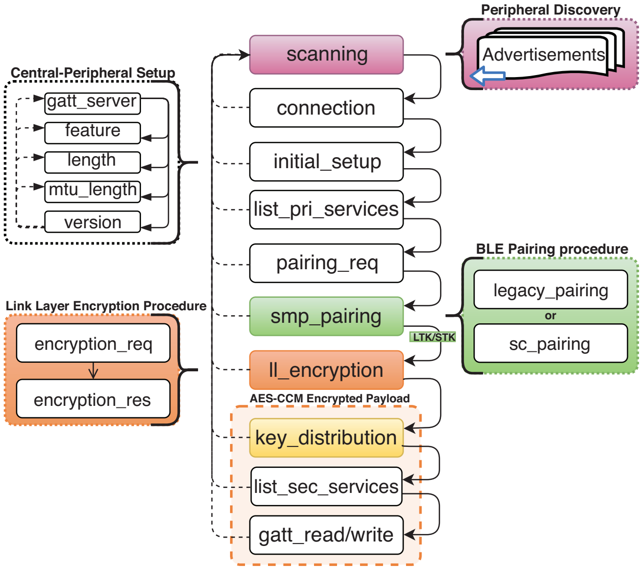

Figure 3: Simplified BLE Protocol Model

If `legacy_pairing` is used, the central and peripheral may optionally go through the `keys distribution procedure` (⑫ in Figure 2) to exchange a long term key (LTK).Otherwise, in `sc_pairing`, the LTK is the STK instead. The LTK can then be used by the central to avoid repeating the pairing process in subsequent connections and directly go to the step ⑪ in Figure 2. In the following stages, the central and peripheral exchange an LTK based on what has been negotiated in `pairing_req` and the central reads more services from the peripheral at the state `list_sec_services`.

After LL connection and pairing, the central discovers all the peripheral's available attributes (i.e., information) by performing the GATT Primary Service Discovery. This consists of sending and receiving a number of `ATT requests` and `ATT responses` (⑬ in Figure 2). so as to fetch predefined ATT attributes. In the next state `gatt_read/write`, we capture the read and write of locally stored ATT attributes at the `list_pri_services` and `list_sec_services` states. This step is to emulate writing malformed ATT attributes via our fuzzing methodology. Thus, the state `gatt_read/write` at the bottom of Figure 3 is not part of the BLE protocol specification. However, it is required to check the behaviour of a peripheral in the presence of malformed ATT attributes.

2.2 Problem Formulation with An Example

In this paper, we consider developing a systematic fuzzing framework that is 1) comprehensive with respect to all BLE stack layers, 2) directed as being with an optimization mechanism to maximally expose anomalies in BLE protocol implementations, and 3) applicable to fuzzing any product embracing BLE SoCs for wireless connectivity. Anomalous behaviours capture non-compliance against the Bluetooth Core Specification. To guarantee the comprehensiveness of cov-

ering all protocol layers, we attentively study the Bluetooth Core Specification and incorporate an all-inclusive state machine model as presented in Section 2.1 at the central side. Thus, at the current state of the central, we monitor responses from the peripheral to check whether they are aligned with the Bluetooth Core Specification or not.

Technical Challenges: Section 2.1 indicates that devising a comprehensive state machine model itself is the first challenge due to the complexity of BLE connections. As shown in Figure 1, each of the BLE layers contains multiple fields that might be an exploitable factor. Furthermore, compared to Wi-Fi, BLE allows *move-back* and *move-forward* state transitions if a timeout event occurs and an expected response arrives, respectively. This also introduces the second challenge, i.e., the timing-critical constraints that must be accounted for fuzzing BLE SoCs. Thirdly, an online validation of peripheral responses is non-trivial at the central side. According to the Bluetooth Core Specification, at a given state, the central waits for two types of responses, i.e., normal responses and failure responses. The latter is a valid response, as a well-formed peripheral has the right-of-way to deny any illegal or unaligned request. Such a feature, again, does not exist in Wi-Fi protocols. Consequently, special care is demanded to distinguish expected and anomalous packets in the context of BLE communications. Last but not the least, uncovering vulnerabilities in BLE implementations requires systematically directing the fuzzing framework. In the following, we take an example vulnerability, i.e., *Key Size Overflow* (*CVE-2019-19196*) discovered by our framework, to illustrate how we resolve the aforementioned challenges.

Discovering* Key Size Overflow *Vulnerability: The *Key Size Overflow* vulnerability is caused only if the three following conditions are jointly satisfied: 1) `key_size` field of `SMP pairing request` is fuzzed, 2) the peripheral receives a certain packet in an inappropriate state, and 3) the peripheral may send a connection failure packet depending on the received fuzzed packet. The vulnerability is illustrated in Figure 4.

In brief, as a fuzzer, our framework mutates protocol layers and each layer's fields in a packet sent from the central to the peripheral under test. The mutation is based on probabilities assigned at both dimensions of layers and fields. It refines such probabilities via a cost function with a return value, say, the count of discovered anomalies, to direct the fuzzing process. Our framework identifies an anomaly by validating received responses. It discovers *Key Size Overflow* as follows. Initially, there is no information about the vulnerabilities. Therefore, the mutation probabilities are randomly assigned. Eventually, at the `paring_req` state, the fuzzer sends a `paring_request`, yet with fields other than `key_size` mutated. The peripheral sends a response `SM failure`, which is still deemed to be normal by the online validation of our fuzzer. Next, the fuzzer sends a malformed packet with mutated `key_size`. *Caveat Lector*: the peripheral of Telink Semiconductor unexpectedly replies with a valid `paring_response` for such a fuzzed, invalid request. Our framework legitimately catches this response as an anomaly. As a result, the mutation probability to fuzz the field `key_size` is increased. Thus, more malformed `pairing_request` packets with mutated `key_size` are sent to the peripheral. We note that our fuzzer also sends valid packets, but at an inappropriate state of the client. Eventually, the fuzzer sends an `encryption_request` to the peripheral immediately after the malformed `pairing_request` packets with mutated `key_size`. This crashes the peripheral, as detected due to the lack of any response from it.

To sum up, the `Key Size Overflow` presents an anomaly and a crash for BLE SoCs manufactured by Telink. During the fuzzing process, the scenario to send a malformed `paring_request` (with mutated `key_size`) followed by an `encryption_request` increases. This is because the response to these malformed packets are anomalous and such anomalous responses increase the value of the cost function (i.e., anomaly count). This, in turn, further increases the probability to fuzz `key_size` and indirectly, the likelihood of discovering the scenario causing the vulnerability.

2.3 High Level Workflow

System Architecture: Figure 5 illustrates the architecture of our fuzzer, which is composed of four main modules organized around the BLE model M_{BLE}: (i) the module of packet manipulation that mutates a packet, (ii) the module of packet

Algorithm 1 Main Steps of our fuzzer

```
1:  $i \leftarrow 0$                                  ▷ $i$ captures fuzzing iteration

4:  ▷ wait to receive mutation probabilities from PSO
5:  $X_i$ ←-- Particle_Swarm_Opt()
6:  ▷ initialize history of sent packets and redundant packets
7:  $\mathbb{P}_{hist} \leftarrow \emptyset$, $P' \leftarrow \emptyset$, $P_{dup} \leftarrow \emptyset$, $P^h_{dup} \leftarrow \emptyset$, $S_0 \leftarrow \emptyset$
8:  repeat
9:      Set central to be in scanning state
10:     ▷ assign expected layers
11:     For each $S \in M_{BLE}$, assign $\{expected(S), rejection(S)\}$
12:     repeat
13:         Wait for peripheral's packet
14:         Let the central receives packet $P_r$ from the peripheral
15:         ▷ monitor states and checks anomalies
16:         $(\theta_{anom}, P_r) \leftarrow$ Run_Validation$\left(S, P', P^h_{dup}, P_r\right)$
17:         $S_0 \leftarrow S$; $S \leftarrow$ Get_Current_State($M_{BLE}$, $P_r$)
18:         ▷ exit the iteration on anomalies and no transition
19:         if $\theta_{anom}$ is false or $S_0 = S$ then
20:             goto line 37
21:         end if
22:         ▷ generate a valid packet from the model
23:         $P \leftarrow$ Get_Packet_from_Model($M_{BLE}$, $S$)
24:         ▷ generate fuzzed packets from $P$ via mutation
25:         $P' \leftarrow$ Mutate_Packet($P, X_i$)
26:         Send fuzzed packets $P'$ to the peripheral
27:         $P^h_{dup} \leftarrow P_{dup}$
28:         Choose a packet $P_{dup} \in \mathbb{P}_{hist} \cup \{\emptyset\}$ s.t. $P_{dup} \neq P$
29:         Send redundant packet $P_{dup}$ to the peripheral
30:         ▷ switch expected layers after fuzzing
31:         if $P' \neq P$ then
32:             $expected(S) \leftarrow rejection(S)$
33:         end if
34:         $\mathbb{P}_{hist} \leftarrow \mathbb{P}_{hist} \cup \{P\}$
35:     until central does not reach the scanning state
36:     ▷ measure cost function value for $X_i$
37:     $CF_i \leftarrow$ Measure_Cost_Function($X_i$)
38:     ▷ send cost function value to PSO
39:     Particle_Swarm_Opt() ←-- $CF_i$
40:     ▷ wait to receive new mutation probabilities from PSO
41:     $X_{i+1}$ ←-- Particle_Swarm_Opt()
42:     $i \leftarrow i + 1$
43: until timeout
```

redundancy that sends arbitrary packets of M_{BLE} to the peripheral at unaligned states (i.e., out of order) with the intention to trigger anomalies on the peripheral's protocol state machine, (iii) the module of packet validation that is responsible for checking the responses from the peripheral and detecting anomalies based on the current state of M_{BLE}, and (iv) the module of fuzzing & optimization that can direct the mutation of packets based on a cost function.

As shown by the arrows in Figure 5, the four modules of our fuzzer interact and collaborate with each other to attain the aim of discovering potential vulnerabilities in a peripheral device. Algorithm 1 illustrates the workflow of it.

Initialization: The fuzzer relies on the protocol model M_{BLE} to generate valid packets and a set of mutation probabilities X_i to probabilistically mutate such valid packets. At the initialization stage (Lines 3 to 5 in Algorithm 1), the fuzzer first loads the model M_{BLE} and receives initial mutation probabilities X_i from the optimization module (iv in Figure 5) by calling the Particle_Swarm_Opt function (Line 5). Next, the central is set to the scanning state and proceeds to wait for the peripheral's advertisement (Lines 9, 13 to 14). Once the central receives a packet P_r from the peripheral, the validation module (iii in Figure 5) checks whether P_r is expected or not via the Run_Validation function (Line 16). In short, the validation module decides the correctness of P_r based on a set of expected layers expected(S) or rejection layers rejection(S), which are generated for every state $S \in M_{BLE}$ (Line 11) at startup. The validation is detailed in Section 3.2.

Fuzzing Iteration: If the validation does not detect any anomaly, P_r is fed to trigger the state transition in the model M_{BLE} by calling the Get_Current_State function (Line 17). Get_Current_State strictly follows the protocol model described in Section 2.1 and returns the new state S of M_{BLE}. Then at the state S, our framework generates a valid packet P (Line 23), which serves as an input to the manipulation and redundancy modules (i and ii in Figure 5). Starting with the packet manipulation via the Mutate_Packet function (Line 25), the contents of P are mutated according to the mutation probabilities X_i associated with the state S, resulting in a mutated packet P' (see Section 3 for details of mutation). Due to the probabilistic nature of X_i, the mutation yields either an incorrect packet such that $P' \neq P$ (i.e., malformed) or a mutated packet which doesn't differ from the original packet (i.e., $P' = P$). If a malformed packet P' is sent to the peripheral, the Bluetooth Core Specification allows the peripheral to respond with a packet that rejects P', i.e., one with a layer in the rejection(S). Thus, the fuzzer perceives an anomaly if the response for a malformed P' is other than a legitimate packet with one of its layers in rejection(S). To this end, the expected set of layers (expected(S)) for state S is set to the rejection layers for state S (rejection(S)) (Line 32).

The redundancy module (iii in Figure 5) keeps a history $\mathbb{P}_{hist}$ (initialized as $\emptyset$ at Line 7) of all the packets P generated by the model M_{BLE} (Line 34) and sends a redundant packet $P_{dup} \in \mathbb{P}_{hist}$ to the peripheral at random chance (Lines 28 to 29). The intention of this logic is to send out-of-order packets that may cause crash or anomalous behaviour onto the peripheral. However, using redundancy may trigger some ambiguous behaviour which is not necessarily an anomaly. For example, some BLE packets are not only tied to one single state and responses to them at a different state should not be flagged anomalous by the fuzzer. In Section 3.2, we present how the validation module resolves such challenges and avoids reporting false positives.

The fuzzing iteration finishes in one of three circum-

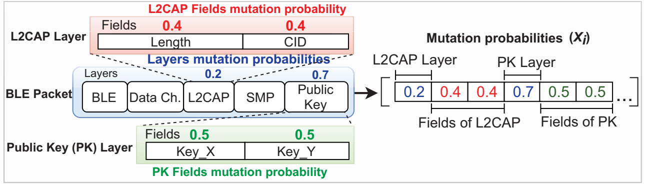

Figure 6: An illustration of our fuzzing. X_i shows the probability values for the packet `public_key` at state S.

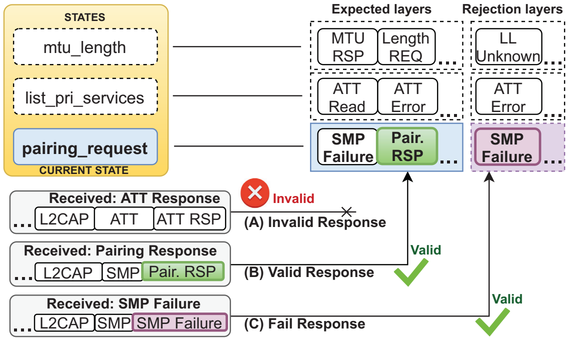

Figure 7: Packet dissection and validation during fuzzing

stances: 1) when the model M_{BLE} reaches the end state `gatt_read/write` (cf. Figure 3) and goes back to `scanning` state, 2) an anomaly is detected (Line 20), or 3) the fuzzer times out due to a crash in the peripheral (Line 13).

Optimization: Once a fuzzing iteration finishes, the mutation probabilities X_i are refined by the optimization module (iv in Figure 5) via particle swarm optimization (Lines 37 to 41). The optimization uses the value of cost function CF_i obtained at the end of every fuzzing iteration (`Measure_Cost_Function`). The rationale of optimization is to guide the mutation probabilities X_i in such a fashion that the value of cost function CF_i is maximized. Specifically, the value of CF_i represents a metric that can direct X_i to fuzz packets that are more likely to optimize CF_i (e.g., the number of anomalies). Moreover, the refined mutation probabilities X_{i+1} are computed iteratively via `Particle_Swarm_Opt` and carried over to the next iteration (Line 41). This approach allows our fuzzer to be directed and facilitates the search for anomalies in the peripheral's protocol implementation.

3 Design of Fuzzer

3.1 Fuzzing and Optimization

The fuzzing effectiveness critically depends on the generation of malformed packets based on mutation. In the following, we discuss how such mutations are performed in detail.

Mutation: On receiving a generated packet from the protocol model, the fuzzing module evaluates it according to the set of mutation probabilities X_i. X_i represents the probabilities to mutate a packet along two dimensions: 1) the `layers`, which correspond to different protocols or packet types of a packet, and 2) the `fields`, each belonging to a layer in the packet. Figure 6 exemplifies the assignment of X_i over the layers and fields of a BLE packet. For instance, consider the Public Key layer to illustrate the use of X_i in generating a packet. The fields of `Key_X` and `Key_Y` can be mutated in an iteration only if the manipulation module randomly hits the layer probability chance (70%). Once a hit happens, the fuzzer needs to decide the set of fields in the layer to be mutated. To this end, the fuzzer iterates over each field within the layer and uses the individual mutation probability (50%) to mutate such fields. We note that all the fields of one layer shares the same mutation probability. This is to reduce the number of parameters during the iterative optimization (cf. Line 39 in Algorithm 1) without losing the efficacy significantly. When the mutation indeed occurs onto a field, the field value is changed via a randomly-chosen `Mutation Operator`.

Mutation Operators: The fuzzing module offers three `Mutation Operators`: 1) **Random bytes** that mutates the value of a packet's fields with random bytes, 2) **Zero filling** that clears the field value to zero, and 3) **Bit setting** that sets the most significant bit of a single-byte field value. The rationale of choosing such operators is to accelerate the search process for an anomaly. In practicality, `Zero filling` and `Bit setting` correlate to setting lower or higher values of a field value to manifest corner cases. These, in turn, are probable to trigger a buffer overflow or underflow in a peripheral's implementation that lacks comprehensive bound checks.

Optimizing Mutation Probabilities: In order to effectively discover anomalies (e.g., crashes or non-compliant behaviours against the Bluetooth Core Specification), our fuzzer employs a cost function to systematically guide the optimization process. The rationale behind such an approach is to measure a cost function value CF_i that informs how well a certain set of mutation probabilities X_i perform with respect to finding new anomalies. Therefore, the goal of the fuzzer is to maximize the discovery of potential anomalies by also maximizing the value of such a cost function. We use the *number of unique anomalies* discovered throughout the fuzzing session as the cost function. This is measured for each individual set of mutation probabilities X_i (cf. Line 37 in Algorithm 1).

The set of mutation probabilities X_i are refined while maximizing the cost function value on each fuzzing iteration by an optimization algorithm (cf. Line 41 in Algorithm 1). For the optimization, we apply the particle swarm optimization (PSO) due to its superior performance in the light of non-linear and stochastic behaviour shown in the protocol model [32]. Moreover, PSO has been successfully applied in a state-of-the-art software fuzzer [23]. The goal of PSO is to optimize the value of a chosen cost function via regulating the *position* of the *swarm of particles* (i.e., the population). In the context of our framework, the *position* is a probability value and each particle within the *swarm of particles* represents a different set of mutation probabilities X_i.

3.2 Packet Validation

The validation module detects responses that deviate from the Bluetooth Core Specification. It emphasizes on the correctness of a response in its *internal packet structure*, i.e., layers of the response, and the *correct reception order*, i.e., the response's arriving state. In particular, given a response packet received at state S, the validation module checks it among `Expected layers` or `Rejection layers` that are dedicated to state S in accordance with the protocol model M_{BLE}.

Validation Exemplified: Figure 7 shows three different cases where a packet from the peripheral arrives in response to a packet sent to the peripheral at state $S =$ `pairing_request`. The packet sent to the peripheral can either be a valid packet P or a mutated packet P'. In **case (A)**, on receiving the `ATT Response` due to a valid P, the validation module flags it as anomaly as none of the layers in the response is found in the `Expected layers` of state S. In **case (B)**, the response packet is deemed to be valid (i.e., `pairing_response`) since its layer is found in the `Expected layers`. On the other hand, after sending a malformed packet to the peripheral, our fuzzer only expects `Rejection layers` (Line 32 in Algorithm 1). In this sense, in **case (C)**, our fuzzer sends a mutated packet P' to the peripheral, and the response with `SMP Failure` is valid as a rejection of P', as `SMP Failure` $\in$ *rejection*(S).

Validation Procedure: More involved cases beyond Figure 7 exist. The validation module must correctly handle responses received due to legitimate, mutated, and/or redundant requests sent at both proper and improper states.

Algorithm 2 illustrates the function `Run_Validation` called in Algorithm 1. It validates if a response P_r is anomalous or not. The response P_r, received at state S, might be due to possible P' and P_{dup} sent in an arbitrary fuzzing iteration (Lines 1 to 5). At start, the validation module prepares the `Expected layers` in ε to be searched for P_r, as P_r might be a response to a non-empty P_{dup} (Line 6 to 10). We first compute the flag Ψ for state S. Ψ holds if the expected layers at S overlap with the expected layers of some other state S' in the protocol model M_{BLE} (Line 7). The flag Ψ does not hold for security-related states such as states involved in SMP pairing and Link Layer encryption, e.g., `smp_pairing` and `ll_encryption`. Specifically, these states (with Ψ false) do not accept any response except those aligned to their respective `Expected layers`. We then check whether a non-empty P_{dup} has been sent at any state M^p_{BLE} (Line 8). The set M^p_{BLE} is a subset of all BLE states (M_{BLE}). Specifically, response to a packet sent at a state $S' \in M^p_{BLE}$ is allowed to be received at any state where Ψ holds (i.e., states other than security-related ones). Thus, given a non-empty P_{dup} sent at a state of M^p_{BLE}, the validation module needs to extend ε if Ψ holds. This is accomplished by joining ε with `Expected layers` of the state P_{dup} belongs to (Lines 8 to 10). With the updated ε, the validation module sets a validity flag based on whether the layers of P_r are expected or not (Lines 11 to 12).

Algorithm 2 `Run_Validation Procedure`

```
 1: Input: Current state $S$ of BLE protocol model (cf. Figure 3)
 2: Input: Packet $P'$ sent from the current state $S$
 3: Input: Packet $P_{dup}$ sent at the immediately preceding state of $S$
 4: Input: Packet $P_r$ sent from BLE peripheral
 5: Output: Absence of anomaly (true or false)
 6: $\varepsilon \leftarrow expected(S)$
 7: $\Psi \leftarrow \exists S' \in M_{BLE} \setminus \{S\}.\ (\varepsilon \cap expected(S')) \neq \emptyset$
 8: if $(P_{dup} \neq \emptyset) \wedge \Psi \wedge (state\_of(P_{dup}) \in M^p_{BLE})$ then
 9:     $\varepsilon \leftarrow \varepsilon \cup expected(state\_of(P_{dup}))$
10: end if
11: ▷ Check if the received packet $P_r$ is valid
12: is_valid $\leftarrow \exists l \in layers\_of(P_r)$ s.t. $l \in \varepsilon$
13: if $(P_{dup} \neq \emptyset) \wedge (state\_of(P_{dup}) \in M^o_{BLE})$ then
14:     $M^p_{BLE} \leftarrow M^p_{BLE} \setminus \{state\_of(P_{dup})\}$
15: end if
16: $M^p_{BLE} \leftarrow (S \in M^o_{BLE})\ ?\ (M^p_{BLE} \setminus \{S\})\ : M^p_{BLE}$
17: ▷ Prevent redundant $P_r$ from transiting the state machine
18: if $(P_{dup} \neq \emptyset)$ and ($P'$ and $P_{dup}$ have the same response) then
19:     Wait for peripheral's response packet $P_r$
20:     Run_Validation($S$, $P'$, $\emptyset$, $P_r$)
21: end if
22: return (is_valid, $P_r$)
```

The validation performs further acts before returning to Algorithm 1. Firstly, in M^p_{BLE} there is a subset, i.e., M^o_{BLE}. The response to the request sent at a state of M^o_{BLE} is allowed to be received in other states, but *only once*. One such state is the `Version` state. A normal peripheral responds to the `version request` only once irrespective of how many `version requests` it receives. Hence, if P_{dup} or P' belongs to some state $S' \in M^o_{BLE}$, then S' is removed from M^p_{BLE}. This ensures that future responses to P_{dup}, which belongs to state S', are classified as anomalies (Lines 13 to 16). Secondly, P_{dup} and P' may have the same response. In this case, we do not trigger a state transition until a response to P' is received (if any before the fuzzer times out). Specifically, after handling the response for P_{dup}, the validation module is recursively called with an empty P_{dup} (Lines 17 to 21). In the end, the anomaly flag and P_r are returned (Line 22).

Crash detection: There are two options to detect a crash or unresponsiveness of the peripheral. The intrusive option is applicable to BLE development boards that expose serial debug ports of their respective SoCs. We can use the debug information to detect a crash. For BLE products without such debug ports, we use a global timer and clear it on every packet response. If no response is received from the peripheral, the timer eventually overflows and a crash is signalized.

3.3 Non-compliant BLE Controller

Manipulation of the Link Layer is essential for fuzzing. However, the Core Specifications [37] undermines Link Layer (LL) manipulation from the host. Firstly, LL packets are heavily timing critical due to BLE frequency-hopping. The host cannot send a packet in a precise time due to the high time variability of the OS scheduler. Secondly, the LL stack runs on a separate and closed source Bluetooth chipset, i.e. the controller. The chipset normally communicates with the host via the Host Controller Interface (HCI) protocol, which does not expose manual control over the LL stack.

To overcome the aforementioned challenges with a *practical* and *low cost* solution, we design a *non-compliant* BLE controller firmware that ignores standardised conventions such as HCI and abstracts away the timing and retransmission requirement between the central and the peripheral. This abstraction simplifies the BLE state machine and allows the host to manipulate all fields of the Link Layer packets.

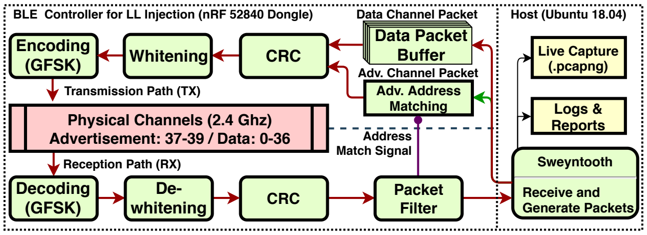

Figure 8: An Illustration of the transmission and reception path of a BLE Packet via the non-compliant BLE controller

Figure 8 details the internals of the non-compliant BLE controller depicted in the fuzzer architecture (cf. Figure 5). The controller reads packets from the host and transmits according to their radio channel type, which is inferred from the *access address* of the packet header. Data channel packets are buffered in the `Data Packet Buffer` and released for transmission after a time period defined by the connection interval. Concurrently, an advertisement packet is only transmitted to the peripheral after the controller receives an advertisement packet from the peripheral first. Upon reception, the `Packet Filter` checks the packet for the peripheral address and upon a match, the advertisement packet stored in the `Adv. Address Matching` is released and transmitted to the peripheral after the inter-frame spacing $\Delta_{IF} = 150us$. Other procedures such as `CRC` calculation, `whitening/dewhitening` and `encoding/decoding` are only necessary to ensure the correct encoding of the packet during over-the-air transmission and as such, do not expose fields for host side fuzzing.

4 Evaluation

Implementation: Our implementation efforts have been mainly spent on two parts: 1) the fuzzer, including the modules of fuzzing, validation and optimization, and 2) the non-compliant BLE controller that enables the over-the-air fuzzing. The fuzzer is written in Python 2.7 and C++ with a total number of 2,836 lines of code (LOC). In brief, our fuzzer extends the `Scapy` v2.4.3 [33] to recognize packet types, parse and validate a response from the peripheral. It also uses the BLESuite library [31] to handle the GATT Service Discovery. As to the fuzzing and optimization, our fuzzer leverages the PyGMO library and its Generational PSO implementation [10] with the optimizer following the common PyGMO structure and the default *pygmo.pso_gen* optimization parameters.

Table 1: Development Platforms used for evaluation

Silicon Vendor	Development Platform	BLE Ver.	Sample Code Name
Cypress (PSoC 6)	CY8CPROTO-63	5.0	Device_Information_Service
Cypress (PSoC 4)	CY5677	4.2	Device_Information_Service
Texas Instruments	LaunchXL-CC2640R2	5.0	project_zero
Texas Instruments	CC2540EMK-USB	4.1	simple_peripheral
Telink	TLSR8258 USB	5.0	8258_ble_sample
STMicroelectronics	NUCLEO-WB55	5.0	BLE_BloodPressure
STMicroelectroncis	STEVAL-IDB008V2	5.0	SlaveSec_A0
NXP	USB-KW41Z	4.2	heart_heart_rate_sensor_bm
Dialog	DA14681DEVKIT	4.2	ble_adv
Dialog	DA14580DEVKIT	4.1	ble_app_peripheral
Microchip	SAMB11 Xplained	4.1	blood_pressure_samb11
Nordic Semi.	nRF51 Dongle	5.0	ble_app_hrs
Nordic Semi.	nRF52840 Dongle	5.0	ble_app_gatts_c

The non-compliant BLE controller is written in C++ (1,096 LOC) within the nRF52840 dongle as the central device. It overcomes the isolation enforced by HCI (cf. Section 3.3).

Evaluation Setup: Table 1 shows the peripheral devices that we have tested. In each of these devices, the CPU is a microcontroller (SoC) that runs an undisclosed BLE stack implementation. IoT products using these devices only have access to interfaces for BLE communications provided by respective manufacturer-provided libraries. As a result, the device's BLE implementation runs alongside the product's main code, and a BLE implementation vulnerability may lead to catastrophic failure and insecurities into the product's functionalities. In other words, once BLE devices are found vulnerable, so are the IoT products relying on them.

We need to install a firmware in each brand new device to enable BLE connectivity. This is accomplished by compiling and programming a sample code provided by the device's corresponding SDK. Once a programmed device advertises itself as BLE peripheral, we can start our fuzzer to test it.

We answer the following research questions (RQs) through the evaluation of our fuzzer.

RQ1: How effective is our fuzzer in terms of generating error-prone inputs?

A summary of testing results is depicted by Table 2. The prefix **V** means a vulnerability while the prefix **A** means some anomalous behaviour that deviates from the legitimate behaviour defined by the Bluetooth Core Specification but is not a vulnerability. Overall, our fuzzer has discovered 11 new vulnerabilities and seven anomalous behaviours over all tested devices. The SoCs of particular vendors, e.g., Texas Instruments, NXP, Cypress and Dialog, have been used in many IoT products for Smart Home, wearables and gadget tracking. These vulnerabilities expose their respective SoCs to crashes, deadlocks or even a complete or partial bypass of pairing procedure. Hence the impact is significant. It's important to emphasize that all vulnerabilities have been automatically discovered by our fuzzer during the packet exchange, except for vulnerabilities classified as `Security Bypass`. After a `Security Bypass` is detected and classified as an anomaly

Table 2: Summary of new vulnerabilities and other anomalies found on the tested platforms. * indicates the case, which is not clear by the Bluetooth Core Specification [36–38]

Vulnerabilities / Inconsistencies		Platform(s)	Model state(s)	Impact Type	Compliance Violated
V1 - Link Layer Length Overflow V2 - Link Layer LLID Deadlock	(CVE-2019-16336, CVE-2019-17519) (CVE-2019-17061, CVE-2019-17060)	CY8CPROTO-063 CY5677 USB-KW41Z	*initial_setup*	Crash Crash, Deadlock	[Vol 1] Part E, Section 2.7
V3 - Silent Buffer Overflow	(CVE-2019-17518)	DA14681 DEVKIT-B	*smp_pairing*	Crash	[Vol 1] Part E, Section 2.7
V4 - Truncated L2CAP Packet	(CVE-2019-17517)	DA14580 DEVKIT-B	*list_pri_services*	Crash	[Vol 1] Part E, Section 2.7
V5 - Unexpected Public Key V6 - DHCheck Skipping	(CVE-2019-17520) (CVE-2020-13593)	LaunchXL-CC2640R2	smp_pairing	Crash Security Bypass	[Vol 1] Part E, Section 2.7 [Vol 3] Part H, Section 2.3.5.6.5
V7 - Invalid connection request	(CVE-2019-19193)	CC2540EMK-USB	*connection*	Deadlock	N.A
V8 - Sequential ATT message	(CVE-2019-19192)	NUCLEO-WB55 STEVAL-IDB008V2	*gatt_read/write*	Crash	[Vol 1] Part E, Section 2.7
V9 - Invalid L2CAP fragment	(CVE-2019-19195)	SAMB11 Xplained	*list_pri_services* *gatt_read_write*	Crash	[Vol 1] Part E, Section 2.7
V10 - Key size overflow V11 - Zero LTK installation	(CVE-2019-19196) (CVE-2019-19194)	TLSR8258 USB	*pairing_req* sc_pairing	Crash Security Bypass	[Vol 3] Part H, Section 3.5.1 [Vol 3] Part H, Section 2.4.4
A1 - Unexpected encryption start response*		SAMB11 Xplained TLSR8258 USB USB-KW41Z	*pairing_request* *smp_pairing*	Non-specified	N.A

BLE Version 4.1			
Texas Instruments	CC2540	1.5.0	V7 / A6,A7
Dialog*	DA14580	5.0.4	V4 / A7
Microchip	ATSAMB11	6.2	V8 / A2,A7

by our fuzzer, a manual check is required to classify it as a security issue. We note that twelve CVEs have been assigned, but at the time of writing this paper, the details of vulnerabilities V1-V11 were publicly undisclosed for confidentiality. Moreover, we followed responsible disclosures and notified all vendors 90 days in advance for them to provide corresponding patches. At the time of writing, all vendors except STMicroelectronics and Microchip have released their patches. Table 3 highlights the SoCs and the SDK versions where these vulnerabilities were first discovered.

For each anomaly, Table 2 also outlines the specific section of the Bluetooth Core Specification being violated. To summarize, the results signalize that the current status of BLE security demands more attention not only onto the design of protocols, but also onto the implementation phases. Specifically, the two critical security bypass vulnerabilities (V6 and V11) are caused due to the lack of handling corner cases in the Bluetooth Core Specification, causing misinterpretations and implementation flaws. A detailed description of the vulnerabilities is shown in the supplemental material.

Table 4: A Summary of Evaluation Time for Each Device. The connection interval is fixed to 20*ms* for all devices.

Platform	Iterations	Total Time	1st Crash	1st Anomaly	Model Coverage
CY8CPROTO-63	1000	1 h. 06 min.	1 min.	<1 min.	27 (50.0%)
CY5677	1000	2 h. 27 min.	<1 min.	8 min.	29 (53.7%)
USB-KW41Z	1000	1 h. 30 min.	<1 min.	2 min.	24 (44.4%)
DA14681DEVKIT	1000	1 h. 16 min.	10 min.	6 min.	30 (55.5%)
DA14580DEVKIT	1000	2 h. 7 min.	5 min.	1 min.	32 (59.3%)
CC2640R2 Devkit	1000	1 h. 57 min.	4 min.	1 min.	31 (57.40%)
CC2540 Devkit	1000	1 h. 37 min.	2 min.	19 min.	34 (62.96%)
Nucleo-WB55	1000	1 h. 45 min.	<1 min.	2 min.	26 (48.15%)
BlueNRG-2	1000	1 h. 14 min.	<1 min.	9 min.	30 (55.55%)
ATSAMB11	1000	2 h. 39 min.	2 min	10 min.	33 (61.1%)
TLSR8258	1000	1 h. 56 min.	5 min.	<1 min.	36 (66.67%)

RQ2: How efficient is our fuzzer?

When our fuzzer exchanges packets with the peripheral, the efficiency in finding anomalies mainly depends on two factors, i.e., the connection interval and the peripheral's capabilities. While the first factor can be initiated by the central, the peripheral decides whether to accept the value of the connection interval proposed by the central. The connection interval is the time between consecutive messages and thus controls the frequency of messages exchanged between central and peripheral. It is negotiated at the `connection` state. A short connection interval naturally leads to an efficient fuzzing process. During the fuzzing process, the connection interval is fixed to a value that is acceptable to all tested devices. Table 4 shows the overall time taken by our fuzzer to complete 1,000 iterations with a connection interval of 20*ms*. Due to the diverse capabilities of devices, the message-processing time varies significantly even with the same connection interval.

For instance, the CY5677 device is much slower in the pairing procedure, resulting in the longest evaluation time.

The time required to find the first vulnerability in a peripheral's implementation depends on its features. As shown by the rightmost two columns of Table 4, most of the first crash or other anomaly have been discovered within 10 minutes. As a result, our fuzzer is opportune to ascertain a vulnerable implementation of BLE device.

Finally, the last column of Table 4 holds the number of different valid transitions traversed in our BLE state machine (cf. Figure 3) after 1000 iterations. Specifically, the BLE model employs a total of 54 valid transitions. Overall, each peripheral traverses the model differently and does not trigger all possible valid transitions in our BLE model. This is because states *initial_setup*, *list_pri_services* and *list_sec_services* allow multiple transitions and peripheral implementations differ in terms of the exact packet sequence accepted in such states. This results in peripherals missing some transitions employed in the BLE model. As per coverage efficiency, the fuzzer takes more time to fully explore unstable peripherals. This is the case for peripherals impacted by vulnerabilities triggered in states with multiple transitions (V1, V2 and V8). For example, peripherals from Cypress, NXP and STMicroelectronics exhibit a slightly lower coverage value for 1000 iterations.

RQ3: How do the different design choices contribute to the effectiveness of our fuzzer?

To answer this question, we disable two components of our fuzzer to make two variants, respectively. Firstly, we only keep the redundancy module active without packet mutation or optimization. This means packets are sent at a wrong state to the peripheral. Secondly, our fuzzer solely relies on the mutation module without optimization. In this sense, we mutate valid packets from the protocol model M_{BLE} according to a random set of mutation probabilities X_i that is not refined after each iteration. The two variants are referred to as "Redundancy" and "Mutation", respectively.

Figure 9 illustrates the number of anomalies with respect to fuzzing iteration for each relevant BLE SoC. The "Evolution" represents the results achieved by our fuzzer with the optimization, which serves as a reference to compare against the two variants. In all cases, "Evolution" results in finding all anomalies due to the collaborative contributions among all fuzzing components, while the two variants miss some anomalies (cf. Figure 9). This is expected and shows that certain vulnerabilities can only be triggered by either redundancy, mutation or a combination thereof. For example, the vulnerability Key Size Overflow (V10, cf. Section 2) associated with Telink TLSR8258, requires that the mutation and redundancy complement during the fuzzing process to trigger it. That explains the superior effectiveness of "Evolution" in Figure 9(b). Also in Figure 9, "Mutation" cannot achieve as many anomalies as "Redundancy". This is because many anomalies indicated for "Redundancy" are due to the fact that A3 to A5 are triggered upon the peripheral receiving redundant packets in the BLE connection, but not by "Mutation" through sending malformed packets.

Table 5: A Comparison among Testing Tools: *Handcrafted* means tests can be manually configured, whereas a *Test Database* contains a corpus of tests for validation

Comparison			Crashes / Anomalies	
Tools	**Supported Layer(s)**	**Fuzzing Strategy**	**WB55, BlueNRG-2**	**Others**
Stack Smasher	L2CAP	Random	0 / 0	0 / 0
BLEFuzz	ATT	Random / Handcrafted	1 / 0	0 / 0
bfuzz (IotCube)	L2CAP	Random / Test database	1 / 0	0 / 0
Our Fuzzer	LL / L2CAP / SMP / ATT	Evolutionary	1 / 2	10 / 7

RQ4: How effective is our fuzzer compared to existing BLE fuzzing tools?

We compare the competitiveness of our fuzzer by evaluating it against publicly available tools, including Stack Smasher, BLEFuzz, and bfuzz that most closely match the objective of our fuzzer. We note that handcrafted efforts were required to apply these tools. Firstly, bfuzz and Stack Smasher demand modifications so that they can send malformed packets through our BLE controller. Secondly, both bfuzz and Stack Smasher were primarily developed for Bluetooth Classic implementations supporting only a few protocols like L2CAP and ATT. Therefore, they also require adjustments for fuzzing L2CAP and ATT layers in BLE implementations. Finally, BLEFuzz is the only tool that supports fuzzing BLE implementations. Table 5 summarizes the comparison between our fuzzer and the three chosen competitors.

For a fair comparison, we run our fuzzer and all the competitors for the same duration (≈ three hours). As shown in Table 5, WB55 and BlueNRG-2 are the only two SoCs for which the competitors discover crashes (third column in Table 5). Specifically, BLEFuzz and bfuzz discovered only V8. For all other SoCs (cf. the "Others" column in Table 5), none of the competitors found either vulnerabilities or other anomalies. In a nutshell, our fuzzer significantly outperforms all competitors, as exemplified in Table 5. The reason is twofold. Firstly, our fuzzer comprehensively models the BLE stack, e.g., it includes modeling and fuzzing SMP and LL protocols, which are not handled by other fuzzers. Secondly, none of the competitors employ an optimization to refine mutation probabilities or send redundant packets. As shown by Figure 9, these features are critical for fuzzing effectiveness.

It is worthwhile to mention that a comparison with the aforementioned tools requires the usage of our non-compliant BLE controller (cf. Section 3.3). This approach is justifiable, *as currently there is no accessible BLE fuzzing alternative with the same level of control and flexibility as provided by our non-compliant BLE controller*. Finally, our comparison did not include traditional fuzzers such as AFL [44] due to their reliance in code coverage. Such a metric is often difficult to obtain in the context of over-the-air-fuzzing, as commercial BLE stacks are undisclosed. Furthermore, traditional fuzzers (e.g. AFL) lack the capability to generate a specific sequence of messages with strict timing constraints. To extend traditional fuzzers with such capabilities requires significant changes to the underlying fuzzing engine. Nevertheless, we

Figure 9: Fuzzing effectiveness w.r.t. design components

Table 6: Products verified to be vulnerable

Product	Category	BLE SoC	Vulnerability	Impact
Eve Energy	Smart Home	DA14680	V3	Crash
August Smart Lock	Smart Home			
Fitbit Inspire	Wearables	CY8C68237	V1,V2	Crash
CubiTag	Gadget Tracking	CC2640R2	V5	Deadlock
eGeeTouch TSA Lock	Security	CC2540	V7	Deadlock

envision that even a loose adaptation of traditional fuzzers would yield results similar to Table 5, as anomalies other than crashes cannot be detected out of the box.

Case Studies on IoT Products: The exploitation of SWEYNTOOTH vulnerabilities, as summarized in Table 2, offers dangerous attack vectors against many IoT products. An investigation of certified products on the Bluetooth Listing site [40] reveals that SWEYNTOOTH is likely to affect ≈480 IoT products using the vulnerable SoCs from Table 3. These products are mainly applied in Smart Home, Fitness, Entertainment and Consumer Electronics. To raise awareness of the threats and risks of potentially vulnerable products available on the market, we performed attacks on some representative IoT products that use the affected SoCs and recorded our observations. Some salient features of these products are outlined in Table 6. In Table 6, we also indicate the BLE SoC used by each product and the vulnerabilities discovered in these SoCs by our fuzzer. We choose these products for their prevalence in the relevant application domains, e.g., Smart Home.

To exploit SWEYNTOOTH on an IoT product, we launch an attack code that captures the exact sequence of packet exchanges in the respective SWEYNTOOTH vulnerability. One such example is an attack code for vulnerability `V5` (found in `CC2640R2`) on `CubiTag`. Next, we describe, for each chosen IoT product, the impact of the launched attack code.

When attacking `Fitbit Inspire`, the smartwatch freezes its screen and immediately restarts when the *Link Layer Overflow* (V1) is attempted. By contrast, *LLID Deadlock* stops Fitbit advertisements for several seconds before the smartwatch abruptly restarts. Similarly, when *Silent Buffer Overflow* is exploited on both `Eve Energy` and `August Smart Lock`, users can immediately experience their smart things being restarted (e.g., via a beep sound in the smart lock and switching off the light attached to the `Eve Energy` plug). This is especially crucial for Eve System products, as the company relies almost entirely on the vulnerable DA14680. As for `CubiTag`, the attack exploiting *Public Key Crash* (V5) immediately stops the tracker to advertise and puts it in deadlock. Only a manual restart by opening CubiTag (e.g., via a screwdriver) and re-attaching its battery brings CubiTag back to a working state. Finally, when the *Invalid connection request* (V7) is exploited on `eGeeTouch TSA Lock`, it hangs and the user needs to manually press the *power on* button for further interaction.

5 Related Work

Security is critical for IoT devices [7]. Existing Bluetooth vulnerabilities, such as Blueborne [34], BleedingBit [15] and

KNOB [1], allow unauthorized remote access or remote code execution. They mostly require tedious manual effort (e.g., reverse engineering and inspecting code) and careful inspection of the protocol standard. By contrast, we provide a systematic and automated approach to discover BLE implementation flaws in any BLE device.

Existing works based on static analysis or verification technologies [14, 25, 27, 42] either suffer from false positives or are incapable to generate concrete packet sequences to trigger communication in real devices. An existing test generation approach targeting network protocol implementations [30] require access to the implementation code. Although a recent work `packetdrill` [5] provides a testing framework of the entire TCP/UDP/IP network stack, it lacks support for automated test packet generation. Similarly, Jero et al. [16] devised a technique to search a reduced state-space for suitable attack injection in stateful protocol implementations, but does not employ a comprehensive and directed approach for fuzzing packets. Furthermore, our validation strategy, being employed directly at the central, differs from passive wireless validation [35] that requires a sniffer. Finally, none of the aforementioned works set foot in Bluetooth.

Directed fuzzing is a prevalent software testing strategy [4, 17, 19, 21, 29, 43], yet faces significant challenges in the context of over-the-air fuzzing. Firstly, vulnerabilities in wireless protocol implementation often appear with a sequence of packets being injected even with strict time constraints. Traditional stateless fuzzers such as AFL [44] are mostly suitable for single input leading to vulnerabilities. Secondly, most of the commercial wireless protocol stacks are undisclosed. Thus, it is often not possible to have a greybox (e.g. based on code coverage) or whitebox approach (e.g. based on symbolic execution) for wireless security testing. Thirdly, wireless protocols often exhibit stochastic behaviour, packet drops and packet retransmissions due to the inherent nature of the wireless medium. This introduces additional complexity in security testing, especially in terms of distinguishing normal and abnormal behaviour. Fourthly, wireless protocol stacks often impose isolation between link layer and host layer protocols. A comprehensive security testing should break such isolation to find zero day vulnerabilities. Finally, detecting critical security issues in a wireless implementation, such as security bypass, requires significant changes to the underlying vulnerability detection logic of traditional fuzzers.

Emulation-based fuzzing [13] can obtain coverage information directly from the firmware and is faster than over-the-air fuzzing [26]. Nonetheless, such approaches require extensive reverse engineering of the firmware (if accessible at all) for a substantial number of wireless devices. For example, Frankenstein [20] is an emulation-based fuzzing approach that works with only specific Cypress/Broadcom firmware and demands significant engineering effort to handle other devices.

Previous works in Bluetooth fuzzing [3, 9, 18] support only L2CAP and ATT layers and do not employ test optimization for fuzzing effectiveness. InternalBlue [24] investigates the lower level of Bluetooth implementation and allows BLE packet sniffing and injection. However, InternalBlue can work only after the peripheral is connected and the number of accessible fields in a packet is limited. Our fuzzing framework, by contrast, allows packets injection, fuzzing and sniffing directly from the host and during the BLE connection process.

Our work is orthogonal to several works on network protocol testing [2, 12, 28] that target text structured protocols e.g. `ftp` and `http`, yet they ignore wireless protocols including BLE. A recent work [8] targets the discovery of memory corruptions in IoT devices by fuzzing the mobile app through which the device is accessible. Our work neither intends to fuzz the application layer nor relies on the availability of a mobile app. Moreover, by design of our validation component, our fuzzer can discover security vulnerabilities beyond memory corruptions e.g. security bypass.

In summary, our work is the first comprehensive approach to systematically and automatically fuzz arbitrary BLE protocol implementations. Also, this is accomplished without changing anything in the OS/firmware of tested device.

6 Conclusion

This paper presents a systematic and automated framework for fuzzing arbitrary BLE implementations. This is engineered with the aim to discover implementation behaviours that deviate from Bluetooth Core Specification. The efficacy of this framework is exemplified via the discovery of 11 new security vulnerabilities, named SWEYNTOOTH, across seven BLE SoCs. Moreover, we exploit several SWEYNTOOTH vulnerabilities on popular IoT products used as wearable, smart home products and logistic tracking, among others. This further shows the danger and criticality of SWEYNTOOTH vulnerabilities, potentially affecting a few hundred types of IoT products. Our fuzzer shares the limitation of any framework based on testing. This means, our fuzzer does not *guarantee* the security of a BLE device even if it fails to discover any anomalous behaviour.

SWEYNTOOTH highlights concrete flaws in the BLE stack certification process. We hope that our work provides an opportunity for further research in the area and initiates technologies to harden and secure current and next-generation wireless protocol implementations. For reproducibility and research, the fuzzer source code is available upon request to sweyntooth@gmail.com. All exploits are publicly available in the following URL:

Abstract

5G edge clouds promise a pervasive computational infrastructure a short network hop away, enabling a new breed of smart devices that respond in real-time to their physical surroundings. Unfortunately, today's operating system designs fail to meet the goals of scalable isolation, dense multi-tenancy, and high performance needed for such applications.

In this paper we introduce EdgeOS that emphasizes system-wide isolation as fine-grained as per-client. We propose a novel memory movement accelerator architecture that employs data copying to enforce strong isolation without performance penalties. To support scalable isolation, we introduce a new protection domain implementation that offers lightweight isolation, fast startup and low latency even under high churn. We implement EdgeOS in a microkernel based OS and demonstrate running high scale network middleboxes using the Click software router and endpoint applications such as memcached, a TLS proxy, and neural network inference. We reduce startup latency by 170X compared to Linux processes, and improve latency by three orders of magnitude when running 300 to 1000 edge-cloud memcached instances on one server.

1 Introduction

The Internet of Things foretells the deployment of billions of devices requiring processing close to the data source to avoid excess bandwidth consumption in the network core. Similarly, latency sensitive cyber physical systems desire communication and processing at millisecond scale, preventing the use of standard cloud platforms. Use cases such as these motivate the demand for "edge clouds", tiny data centers that can be deployed as close to users as possible (*e.g.* at an Internet Service Provider (ISP) or a nearby telco central office [55]).

An edge cloud site is expected to serve a large number of clients with high performance. Many edge services such as Network Function Virtualization (NFV) middleboxes that must act as a "bump in the wire" are latency-sensitive and throughput-intensive. However, given the large number of edge cloud sites, each is expected to only have a small number of powerful servers due to space, power, and cost constraints (*e.g.* the HPE EL4000 has 64 cores and AWS Snowball Edge has up to 52 cores). To utilize resources in an efficient, elastic and scalable way, an edge cloud must support dense multi-tenancy—each edge cloud will be *highly resource constrained* compared to a centralized cloud, yet it may need to host many *securely isolated* services for the clients connected to it, and often these clients have a short lifespan (*e.g.* a mobile user), leading to high churn.

Unfortunately, the combination of limited resources, large number of clients, and diverse services of edge clouds pose major challenges for traditional system software designs. To protect clients and services, an edge system needs to provide two types of isolation:

- **Client Isolation**: Multiplexing an edge service among multiple clients exposes them to malicious exploitation that could impact every client (*e.g.* a compromise in the TLS implementation as in Heartbleed). Thus ideally, untrusted clients should not share a protection domain (*e.g.* a process, a container, or a virtual machine).
- **Service Isolation**: An edge server needs to serve multiple services from different tenants. Some services may be vulnerable and tenants may even be malicious. Thus, a service should not share any resources, such as memory, with other untrusted services.

Current systems fail to provide both high performance and strong isolation–particuarly between clients. Recent Network Function Virtualization platforms achieve high throughput with the use of kernel-bypass networking and zero-copy techniques, but they often trade isolation for performance [23, 27, 72]. This works for a single service, but the edge cloud needs to serve multiple services from different tenants. Lightweight virtualization techniques based on unikernels [32] and hypervisor optimizations [47] have been proposed to reduce boot times and density, but don't address providing many isolated clients high throughput. Recent support for HW virtualization, such as SR-IOV capable NICs, reduces virtualization layer costs, but comes at the expense of scalability. It works for a few dozen clients, but can't be used for an edge server that needs to support thousands of clients.

We address these challenges by designing EdgeOS, a new system that achieves the difficult combination of strong isolation, efficient communication, and fast boot times. Our key idea is to dynamically start *a new isolated domain for each client*, and to use *data-copying* to move messages. This idea is based on two intuitions. First, for a large number of short-lived clients, starting a new protection domain can be more efficient and secure than maintaining many long running yet infrequently accessed ones. Second, in contrast to long-standing networking subsystem guidance that dictates that zero-copy is necessary [24, 66] – often at the price of isolation, we observe memory can push data at sufficiently high rates for edge environments such as 5G base stations that have bandwidths in the low 10s of Gb/s [21, 39]. Thus memory copying can provide stronger isolation, without becoming a performance bottleneck as long as it is faster than line-rate.

Based on these insights, EdgeOS contributes:

- A carefully optimized "Memory Movement Accelerator" (MMA) communication and buffer management architecture that enforces isolation with data copying, while retaining high throughput and low latency.
- A "Feather Weight Process" (FWP) that redefines the process abstraction to a minimal memory footprint and set of capabilities needed to support dense deployments of edge computation, and provides strong isolation between each client in multi-tenant environments.
- A control plane with flexible routing and FWP chain caching to support microsecond speed initialization of complex services in high churn environments.

Combined, these features produce a novel architecture that eschews the current trend towards zero-copy I/O in order to provide stronger *per-client* isolation, yet still offers better performance scalability, reduced tail latency, and dramatically better support for high churn edge environments than any system we are aware of.

We extend the Composite μ-kernel [67] to implement the EdgeOS prototype. We target two key categories of edge applications: network functions (e.g., middleboxes from the Click software router [28]) and latency sensitive endpoint services (e.g., HTTPS servers, neural network inference, and the memcached key-value store). These services can be combined to build flexible service chains, while providing stronger isolation and latency guarantees than existing approaches.

Our evaluation illustrates how our isolation and communication abstractions offer dramatically better scale, density, and performance predictability than traditional approaches. We execute 1000s of FWPs per host, instantiate them 170X faster than a Linux process, maintain a `memcached` latency under 1 ms even when running 600 isolated instances on a single host, improve the throughput of HTTPS processing by almost a factor of 2.3, and even CPU-bound neural network inference tail latency improves by almost 50%.

2 Motivation

We first introduce our threat model and isolation properties. Then we discuss performance challenges that edge clouds pose to existing isolation platforms, motivating the need for a redesign of the underlying communication mechanisms and OS primitives.

2.1 Threat Model

There are three types of parties in our model: (1) A system run by the trusted edge cloud operator that provides isolation mechanism and hosts edge services. (2) Edge services deployed by different cloud tenants who supply untrusted code or binaries. (3) Untrusted clients who send requests to the edge services of one or more tenants. The goal of attackers is to compromise security systems, exfiltrate user data, or disrupt edge services. We assume an attacker has capabilities to evade system security mechanisms by exploiting vulnerabilities in the edge service binaries. We consider two general attacker cases: malicious tenants and malicious clients.

Malicious tenant. A tenant could provide malicious or vulnerable services in order to affect the operation of services run by other tenants. After initialization, a tenant's services are trusted only with the permissions given to them by the system for specific resources, such as memory, communication endpoints or system calls. However, a service can make arbitrary use of the permitted resources regardless of whether they are shared by other services.

Malicious client. A client could try to tamper with other clients' traffic by exploiting a vulnerable service. Clients can request any service or send arbitrary packets. After a client successfully attacks a service, we assume it can access any data or resources that are permitted to the controlled service.

EdgeOS seeks to grant resource access permissions to services and enforce isolation among them in order to limit the effects of malicious tenants and clients. In particular, the system wants to maintain tenant-isolation (i.e., a malicious service should not be able to disrupt services from other tenants) and client-isolation (i.e., a malicious client that exploits an instance of a service should not be able to affect other clients). We do not attempt to prevent a malicious tenant's services from affecting its own clients, just as a normal cloud provider does not try to validate client services.

Isolation model. EdgeOS provides a strong form of isolation based on constraining both inter-tenant *and* inter-client (running code for a specific tenant) interference. Tenants provide *chains* of FWPs, each of which executes as a separate, preemptive thread, and protection domain (including page-table-constrained memory). As such, FWPs access disjoint sets of read/write memory, interact only with adjacent FWPs in their chain using message passing, and receive proportional execution time. The lack of shared resources (*e.g.*, no shared memory) and ambient authority (*e.g.*, no shared filesystem namespace) provide strong logical isolation. Preemptive scheduling policies prevent CPU-based resource consumption attacks. EdgeOS ensures that FWPs in a chain cannot be bypassed, and that the output packets cannot be modified by upstream FWPs. As such, FWP chains constitute a high-performance implementation of assured pipelines [7].

We enable a *chain* of FWPs to processes client requests – as opposed to requiring a tenant to provide a *single* FWP– for multiple reasons: (1) FWPs at the start and end of the chain can be required by the system and provide the likes of firewalls and rate-limiting, (2) some applications are naturally implemented in a separate address space, thus using multiple FWPs to provide legacy support, and (3) it allows tenants to more strongly isolate at-risk computations from those that are more important (*e.g.* TLS termination).

EdgeOS's strong isolation between FWPs ensures isolation between tenants. When paired with fast FWP instantiation, it provides per-client isolation. New connections addressed to a tenant's service can (optionally) be served by a *separate* FWP chain, thus lifting the inter-FWP isolation to provide both inter-tenant, and inter-client isolation.

2.2 Existing Isolation Options

In order to support extreme dense per-client isolation, we propose that a protection domain should have the following properties. 1) it is *sealed* [26] so both the binary and configuration cannot be modified after initialization; 2) it has minimal access to system APIs and resources; 3) it cannot share any resource, such as memory, with other untrusted protection domains; 4) once a client's computation is finished, instead of reusing its protection domain – which would allow compromises to impact future executions – it is re-initialized to a safe state.

In contrast, current systems that use process pools or virtualization do *not* provide this inter-instantiation isolation. Existing solutions provide weaker isolation:

- UNIX processes are exposed to large system call interface and TCB in the kernel. Even containers using more security features, such as `cgroups`, `namespaces`, `seccomp-bpf` and `chroot`, still maintain significant state (including signals, file descriptors, memory mappings) that increases attack surfaces.
- Virtualization encapsulates a hardware abstraction along with multiple enclosed processes and system state. Thus it introduces an extra hardware-enforced isolation boundary. Though research has optimized implementations [2,32], the memory overhead, and startup latencies are not sufficient for per-client isolation.
- Language techniques use software-based isolation, but either don't provide temporal isolation, instead executing tenant computation non-preemptively [52] or using heavyweight language runtimes [22].

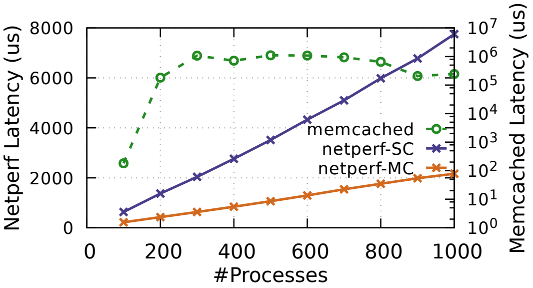

Figure 1: Round-trip latency of N `netperf` or `memcached` instances. Compared with the 1ms round-trip of 5G networks, `netperf` latencies represent a 2x/8x latency increase using one/sixteen cores, while `memcached` exhibits a 1000x latency increase.

2.3 Multi-tenancy and Churn

Given the increasing number of stakeholders that can benefit from edge cloud execution, supporting multi-tenant execution is critical. Network slicing [1, 45, 49] is essential to best utilize edge resources for 5G networking. The challenge [58] is to efficiently share the relatively constrained resources at the edge (often between less than one and low tens of racks [13,14]), while efficiently isolating tenants. Complicating this is the dynamic behavior [43, 44] of these systems which requires adaptation to the environment's inherent churn.

Churn and isolation overheads. Unfortunately, even relatively efficient mechanisms such as containers impose significant overhead when new clients require isolated computation. This is because those mechanisms rely on layers of abstraction and management of a large number of namespaces.

Percentile	Docker	Firecracker	fork()	EdgeOS
50th	521	126	0.26	0.048
90th	574	129	5.8	0.054

The table above depicts the cost in milliseconds of leveraging various isolation facilities; we measure the time to start a minimal service and then fault in 8 pages of memory to show the unpredictability of Linux's Copy on Write (full details in Section 5.2). Using `docker start` can take hundreds of milliseconds due to the cost of initializing namespaces and setting up Docker [10] metadata. Amazon's Firecracker [2, 19] still takes over one hundred milliseconds. Even Linux `fork()`, which has a much lower cost than Docker, exhibits high variance, with the 90^{th} percentile being over 20 times slower than the median. In contrast, our EdgeOS platform improves median start time by 5X compared to Linux, and has minimal variability. Later we show we can improve EdgeOS by another order of magnitude by maintaining a cache of fresh services that can be started near instantaneously.

2.4 Latency and Throughput at Scale

Lightweight isolation mechanisms such as containers facilitate running large numbers of applications (e.g., hundreds of Docker containers per server), but they cannot provide

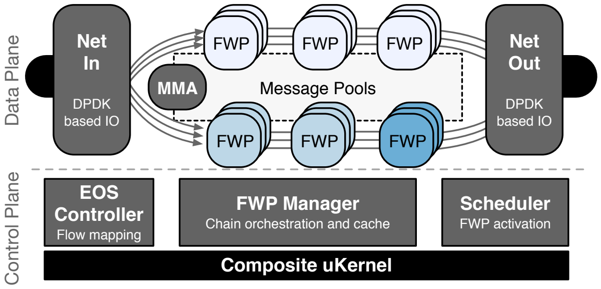

Figure 2: EdgeOS Control and Data Plane Architecture

performance predictability as the scale rises. This leads to the second key challenge in edge infrastructures: predictable performance, particularly latency, at large scale.

Scaling isolation facilities. Unfortunately, current infrastructures suffer poor performance not only under churn, but also at high scale. Both VMs and containers see overheads due to the expense of traversing the host's software switch to determine the appropriate destination to deliver incoming data. Even prevalent and widespread OSes such as Linux suffer from this issue. To evaluate the latency behavior of Linux, we adjust the number of `netperf` servers sharing a single core (`netperf-SC`) or spread across multiple cores (`netperf-MC`), and the number of `memcached` instances spread across multiple cores. A second, well provisioned host transmits traffic to the test server over a 10 Gbps link. Using multiple cores still cannot achieve ideal latency due to poor scalability as shown in Figure 1. Real applications such as memcached are quickly overwhelmed and can only support a hundred or fewer instances (full details in Section 5.6). This illustrates the inability of existing OS isolation mechanisms to provide fine grained performance isolation at high scale. EdgeOS is designed to support isolation with both high scalability and predictability.

3 Design

Figure 2 shows the overall EdgeOS architecture, with trusted components having white lettering. The EdgeOS data plane is composed of Memory Movement Accelerators (MMA) that efficiently and securely copy data between services deployed by tenants as Feather-Weight Processes (FWP), which can be composed into chains to build complex services. The EdgeOS control plane instantiates and schedules these components and routes messages to them.

3.1 Design Principles

Our EdgeOS is designed under the guidance of widely accepted secure system design principles [8, 35, 64].

Avoid shared resources (P1). Every shared resource may open an attack channel [35]. EdgeOS avoids sharing of all types of resources, such as memory, communication endpoints and system services to prevent malicious activities.

Mediated communication (P2). This principle states that communication should be passed via a trusted component, and rules out shared memory based communication. Within EdgeOS, the kernel and MMA mediate all communication initiated from untrusted services.

Least privilege (P3). This well-known principle requires every component to have minimal privileges to limit damage from a system compromise. However, current isolation mechanisms, such as containers or VMs, are usually running on top of monolithic systems, whose kernel or hypervisor has full privilege. EdgeOS applies this principle not only to untrusted components, but also low-level system services, such as MMA and scheduler.

3.2 Memory Movement Accelerators (MMA)

Copy-based communication. Existing high throughput systems [51, 52, 72] often eschew isolation and use shared memory to pass data among isolated services. In contrast, EdgeOS eliminates shared memory between services (**P1**). A key EdgeOS design is that all communication between untrusted services use *data copying* and are mediated by MMA (**P2**).

As long as memory copying is higher bandwidth than the network line-rate, it is a viable form of data movement that provides strong isolation. On our processor, memory throughput is 472 Gb/s, and though networking throughput is ever-increasing in the data-center, it is more limited on the edge. Practically, in §5.1 (Figure 5(c)) we show that the MMA can sustain throughput competitive with a middlebox framework – that avoids copying by sharing packet memory – up to 54 Gb/s. For perspective, 5G cells provide on the order of between 2Gb/s [21] and 20Gb/s [39]. This design is counter to long-standing networking subsystem guidance that dictates that zero-copy is necessary [24, 66] – often at the price of isolation, EdgeOS optimizes the MMA implementation and treats it as a specialized processor (§4.2) to achieve the line-rate. As a result, EdgeOS maintains strong isolation without practically sacrificing performance.

Efficient data copying with the MMA. The MMA acts as a software DMA engine to move message data between services, and runs on one or more *dedicated cores* in order to perform out-of-band data movement. The MMA retrieves messages from an upstream service's message rings, copies them and adds them into a downstream service's message rings, and alerts the scheduler that the destination service needs to be activated to receive it. EdgeOS further separates memory into a *message pool* that is used for communication, and *local memory* for each service's local state. This separation enables memory allocations to be optimized for the purpose and use of the memory (§4.1). MMA only has the access rights to copy into, or from message pools (**P3**).

Network Gateways. In and Out gateways leverage DPDK [11], run on dedicated cores[1] and pull packets into message pools with no kernel interactions. MMA then copies

[1] Note that current edge offerings include between 20-64 cores, and we show (§5) that, in aggregate, EdgeOS is efficient despite specializing cores.

packets into the destination service, thus enabling strong protection among both (untrusted) edge services and (trusted) system services.

3.3 Feather-Weight Processes (FWP)

A Feather-Weight Process (FWP) is a minimal abstraction wrapping only memory and a small set of simple kernel resources. FWP achieves strong isolation by (1) capability-based access control which minimizes access to the rest of the system; (2) library-based services to avoid sharing of sensitive information; (3) FWP caching that re-initializes a FWP's context before serving a new client.

Capability-based resource isolation. In EdgeOS design, access to all resources relies on capability-based access control [9] using kernel-mediated references, removing any ambient authority [37] (**P2, P3**). These resources include local memory, the message pool that is used to receive and send data, and synchronous communication end-points to request operations from system-level services. Capabilities to memory are enforced by hardware page-tables, while other capabilities are protected by the kernel. Each FWP is encapsulated within its own capability space, which restricts the granted resource to only the allowed tenant. No memory is shared between FWPs, instead MMA copies data between FWPs.

Library-based services. Notably absent in EdgeOS are default access to conventional shared OS services. Similar to Unikernels [30, 31, 69], FWPs make use of library-based implementations [18], thus enabling the inclusion of only the application-required services without sharing with other FWPs (**P1**). We have ported a TCP/IP networking stack and a simple in-memory file-system to FWPs. The memory-based file system is used to store transient and configuration data. If global persistent state is required, then network-accessible storage services can be used (similar to a serverless computing model). This decoupling enables a simplified and efficient FWP execution environment to enable high density and line-rate computation.

FWP Caching. A new client should not be allowed to see old context accumulated from previous clients. Current practices either ignore this, such as process pools, or manually terminate and restart the service [3, 5], which repeatedly incurs unnecessary initialization overhead. EdgeOS employs an FWP checkpoint cache, that both avoids reusing possibly compromised state of previous executions and avoids redundant initialization computations. In doing so, EdgeOS guarantee that (1) an FWP is sealed so it cannot be modified after checkpointing; (2) an FWP is restored to the cached post-initialization state. Thus its memory is placed into a known and safe state, ensuring the integrity of future FWP instances. Checkpointing details are described in §4.3.

FWP Chains. To provide more complex functionality, FWPs can be arranged into chains, thus the entire chain can be efficiently managed as a whole. A FWP chain composes multiple checkpointed FWPs and are maintained in a *FWP-chain cache* that caches entire chains of FWPs, their interconnections, and their message pool. MMA copies data between adjacent FWPs within the same chain, avoiding shared memory.

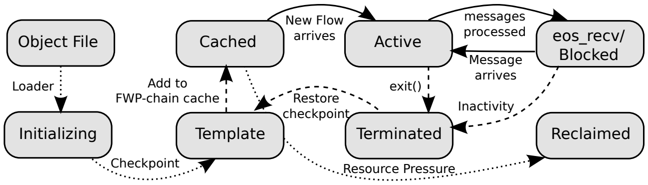

Figure 3: Lifecycle of a FWP-chain: Dotted lines indicate FWP manager operations conducted once to load and then checkpoint a FWP-chain, or to reclaim the FWP's resources when memory pressure exists. Dashed lines indicate operations to re-initialize terminated FWP-chains for future use. Solid lines are *data-path* operations performed by on the critical path.

3.4 EdgeOS Control Plane

The EdgeOS Control Plane is composed of: (1) the EdgeOS Controller that maps incoming flows to FWP chains, (2) the FWP Manager that controls the lifecycle of FWPs and optimizes their startup, and (3) the Scheduler that determines which FWP to run on each core and activates them in response to incoming messages.

Flow matching with the EdgeOS Controller. When new requests arrive from connected client devices, they need to be routed to the appropriate FWP chain. The EdgeOS Controller allows tenants to define FWP chains and the packet filtering rules that specify what traffic should be routed to them. These rules are pushed to the Net-In data plane component. Net-In applies rules similar to SDN match-action rules: packets are split into flows based on the header n-tuple (*e.g.* src/dest IP and port) and a rule is found that matches the flow. The rules indicate the FWP chain that will process that flow.[2] Since our focus is on fine-grained isolation and high scale, a rule can indicate whether all flows that match the rule should be handled by a single chain, or if each client flow should be given a dynamically started instance of the chain.

FWP Manager. Figure 3 illustrates the lifecycle controlled by the FWP Manager. Similar to a Linux process, an FWP starts as an object file, which must be loaded into memory. Once execution begins, FWPs perform some initialization routines, and are checkpointed to a Template. Then multiple identical copies are forked off the Template and put into FWP cache. As new clients arrive, they are paired with corresponding FWP-chains from the cache. The selected FWPs will be Activated, allowing them to process messages or transition to the Blocked state, before eventually Terminating when no longer needed. When a FWP chain terminates, the Manager reuses the chain by Restoring it to the post-initialization state and puts it back into the FWP-chain cache. If there is memory pressure, cached FWP templates and chains are Reclaimed.

[2] Our implementation currently assumes flow rules are statically preconfigured, but this could be extended to support on-demand flow lookups similar to SDN controllers, with a northbound interface to application logic that would assign a rule dynamically to each flow.

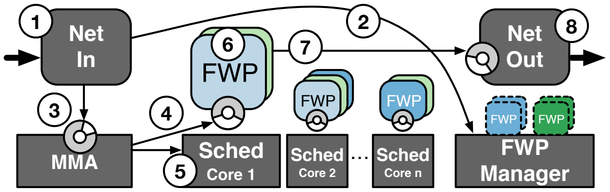

Figure 4: EdgeOS Timeline

Scheduling and inter-FWP coordination. Once a set of FWPs are activated, they are distributed across cores, and partitioned scheduling (*i.e.* without task migrations) multiplexes the core's processing time.

Traditional systems often use shared data-structures and Inter-Processor Interrupts (IPIs) for scheduling notification. For example, Linux activates threads by accessing that thread's data-structure directly to see if it is already awake, and if not, an IPI is sent. The resulting cache-coherency traffic and IPI overheads, can be significant, especially if used for message notifications arriving over a network at line rate. Motivated by these overheads, NFV platforms based on DPDK such as OpenNetVM [72] use active polling for communication between threads on different cores, thus avoiding blocking. However, as the number of processes ("network functions" in OpenNetVM) grows beyond the number of cores, spin-based event notification is inefficient.

All inter-scheduler coordination in EdgeOS is via message passing, avoiding shared memory synchronization. When a FWP-chain is activated, or when a message is sent to an FWP, the MMA notifies the scheduler of the activation. On the other hand, a FWP will be blocked after processing all of its messages. FWPs avoid spinning to ensure efficient multi-tenant computation. We currently use a simple and efficient preemptive, fixed-priority, round-robin scheduling policy. This aims to provide *temporal isolation* between untrusting FWP chains which prevents them from monopolizing the CPU, and from interfering with the progress of other tenants' FWPs.

Timeline Summary. Figure 4 shows the complete timeline for processing a packet. (1) A packet reception at the Net-In gateway causes a flow lookup to decide which FWP chain should process the packet. (2) If there is a miss, the FWP Manager spawns a FWP chain from its cache. (3) MMA copies the packet and (4) adds it to the first FWP's ring of the destination FWP chain. (5) MMA messages the scheduler on the FWP chain's core to activate it. (6) The FWP chain processes the packet and (7) the last FWP in the chain asks the output gateway to DMA the packet out the NIC.

3.5 Isolation Analysis

We summarize how EdgeOS achieves the isolation requirements listed in §1 based on our design principles. EdgeOS executes on top of a micro-kernel, with a smaller TCB than monolithic systems (on the order of 10K lines of code). FWPs access system resources through a capability-based access-control system provided by the kernel [67]. Capabilities protect and control access to kernel resources including synchronous and asynchronous IPC end-points, threads, time [20], and memory. The capability model is similar to that in seL4 [17], and relies on user-level retyping of untyped memory into both kernel resources and virtual memory. The most notable difference between EdgeOS's capability model and seL4's is that EdgeOS doesn't allow IPC-based delegation, instead relying on a user-level component with capability-based access to a FWP's capability-table to copy capabilities (thus access to kernel resources) into that FWP. EdgeOS leverages the kernel's capability system to tightly constrain FWP's access to system resources. Each FWP has access to only its own memory and to IPC endpoints to the scheduler, and to the FWP manager to block awaiting further execution, and expand their heap, respectively.

Trust model: §2.1 discusses the threats from untrusted tenant code, and from clients that can compromise that tenant code. As such, we assume that any resources available to an FWP will be used, where possible, to escalate privilege, and that all FWP system interfaces will be comparably stressed.

EdgeOS is implemented as a set of trusted, user-level components that have access to various FWP resources. The MMA has shared memory access to each FWP's message pool, and is trusted to properly move messages between adjacent FWPs, to and from the network gateways, and to notify schedulers of FWP activation. Similarly, the network gateways (using DPDK) are trusted to properly interface with the NIC and the MMA and to properly implement a tenant's flow matching rules. Per-core schedulers [54] have the ability to dispatch FWP threads, and are trusted to properly preemptively schedule FWPs and coordinate with the MMA to properly activate them. The FWP manager is relied on to quickly and correctly create new FWP instances, perform capability delegations into the FWP, maintain the FWP cache, and dynamically expand FWP heaps. The FWP manager delegates resources to FWP chains such that all readable/writable resources are partitioned per-FWP. Thus, each chain is mutually isolated, and when a chain is assigned to a client, clients are mutually isolated. Finally, the kernel is depended on to maintain the capability-based access model that constrains the set of resources available to each FWP.

FWP isolation: FWP memory is initially allocated by the FWP manager, and is of three types: (1) shared executable and read-only data derived from a tenant's FWP's image, (2) read-write memory in the global data segment and heap that is *not* shared among FWPs, and (3) message pools that are shared only with the MMA. Finally, each FWP has access to IPC end-points to request heap expansion, and to await the next message's arrival. Messages are sent downstream, and received from upstream FWPs using message pool, thus interfacing with the MMA using only simple wait-free ring buffers. The MMA maintains associations between an upstream FWP's message pool and the downstream FWP, thus only allowing data-flow within a chain. EdgeOS's design ensures that a malicious FWP – or a compromised FWP – will not be able to intercept data outside of the FWP's chain, nor impact the integrity of correct services.

Inter-FWP *temporal isolation* is enforced by preemptive scheduling. Each FWP executes in a separate thread controlled by per-core, round-robin scheduling logic. In contrast, many of the most efficient language-based techniques (e.g., NetBricks [52]) cannot prevent a buggy or malicious tenant's infinite loop from preventing progress for all tenants.

Inter-client isolation: Each client is served by a separate FWP (chain), the FWP (chain) is re-initialized before serving each new client, and when created, each FWP (chain) is delegated disjoint read/write resources by the FWP manager. Thus, a malicious client cannot impact the execution of future clients. In contrast, VM techniques often create a VM per-tenant [2], which executes multiple clients, thus potentially exposing clients to past compromises. Even webservers are typically architected to service multiple clients within a single protection domain.

When inter-client sharing is required by a tenant (*e.g.*, to implement a shared cache), FWP chains can either access network-accessible storage, or use Net-In gateway rules that send new clients to an existing FWP chain storing common state (§3.4). The former is similar to the stateless design of many serverless and microservice applications; in fact, FWPs provide more flexibility since per-user state can be maintained across multiple requests if desired. In the latter case, isolation is traded for sharing, which is evaluated in §5.6. More complex routing rules that cluster specific sets of clients into different, potentially existing, FWP chains are beyond the scope of this paper.

Per-client isolation in EdgeOS is, in many ways, most similar to systems to provide Distributed Information Flow Control (DIFC) [40]. Such systems track information as it flows (via IPC and other interactions) between processes, and define policies to determine when that flow is allowed. When a single process is needed in two conflicting information flows, a common strategy [15, 41, 62, 71] is to create a *new instance* per flow. This is similar in mechanism and motivation to the per-client FWP chain instantiation in EdgeOS. Importantly, EdgeOS focuses on providing instantiation of full FWP chains, low overhead (an order of magnitude less than Linux `fork`), and line-rate performance. Despite strong FWP isolation, EdgeOS achieves *per-packet* overheads on the order of dedicated middlebox infrastructures that do not provide comparable isolation.

4 Implementation

We implemented EdgeOS in Composite (`composite.seas.gwu.edu`), an open source μ-kernel that externalizes traditionally core kernel features into user-level *components* that define the resource management and isolation policies [67]. In Composite, components interact through highly-optimized Inter-Process Communication (IPC) to leverage system logic and resources. Composite is based on a capability-based protection model [17, 61] that controls component access to kernel resources. The kernel includes no scheduling policies, instead implementing schedulers at user-level [54]. The Composite kernel scales well to multiple cores as it has no locks and is designed entirely around store-free common-paths, wait-free data-structures, and quiescence [67]. MMA can be implemented in other OSes such as Linux. In EdgeOS we pair it with the FWP abstraction to provide fine-grained isolation and adaptability to churn.

EdgeOS prototype consists of the MMA, FWP management, DPDK-based network access and schedulers. In total, EdgeOS adds fewer than 6000 lines of code. We plan to release our code and experiment templates for repeatable research.

4.1 Message Pool Management

Memory management integration into ring-buffers. Each FWP's message pool is associated with two ring buffers that track *both* how to transmit and receive messages, *and* the allocation and deallocation of messages. EdgeOS observes that general purpose memory allocation facilities (`malloc/free`) can have significant overhead. Thus, we integrate memory with message management by tracking free memory in rings.

A reception ring buffer contains a set of references to message slots into which incoming data can be copied, and the transmission ring buffer contains references to messages to move downstream in the FWP chain. The MMA orchestrates data movement between different FWP's packet memory regions, thus acting as a software DMA accelerator.

Message pools are managed by FWPs as a span of MTU-sized message slots, and unlike traditional NIC DMA ring buffers, the ring buffers include an entry for *each* message slot. Ring entries that have been transmitted by an FWP, and have been copied by the MMA are marked as free, and are used for packet allocations. FWPs must maintain a sufficient number of messages in reception rings to buffer messages that queue up due to the system's scheduling latencies. Thus, after FWPs finish processing pending messages, they move batches of freed messages from the transmit ring into the reception ring. This avoids `malloc` on the fast path, as message *liveness* is managed indirectly through the ring buffers.

Message pools and isolation. The ring buffer design decouples the *message pool* from the *meta-data* to coordinate the data movement and liveness between FWPs and the MMA. This avoids lock-based protection of the rings, instead relying on wait-free mechanisms. This is necessary to avoid the high costs of synchronization, and ensure progress of the MMA in spite of possibly malicious FWPs.

4.2 Memory Movement Accelerator

Our initial experiments showed that naively copying packets in a DPDK-based NFV pipeline decreased throughput by more than 50%. However, a MMA core has a throughput of around 54 Gb/s on our hardware, which is sufficient for line-rate. For networks that require a higher throughput, more cores can be specialized as MMAs. In the limit, MMA's throughphut is bounded by the chip's memory bandwidth, which for our processor is 472 Gb/s. By using the parallelism of the underlying processor and specializing cores to run the MMA, we achieve both isolation and high throughput by taking message movement out of the critical path.

The MMA has read-write access to all message pools. It maintains a mapping between both pairs of transmit and receive ring buffers for subsequent FWPs in a chain, and continuously iterates through all such pairs, transferring messages when it finds a transmitted message. The MMA provides two essential services: *data-movement by copying transmitted messages*, and *event notification of the receiving FWPs*. The MMA's FWP event notification is efficient as it simply sends a message to the scheduler controlling the target FWP's, and relies on the scheduler to asynchronously process events.

MMA optimizations. As the MMA is on the data-path of all FWP interactions, including message reception, it must be able to move messages at faster than line rate. The data-structures linking transmit and reception rings are laid out in an array to leverage the processor's prefetcher as the MMA iterates over them. The initial implementation of the operations on the ring buffers were straight-forward, but cache-coherency traffic, possibly a cache-line transferred for each ring entry, hurt throughput. To address this, we optimize the MMA:

- Double-cache-line (128B) *caches* are added to both the enqueue and dequeue operations. These caches are in local memory outside of the ring, thus their modifications avoid coherency traffic. When retrieving to the ring, a batch is copied into the cache, and when transmitting messages are queued in the cache, and batch copied into the ring. To ensure message delivery, the cache is flushed by an FWP before it blocks.
- These caches enable messages to be transferred in batches. We use explicit software prefetch instructions to load all referenced messages in the cache to avoid CPU cache misses on message processing.
- Messages are efficiently addressed and copied as the MMA has shared memory access to all message pools. To maintain protection, the MMA validates that FWP messages are within a valid message pool.

4.3 Optimized FWP checkpointing

EdgeOS caches the images of *chains* of FWP binaries so they are ready for prompt activation. These ready-to-execute images are *asynchronously* prepared, thus moving the overhead for FWP preparation off the fast-path. The cached FWP's state is identical to the *initialized* state of a ready-to-execute FWP.

We utilize a few optimizations to efficiently generate post-initialization FWP snapshots: (1) the post-initialization checkpoint of the FWP-chain is laid out contiguously in memory so that chain re-initialization is as close to `memcpy` / `memset` overheads (for which we use the `musl` libc, unoptimized versions), (2) we do not eagerly reclaim – and thus later re-allocate – heap memory from terminated FWPs, instead only zeroing it out to maintain confidentiality, and using it to satisfy future heap allocations, (3) we reuse the threads active in each FWP by only resetting their registers to the appropriate post-initialization state, which avoids the overhead of thread destruction and allocation, and (4) only if there is memory pressure do we reclaim first spare FWP heap memory, then cached FWPs. Re-initialized FWPs maintain zero state from their previous execution: the stack, heap, and writable data sections are reset to the initial state. These optimizations culminate in a system that can handle exceedingly high churn and scalability: FWP chain initialization is dominated by `memcpy`/`memset` overheads, and new client chain activation takes in the low 10s of μ-seconds.

5 Evaluation

All experiments are run on CloudLab Wisconsin c220g1 series nodes [57]. These are 2 socket, 8 core, Intel(R) Xeon(R) CPU E5-2630 v3 @ 2.40GHz processors with 128GB ECC Memory. Note that these systems have fewer cores than current edge offerings, thus pressuring EdgeOS's design that dedicates cores to different functions. Systems are connected via Dual-port Intel X520-DA2 10Gb NIC (PCIe v3.0, 8 lanes).

5.1 Latency and Throughput

We first evaluate the latency and performance predictability of EdgeOS compared to other high performance networking platforms. Figure 5(a) shows the response time distribution (in microseconds) for an ICMP ping response Click [28] element implemented as either: a DPDK process, an OpenNetVM NF (ONVM), a standard linux process with kernel-based IO, a ClickOS NF in a Xen VM, or an FWP in EdgeOS. The results show that EdgeOS significantly outperforms all of these techniques (by up to 3.8X in average latency), except for DPDK. DPDK is slightly better because it can run only a single service at a time and thus does not need to copy packets from the initial receive DMA ring to a separate pool. In contrast, EdgeOS provides a platform to potentially run thousands of distinct services, and thus needs to offer stronger isolation via copying.

Figure 5(b) shows the maximum throughput of different approaches when forwarding traffic from `pktgen`, a high speed packet generator. EdgeOS again provides better performance than ClickOS, while offering stronger isolation than DPDK and ONVM, which rely on globally shared memory pools for zero-copy IO.

Next we compare the performance of EdgeOS communication with ONVM. We run a chain of NFs on the same core that each forward small (64B) or big (1024B) packets, thus both

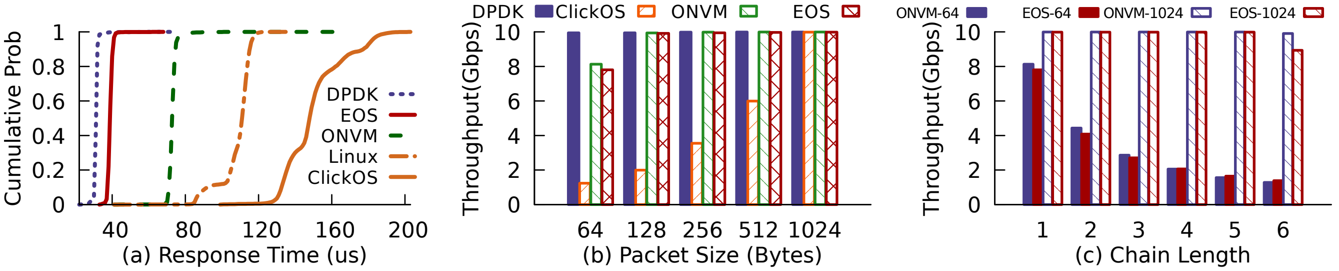

Figure 5: (a) EdgeOS provides substantially better latency, and reduced jitter compared to Linux processes and NFV platforms like OpenNetVM and ClickOS. (b) Throughput of each system with different packets sizes. (c) EdgeOS provides isolation and adds negligible overheads compared to OpenNetVM (no isolation) for different chain length for messages of size 64 and 1024 bytes.

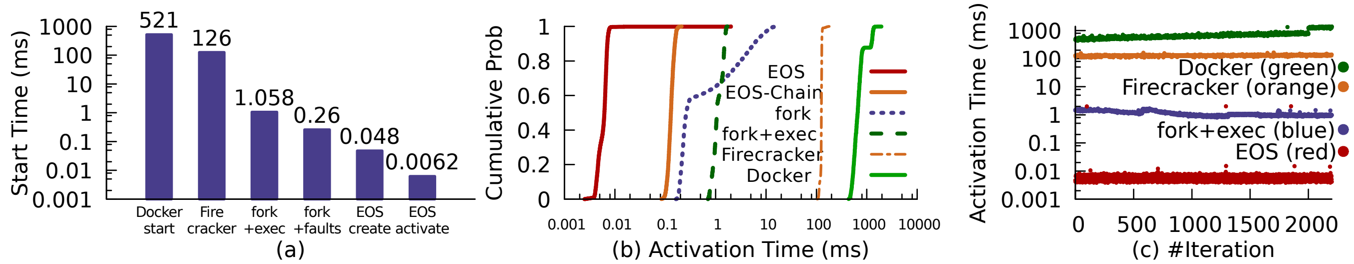

Figure 6: EdgeOS provides orders of magnitude better startup time than other approaches and does not suffer from scalability problems when starting larger numbers of FWPs.

systems have context switch overhead by passing a packet to the next NF. In addition, EdgeOS has copying overhead from the MMA to enforce isolation. The results in Figure 5(c), show that as the chain length increases, the throughput of 64B packet drops for both EdgeOS and ONVM. The main overhead of EdgeOS is data copying, while the overhead of Linux context switches and scheduling dominates ONVM. When the chain length is smaller than 3, the overhead of copying is less than 8%, and EdgeOS outperforms ONVM when the chain is longer as the Linux system overheads increase. The throughput with 1024B packets maintains line rate for both systems when the chain length is smaller than 6, at which point EdgeOS sees a throughput decrease. Even at length 6, the MMA is able to maintain an aggregate of 54 Gb/s.

5.2 Startup Time

FWP Initialization and Activation. In Linux, initializing a process involves calling `fork` (and possibly `execve`). For Docker containers, a `docker run` command is similar, but includes additional system calls to configure namespaces and maintain container metadata. For Firecracker, we use the recommended "hello" image and use 1 vCPU and 128 MiB RAM. In order to optimize the fast path of readying a cached FWP, EdgeOS separates out creation from activation. For EdgeOS, creation involves transitioning from the Object File to Cached state in Figure 3, including setting up page tables, capability tables, and thread creation. We record the start time for 10,000 iterations of starting a container, VM, process, or FWP and report the median in Figure 6 (a). Note the log scale. We use median time values as Container creation cost increases slowly over time so the mean is skewed by these outliers. We compare against two variants of Linux processes: "fork + exec" loads a different binary whereas "fork + faults" mimics loading the service's working set by issuing writes to eight different pages to trigger page faults (the size of the minimal FWP). These approaches are 5-20X slower than the comparable "EOS create" approach (dashed lines in Figure 3).

Once an FWP has been created, EdgeOS keeps copies of it in a cache which can be quickly activated on demand (solid lines in Figure 3). Cached activation improves EdgeOS performance by another order of magnitude, allowing new processing entities to be instantiated in 6.2 microseconds. Figure 6(b) presents a CDF of these approaches, including the activation cost for a full chain of 10 isolated FWPs, which remains an order of magnitude faster than fork+exec.

FWP Scalability and Middlebox Computation. Containers and VMs suffer from poor scalability: as the number of instances rise, the start time increases [32]. In Figure 6(c) we show the time to start a new container, create a Firecracker VM, exec a process, and activate an FWP, when up to 2200 are started incrementally. The Container case gradually drifts upward before hitting a step after 2000 containers (note log-scale) – the last container takes 1.368 seconds versus 0.467 seconds for the first. FWPs provides nearly constant start time regardless of scale. EdgeOS has a few outlier points (11 out of 15K measurements are at 2ms), which we believe to be Non-Maskable Interrupts, or a bug in our scheduling logic.

5.3 Isolation

Just in Time Service Instantiation. To evaluate the impact of client churn in edge environments, we measure client response time for a ping that creates a new FWP. Clients send requests at a configurable interval, and we assume that each new client requires a new, isolated FWP. The new FWP re-

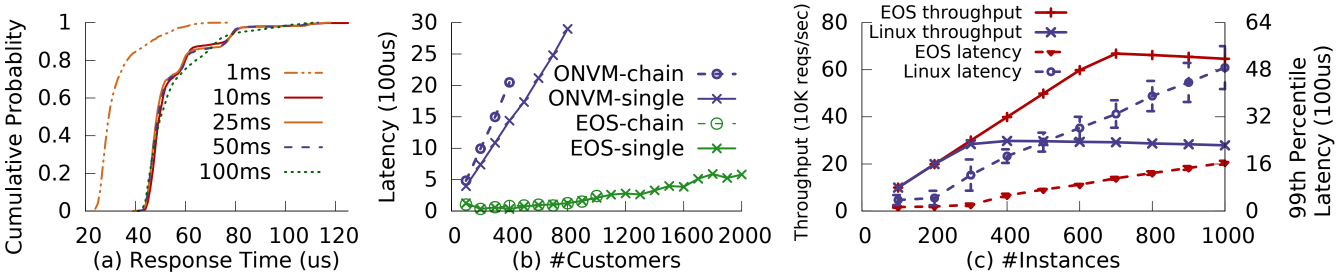

Figure 7: (a) EdgeOS just in time service instantiation for each for mobile client connection with varying client inter-arrival rates; (b) Routing and processing latency for middlebox routing `netperf` traffic for an increasing number of clients; (c) TLS termination performance for up to 1000 end points (solid lines: throughput, dashed lines: tail latency).

ceives the incoming packet, produces a reply, and then terminates, representing a worst case churn scenario. Figure 7(a) shows a response time CDF for EdgeOS under different client arrival patterns. The results show that even when a new client arrives every millisecond, 90% of requests are serviced within 50 microseconds This experiment mimics that in LightVM [32], and although we have not been able to successfully run the LightVM software on our testbed, we note that their paper produced a 90th percentile response time of 20 milliseconds (more than 400X worse) with 10ms client arrivals. The EdgeOS performance advantage comes from our extremely lightweight FWP abstraction and our template cache that allows nearly instant instantiation.

Multi-Tenancy and Customer Isolation. An important job of edge-cloud systems is to act as a middlebox to monitor traffic close to the source. Figure 7(b) depicts the processing latency of a middlebox deployed between `netperf` client and server machines for an increasing number of concurrent clients. We use three nodes, two running `netperf` clients and servers, and the third running EdgeOS or ONVM in the middle. The systems run either a single firewall to filter flows or a 2 FWP chain of firewall plus monitor, all implemented in Click, to further maintain statistics about flows. Each customer is serviced by its own "personal firewall" or chain, thus preventing malicious clients interfering with others. We measure the middlebox latency overhead (i.e., the added cost versus direct client/server connections from Figure 1) as we increase the number of clients, and thus number of FWPs (EdgeOS) and Network Functions (NFs in ONVM).

Though ONVM is a highly optimized middlebox infrastructure, it relies on containers and expensive coordination mechanisms between NFs and the management layer. Because of this, ONVM cannot scale past around 820 containers or 410 chains, and the added latency rises quickly with each new client. FWPs enable the system to scale past 2000 clients with an average increase in the latency of only around $0.3\mu s$ per additional client. Chaining in EdgeOS adds negligible latency overhead thanks to efficient FWP scheduling and activations, while ONVM sees an increasing gap since it relies on Linux's more heavyweight futexes.

5.4 TLS Termination

For our first edge cloud use case, we consider the deployment of edge-based TLS termination proxies, such as for a CDN serving `https` traffic or for IoT devices sending encrypted data streams. This requires an edge end-point for TCP connections, a TLS handshake to share public keys, and continued encryption/decryption of transferred contents. As the majority of web traffic is over `https` [59], TLS implementations are a high-priority target for compromises, and have a history of high-impact vulnerabilities, e.g., Heartbleed [12]. Therefore, instead of sharing one `https` end-point among many clients, we instantiate an isolated TLS FWP for each client. Toward this, we ported `axtls` (`axtls.sourceforge.net/`) (version 2.1.4), which includes a lightweight `https`-based web proxy optimized for embedded systems, and the `lwip` (`savannah.nongnu.org/projects/lwip/`) TCP/IP networking stack (version 2.1.2) to EdgeOS.

In our experiment we use a single cloudlab node as the edge server, and use five additional nodes to drive the client workload. We style this experiment after the setup in [32], and request zero-length files hosted at the proxy (headers are still encrypted). Each client uses ab (version 2.4.39) and keep-alive sessions to make a series of requests over a TLS-encrypted session. We modified ab by adding a `nanosleep` to rate limit each client to 1000 requests per second. We disable Nagle's Algorithm for these experiments since it leads to very low throughput and low network utilization due to an adversarial interaction with delayed ACK support. For fairness, `axtls` on Linux stores files in a ramdisk.

Figure 7(c) depicts the results of running an increasing number of clients making `https` requests. Both Linux and EdgeOS saturate the CPU at around 350 and 700 clients and reach 297K and 668K requests per second, respectively. Similarly, EdgeOS achieves around three times lower 99th percentile latency than `axtls`, and has lower variability across clients compared to Linux as shown by the error bars.

In addition to fast FWP instantiation, and efficient communication, the following FWP optimizations are significant: (1) the FWP abstraction focuses on communication with a *single* client, it avoids event multiplexing through `select` and the associated overhead, and (2) similarly, the share-nothing nature of the FWP abstraction enables synchronization-free

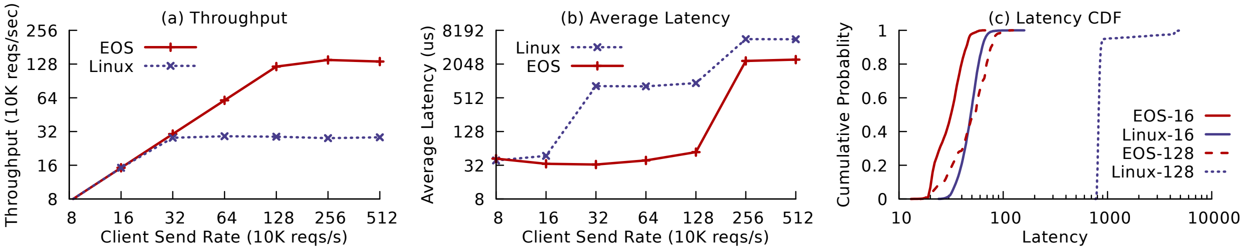

Figure 8: Single memcached instance on one core.

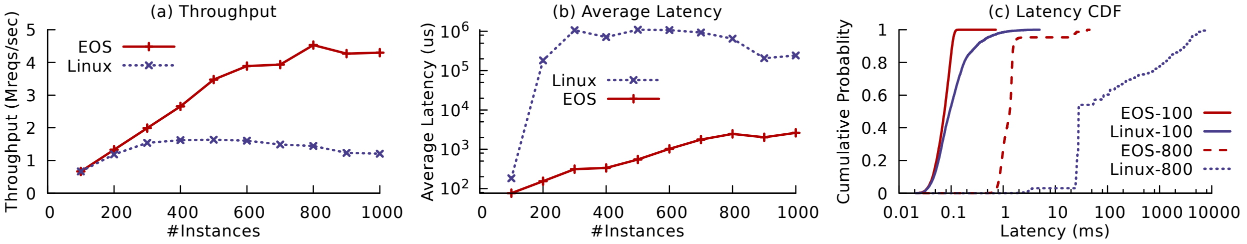

Figure 9: Multiple memcached instances (one per tenant) on 16 cores.

networking using the simple `lwip` stack (in contrast to some unikernels that cannot push `lwip` to Linux-level throughput [32]). Though EdgeOS provides significantly stronger isolation (a TLS instance per client), the FWP model still enables efficient, predictable scalability.

5.5 Edge Inference

Edge based neural network inference enables resource constrained embedded systems to offload computationally-heavy work such as live image recognition. For our second use case we port the CMSIS NN Library (version 1.0.0) neural network inference library to EdgeOS. We use the example CIFAR-10 configuration which takes as input a 32x32 pixel color image which classifies to number 0-9. We focus on providing each tenant with isolated inference services. Thus, we compare an EdgeOS CMSIS NN FWP-per-client against a simple Linux server that `fork`s a process for each client.

	Linux Clients		EdgeOS Clients	
	100	500	100	500
Mean latency (ms)	13.8	69.2	14.6	70.1
99th percentile (ms)	25.4	135	14.8	71.3

We utilize a PowerEdge R740 server with two 24-core Intel Xeon 8160 sockets that represents the Amazon and HPE edge offerings. We use either 100 or 500 clients (separate columns), each requesting 500 inferences. This application is particularly CPU-heavy (each inference taking around 6ms), thus penalizing EdgeOS' design that specializes cores, i.e., Linux can use all cores on the system for inference, whereas EdgeOS sets aside 4 cores for MMA and control services.Despite this, EdgeOS has only slightly lower throughput than Linux, losing 2.5% to 4.6%. However, the simpler FWP runtime in EdgeOS minimizes scheduling interference, reducing latency jitter. Together with EdgeOS's more efficient activation, this yields significant decreases in tail latency – 42% and 47% at 100 and 500 clients, respectively.

5.6 Memcached

Finally, we evaluate how EdgeOS can provide a platform for low latency endpoint applications that don't require rapid instantiation. We implement memcached as an FWP that uses UDP for requests. We mimic a scenario where one or more edge tenants store data, each with many clients making requests. Isolating these tenants from each other is necessary as they should not be able to access (maliciously or not), other tenant's cached data. The EdgeOS controller is used to map incoming requests either to a single memcached FWP (e.g., representing a typical edge cloud data cache) or one FWP per tenant (e.g., representing data stores for different sets of edge-connected IoT devices). We compare EdgeOS against Linux, with a single, or multiple memcached instances. Our workload uses 135 byte value sizes and a 95% get, 5% set request mix generated by the mcblaster client as in [46]. We use multiple 16-core client machines, each running mcblaster processes to ensure the client will not be a bottleneck.

Figure 8 shows a single memcached instance while Figure 9 shows a variant number of instances, representing different edge-cloud tenants. We report the aggregate throughput across all requests, the average latency, and a CDF of the latency (with 16K or 128K clients) to understand the tail. The single instance focuses on the data-path efficiency of the system, while the multi-instance evaluates each system's scalability to an increasing number of tenants on the limited edge hardware.

The efficiency of both systems is seen in their aggregate throughput. EdgeOS processes over 5x the throughput for a single instance, and can scale more gracefully up to 800 instances whereas Linux handles up to 400. EdgeOS' response time for a single memcached instance is substantially lower than Linux: it handles 8X the client request rate before seeing an increase in latency. Since Linux is not able to keep up, it drops a large number of requests, e.g., 5.2% at a 320K req/sec client rate. In contrast, EdgeOS does not see any requests drops at a 1.2M req/sec client rate. For multiple instances, Linux has a response time of nearly 1 second, whereas EdgeOS has an average latency below 1 millisecond for up to 600 memcached instances. From the latency CDF, we observe that even with only 100 memcached instances, Linux has much higher tail latency than EdgeOS, and that with 800 instances Linux has more than three orders of magnitude worse tail latency. These latency metrics ignore dropped requests – with 800 instances, EdgeOS drops 13% of requests, whereas Linux drops 66%.

6 Related Work

Multi-tenant isolation. Significant research addresses isolation in a multi-tenancy environment. Bolted [38] presented an architecture for a bare metal cloud supporting security sensitive tenants. PSI [70] enables fine-grained and dynamic security postures for different network devices by assigning each device an NF. Denali [68] separates the protection provided by a Virtual Machine Manager (VMM) from the abstractions within a VM, and enables lightweight VM contexts. Multi-tenancy virtual switch designs are proposed in [60, 64]. In contrast, EdgeOS is motivated by the potentially enormous churn and large-scale isolation requirements of the edge cloud, providing service to transient mobile and IoT devices. For isolated edge computation instantiation, FWP compares favorably to forking of minimal Linux processes (two orders of magnitude faster start-time) which is the lower-bound for many such techniques. Re-initializing FWPs to safe states is partially motivated by ChaosMonkey [3, 5].

Lightweight isolation. Wedges [6], LWC [29], and SpaceJMP [16] expand the UNIX interface to include lightweight facilities for controlling and changing protection domains. Similarly, Dune [4] uses hardware virtualization support to provide user-level control over page-tables, and both dIPC [65] and Skybridge [36] use hardware support to bypass the kernel during inter-protection domain communication. Several projects have increased the efficiency of containers. Cntr [63] includes only the application-specific context in a container, while SOCK [48] specializes the container to use efficient kernel operations, and uses a Zygote mechanism paired with a cache to accelerate container creation for stateless computations. EdgeOS targets at abstractions to support immense churn rates, efficient communication with strong isolation via the MMA and a narrow system attack surface. To efficiently use the limited resources in the edge cloud, EdgeOS leverages this support to scale to more than two thousand FWPs in less than 1GB of RAM while maintaining line-rate communication.

Other isolation mechanisms. DMA shadowing [33] utilizes extra memory copies for DMA buffer to provide full IOMMU protection. DAMN [34] introduces DMA-aware packet memory allocator to achieve efficient IOMMU protection. MMA also uses data-copying to avoid shared memory communication between untrusted FWPs. LXDs [42] runs isolated kernel subsystems on dedicated cores. EdgeOS achieves similar isolation with the micro-kernel approach. EdgeOS implements its system-level services in user-level, and further spreads them to different cores.

New hardware features are used to enhance memory isolation, such as Intel MPK [25, 53] and SGX [50, 56]. They are complementary to EdgeOS. Language techniques such as NetBricks [52] implement network processing functions in a memory-safe language. These techniques rely on software isolation within a *single thread*. Without multiplexing the CPU among untrusted FWP chains via preemptive scheduling, *temporal isolation* is challenging. EdgeOS effectively uses the MMA to maintain memory safety, but also provides temporal isolation by executing all FWPs in separate threads that are preemptively scheduled. We also support the direct execution of legacy code modulo the confines of FWP APIs.

7 Conclusions

The increasing prevalence of mobile computations and the Internet of Things requires both scalable isolation facilities for multi-tenancy in the edge, and the agility to handle high churn. This paper has described an optimized copy-based MMA architecture that provides strong mutual isolation without performance penalties. We introduced FWP for scalable isolation that is paired with a cache of post-initialization checkpointed FWP-chains to provide microsecond scale activation times for high churn.

Our evaluation shows EdgeOS substantially improves performance for a wide range of applications from network middleboxes to endpoint services. We show that EdgeOS provides more than a 3.8X reduction in ping latency and more than 2X throughput increase compared to ClickOS – a system that also provides isolated computation – for middlebox computations. More importantly, EdgeOS can create FWPs for client computation in 25-50 microseconds, even when they are created every millisecond, and can scale to over 2000 FWPs while maintaining low latency, even with a very limited amount of memory. For edge applications like memcached, EdgeOS has more than three orders of magnitude decreases in latency when running over 300 server instances simultaneously, and even CPU-intensive TLS termination shows a factor of three tail latency decrease, all while maintaining strong isolation. We believe that EdgeOS paves the way for closely integrating the edge cloud into – and augmenting the capabilities of – the increasing prevalence of mobile and embedded devices.

Acknowledgments. We would like to thank the anonymous reviewers, especially our shepherd Trent Jaeger, for their tremendous feedback that has significantly improved the quality of this paper. We are also thankful to Phani Kishore Gadepalli, Zheng Yang and Runyu Pan for their help on the Composite system. Firefly: Untethered Multi-user VR for Commodity Mobile Devices

Xing Liu   Christina Vlachou   Feng Qian   Chendong Wang   Kyu-Han Kim**
*University of Minnesota, Twin Cities   *Hewlett Packard Labs*

Abstract

Firefly is an untethered multi-user virtual reality (VR) system for commodity mobile devices. It supports more than 10 users to simultaneously enjoy high-quality VR content using a single commodity server, a single WiFi access point, and commercial off-the-shelf (COTS) mobile devices. Firefly employs a series of techniques including offline content preparation, viewport-adaptive streaming with motion prediction, adaptive content quality control among users, to name a few, to ensure good image quality, low motion-to-photon delay, a high frame rate at 60 FPS, scalability with respect to the number of users, and fairness among users. We have implemented Firefly in 17,400 lines of code. We use our prototype to demonstrate, for the first time, the feasibility of supporting 15 mobile VR users at 60 FPS using COTS smartphones and a single AP/server.

1 Introduction

Virtual Reality (VR) has registered numerous applications. In this paper, we focus on *multi-user VR* where multiple users jointly participate in exploring a VR scene. This enables many applications that single-user VR cannot support such as team training, social VR, group therapy, collaborative product design, and multi-user gaming.

We envision the following use case with more than 10 collocated users in a VR room. To start multi-user VR, each user simply launches the app on her smartphone and plugs the phone into a VR headset (*e.g.,* a $50 Samsung Gear VR [18] or even a $10 Google Cardboard [9] with a $6 VR controller [5]). These mobile devices fetch the VR content from an off-the-shelf server based on the users' real-time motion. The devices and the server communicate wirelessly over a single WiFi access point (AP). The users can enjoy the high-quality VR content as if it is rendered by a desktop PC with a powerful GPU. Meanwhile, each user can see and possibly interact with other users in the virtual world.

This paper aims at realizing the above ambitious use case. We design and implement Firefly, a novel multi-user VR system for mobile devices. The goals of Firefly are the following. First, Firefly works with affordable, commercial off-the-shelf (COTS) mobile devices, server, and AP. This helps reduce the deployment cost and facilitate the "bring-your-own-device" (BYOD) policies that many enterprises adopt today [6]. Second, Firefly employs untethered, wireless VR to overcome the inconvenience and trip hazards incurred by wired cables [19]. This is important for multi-user VR where multiple users' cables may easily get intertwined. Third, Firefly offers high content quality, low "motion-to-photon" (M2P) latency, and a high frame rate. An M2P higher than 16ms can cause nausea to VR users [11]. We target Quad HD (1440p) resolution, 60 frames per second (FPS) that can provide a good experience even for fast-paced VR gaming – the most demanding VR task [10]. Fourth, Firefly aims at supporting ∼15 users who can form a sizeable group of, for example, co-workers, students, or patients. To our knowledge, no existing system can achieve this using a single commodity server and WiFi AP. Recent work on multi-user VR only demonstrated 4 concurrent emulated users [47]. Fifth, Firefly allows complex VR scenes with both background and dynamic foreground objects, such as other users' avatars that users can interact with.

The above goals pose multiple challenges. The CPU/GPU power of a smartphone is at least one order of magnitude lower than its desktop counterpart [57], not to mention the energy/heat constraints; the heterogeneity of their computational capabilities should also to be taken into consideration; the bandwidth offered by a single AP is limited for multiple users; another key challenge is multi-user scalability, which calls for strategic decisions of splitting the client-server workload, as well as scalable approaches for rendering and distributing the content. To address the above challenges, Firefly makes a series of judicious design decisions as follows.

• Firefly performs one-time, offline content preparation by enumerating, pre-rendering, encoding, and storing the views at all positions reachable in a virtual scene [27]. At runtime, given a user's position and viewing direction, the server directly retrieves the stored high-quality content and delivers it to the user. This completely eliminates the online rendering overhead. Prior work [27] applies offline rendering to a single mobile device for local VR scenes, while Firefly further extends this concept to networked multi-user VR where offline rendering is found to be an indispensable mechanism ensuring scalability (§3.1).

• To reduce the network bandwidth consumption, Firefly takes a viewport-adaptive approach: each user only requests for the content that the user is about to perceive based on motion prediction. We conduct a thorough analysis of 25 human users' motion traces collected from an IRB-approved user trial. The results shed light on developing a lightweight yet effective motion prediction approach for Firefly. In the literature, several studies [24, 33, 39] have examined 360° video viewers' viewing patterns that only involve rotational movement (yaw and pitch). Our study instead investigates generic VR users' motion that consists of both the rotational and translational viewport movement as well as their interplay (§3.2).

- Firefly supports *Adaptive Quality Control (AQC)*, which determines the content quality of each user based on the total network bandwidth, the bandwidth available to each user, and the amount of to-be-delivered content. AQC essentially extends traditional video bitrate adaptation [40, 41, 51, 66]: from handling a single client to multiple clients, from dealing with regular videos to immersive VR content, and from being invoked at the second level to the millisecond level to adapt to users' motion. These differences require AQC to be effective, lightweight, fair, and scalable as reflected in our design (§3.4).
- Firefly handles dynamic foreground objects in a scalable and adaptive manner. Specifically, objects' 3D models are distributed to the clients offline. They are then rendered locally by the client. This eliminates the uncertainty caused by the network as well as the potential resource competition from other users compared to a server-side approach. To prevent too many objects appearing in the viewport from slowing down client-side rendering, Firefly supports adaptively reducing the objects' fidelity to maintain a high FPS (§3.6).

Additionally, Firefly has integrated several system-level optimizations, such as motion prediction error toleration (§3.3), client-side hierarchical cache (§3.5), and AP-assisted bandwidth estimation (§4). Our implementation on commodity Android/Linux platforms involves 17,400 lines of code. We conduct extensive evaluations using commercial VR scenes, real users' motion traces, and off-the-shelf smartphones/AP/server. We highlight the evaluation results as follows (§5).

- Firefly achieves very low motion-to-photon delay (≤15ms for 99% of the frames), low stall duration (around 1 second per minute), a frame rate at 60 FPS, and fairness among the users when supporting 15 concurrent users with a single server and a single 802.11ac AP (§5.2).
- Firefly is adaptive to users dynamically joining and leaving the system as well as network bandwidth changes (§5.4,§5.5).
- Firefly significantly outperforms existing systems. We extend Furion [44], a state-of-the-art single-user VR system over WiFi, to support multi-user VR. Due to its more efficient content fetching strategy, Firefly exhibits 18% higher median FPS, 6.9× lower stall duration, and much higher content quality, compared to multi-user Furion (§5.2). We also use our 15-user dataset to evaluate MUVR [47], a very recently proposed multi-user mobile VR framework. Through simulation, we find that for 27% of the time, the MUVR server still needs to perform online rendering for more than 5 devices. This makes MUVR not scalable to many users (§5.6).
- Firefly incurs acceptable CPU, GPU, and memory usage. When tested on 5 modern smartphones, after 25-minute VR sessions, the battery life percentage drops by 4% to 8%, and the devices' temperature reaches no higher than 50°C (§5.7).

Firefly is to our knowledge the first system that can scale untethered multi-user mobile VR. We make multi-fold contributions in this work: (1) the design of Firefly, (2) the study of real VR users' motion, and (3) our prototype implementation that demonstrates the support of 15 VR users at 60 FPS using COTS smartphones and a single AP/server. With emerging wireless technologies (*e.g.*, 802.11ax and 5G), we believe that Firefly has the potential to scale up to even more users.

2 Motivation and Overview

Firefly enables multiple users (10+) to simultaneously enjoy high-quality VR at 60 FPS using commodity smartphones, a single off-the-shelf server, and a single WiFi access point. We consider three high-level architectural design options.

A Serverless Design does not involve a server, so all the VR content is stored on users' mobile devices, which also perform full-fledged rendering. Most of today's commercial 3D games and VR mobile apps use this approach. However, previous studies [27, 44] indicate that today's commodity mobile devices are far from being powerful enough to perform heavy-duty real-time rendering for high-quality VR. Other concerns include excessive energy consumption and heat dissipation.

Server Performing Online Rendering. This design option offloads the rendering task to an (edge) server, which performs real-time rendering of the VR scene for all users based on their positions and viewports. The rendered scenes are then distributed to the users wirelessly as encoded video frames. This approach has been adopted by a prior single-user, cloud-assisted VR system [44]. It drastically reduces the client-side overhead, but in the multi-user scenario, the rendering and video encoding workload becomes too high for a single server to handle. To illustrate this, we perform an H.264 encoding experiment on a high-end workstation equipped with an Nvidia GTX 1080 GPU. The achievable encoding performance is 92 FPS, 199 FPS, and 342 FPS for 4K, 2K, and 1080p resolutions, respectively. This clearly cannot support 10+ users, each requiring a frame rate of higher than 60 FPS.

Server Performing One-time, Exhaustive Offline Rendering. The server exhaustively enumerates all possible views at all positions, renders them at a high quality, encodes them into video frames, and saves the frames in the storage [27]. At runtime, the server simply retrieves and transmits the pre-encoded frames based on each user's position and viewport. In this way, the rendering/encoding overhead at runtime is completely eliminated, so the server can easily scale to tens or even hundreds of simultaneous users. These benefits come at the cost of high storage usage, which is largely not an issue given the cheap storage today.

System Architecture. Firefly employs the third approach given its good runtime performance and superior scalability. Figure 1 plots the overall architecture. As shown, Firefly consists of a content server and multiple commodity mobile

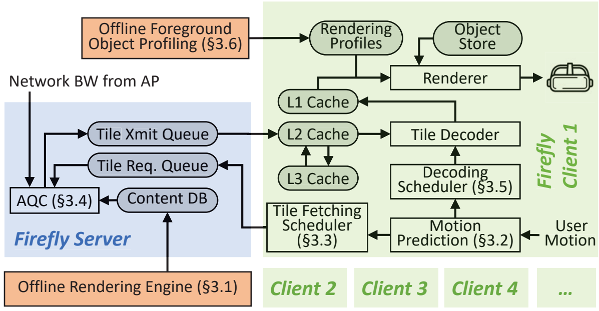

Figure 1: The Firefly system architecture.

devices. They are wirelessly connected through a WiFi access point (AP). This setup can be easily realized in enterprise or home environments at a very low cost. Note that prior work [27] applies offline rendering to a single mobile device for local VR scenes, while Firefly further extends this concept to networked multi-user VR where offline rendering is found to be an indispensable mechanism ensuring the scalability.

The server consists of a content database that stores rendered/encoded content indexed by a user's position and viewing direction. The database is built by the Offline Rendering Engine that performs the aforementioned exhaustive content generation (§3.1). Another critical component is the AQC module that is introduced to scale the system and to handle the wireless bandwidth fluctuation. It determines in real-time the content quality for each user. Designing AQC is challenging due to multiple requirements including boosting users' QoE, maintaining good performance, ensuring scalability, and achieving fairness. We detail its design in §3.4.

On the client side, there are two high-level design choices on the content fetching strategy for background frames. First, the client can prefetch all surrounding frames at every new virtual position [44]. However, this technique may consume high bandwidth with a considerable amount of wasted traffic (*i.e.,* the fetched content is not viewed by the user, see our evaluation in §5.2), making it infeasible for multi-user VR. Second, to reduce the bandwidth footprint, the client can use its historical motion trajectory to predict the future viewport and to prefetch only the portions that will likely be consumed in the near future. Firefly is the first to incorporate this viewport-adaptative approach into generic VR using robust motion prediction (§3.2,§3.3). The client also efficiently manages its local cache (§3.5) and handles foreground dynamic objects in an adaptive and scalable manner (§3.6).

3 System Design

3.1 Offline Rendering Engine

The offline rendering engine produces the content database. The whole VR world is discretized into grids. At each grid position that the user can reach, the rendering engine renders a *mega frame* that captures the 360° panoramic view [28] that the user can possibly perceive at a high quality. Firefly uses Equirectangular projection [7] to generate the panoramic representation, but other projection algorithms [8, 14, 67] can also be applied. As shown in Figure 2, besides the color frame (top), a mega frame also includes a panoramic depth map (bottom) where the brightness of each pixel indicates its distance from the user. The depth map will be used to ensure the correct occlusion when overlaying foreground objects such as avatars of other users onto the scene (§3.6).

We next apply the *tiling* technique [38, 53] by dividing each mega frame into *mega tiles*. Each tile is independently encoded and can be separately transmitted and decoded. The rationale is that, since the user only sees a portion of the whole panoramic scene at a given time, there is oftentimes no need to fetch the entire mega frame. The mega tiles thus allow users to (pre)fetch the content more adaptively at a finer granularity, to reduce the network bandwidth consumption. Note that although viewport-adaptive tiling has been used in 360° video streaming, applying this concept to generic VR (in particular, multi-user VR) is new. Tiling requires the user to predict its viewport, *i.e.,* to determine which tiles to fetch based on the observed viewport trajectory (both translational and rotational), as to be detailed in §3.2 and §3.3.

A decision we need to make is to determine the number of tiles and their layout. While having more tiles provides more bandwidth saving opportunities, in the meantime it increases the decoding overhead and makes compression less efficient. After carefully studying the above tradeoffs using real users' viewport trajectory data (§3.2), we decide to vertically segment each mega frame into four mega tiles as shown in Figure 2. We choose vertical segmentation because according to our data collected from 25 users, users tend to keep their sight vertically centered (*i.e.,* looking at the equator) while moving the viewport horizontally. This makes horizontal segmentation at the equator (0° latitude) inefficient because the vertically centered viewport will always overlap with at least two tiles, *i.e.,* one above and the other below the equator.

As described above, at each position, the offline rendering engine generates four tiles capturing the panoramic view and depth. Each tile is then independently encoded into video frames with multiple quality levels. The rendered and encoded tiles are stored in the content database, indexed by the user's grid (translational) position, the tile ID (rotational position, 1 to 4), and the quality level.

3.2 VR Viewport Movement: Characterization and Prediction

Users' motion makes VR immersive and interactive. In the literature, many studies have investigated users' head *rotational* movement when watching 360° videos [24, 33, 39]. Generic VR differs from 360° videos in that it further involves *translational* movement. To our knowledge, no prior study has comprehensively investigated VR users' motion patterns and their predictability, which are our focus here.

Collecting Viewport Movement Data from Real Users.

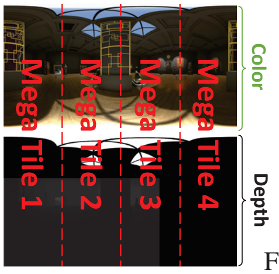

Figure 2: Mega frame.

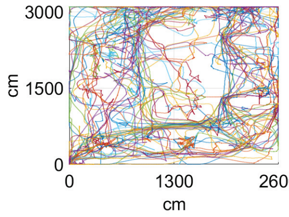

Figure 3: Users' translational trajectories (the Office scene).

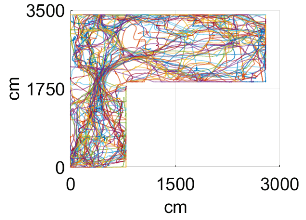

Figure 4: Users' translational trajectories (the Museum scene).

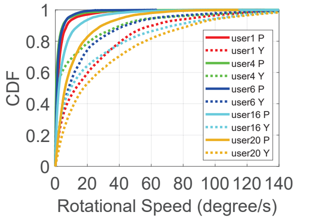

Figure 5: Five users' rotational speed (P=Pitch, Y=Yaw).

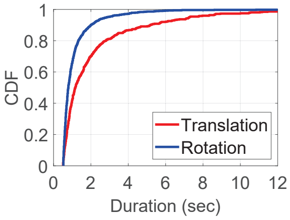

Figure 6: SP duration per pause.

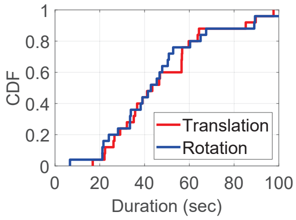

Figure 7: Total SP per user.

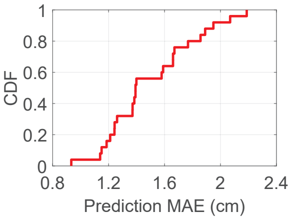

Figure 8: Trans. prediction MAE.

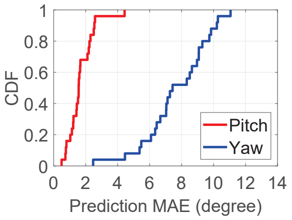

Figure 9: Rot. prediction MAE.

We conduct an IRB-approved user study involving 25 voluntary participants recruited from a large university. Among the 25 users, 9 are female. The users are from 8 departments as undergraduate (16), master (4), and Ph.D. students (5). During the study, each subject wears an Oculus Rift headset [15] connected to a high-end PC. The subject can freely make rotational movement by moving her head as well as perform translational movement using the handheld controller.

We obtain two large VR scenes from the Unity store: Office [16] (30m×26m) and Museum [13] (35m×30m, L-shape). We then develop a custom VR system that loads each scene for the users to explore. Our system logs from each user the precise viewport trajectory. We let each subject explore each scene in a random order for 5 minutes, with an arbitrarily long break allowed between the two sessions.

Motion Trace Characterization. We now characterize the unique dataset above to reveal VR users' motion dynamics and to provide insights for Firefly's design. To begin with, Figures 3 and 4 plot the translational movement trajectories of all users, represented by different colors, for the two VR scenes. As shown, in most locations, the users' trajectories are highly heterogeneous. This finding suggests that the server should not use broadcast or multicast, simply because users typically see different content at a given time.

Fast motion may cause difficulties for viewport prediction. We thus quantify the users' motion speed. The translational movement speed is fixed at 1m/s (set based on reported experiences from another user study) when the user presses the controller button. Figure 5 plots the distributions of rotational movement speed, calculated by sliding a 500ms window over the trajectory, across all window positions for five randomly selected users. As shown, the users exhibit different speeds, whose medians range from 1.3°/s to 18.6°/s for yaw and from 0.5°/s to 7.0°/s for pitch. The median speed across all 25 users is 10.2°/s and 2.4°/s for yaw and pitch, respectively. Interestingly, such speeds match those for typical 360° users [53], implying that translational movement does not necessarily slow down the rotational movement.

Another challenging scenario is users' sudden movement after a stationary period. How often do stationary periods (SPs) occur? Figure 6 plots the distributions of SP duration per pause, which by our definition has to last at least 500ms. Figure 7 plots the total SP duration per user. As shown, an SP is typically short: 69% of translational SPs and 89% of rotational SPs are shorter than 2 seconds. However, Figure 7 indicates that they occur frequently: within a 5-min VR session, a typical user spends 43 seconds (median) being stationary. Such frequent SPs lead to bursty, non-continuous movement patterns that pose difficulties for viewport prediction. To deal with SPs, we design mechanisms such as conservative tile scheduling (§3.3) and bandwidth reservation (§3.4). We also find that translational and rotational SPs are not correlated, *i.e.,* a user is typically looking at a fixed direction while moving, or looking around while standing still. This motivates us to separate the translational and rotational dimensions when performing viewport prediction (see below).

Viewport (Motion) Prediction is required by the tiling scheme (§3.1). We make two decisions regarding Firefly's viewport prediction scheme. First, we decide to run it distributively on client devices to make the server scalable. Second, given the above measurement results, we predict each dimension separately (yaw/pitch for rotational movement and X/Y/Z for translational movement), and then combine them into the final predicted view. We find that this strategy greatly reduces the computational complexity while achieving a decent accuracy – a desirable tradeoff we want to strike. Regarding the actual algorithm, we continuously train a linear regression (LR) model using the motion trajectory observed within a history window of H milliseconds; we then use this model to predict the future trajectory within a prediction window of P milliseconds before discarding the model. The simple LR model is found to be very lightweight yet effective for 360° videos [53]; here we investigate its effectiveness for generic VR motion prediction. Further improvement using more powerful machine learning tools is our on-going work. Ideally, P should be set to the duration of the entire tile processing pipeline (form request being sent to tiles being decoded) plus some safety margin. Guided by this, we set P to 150ms based on empirical profiling. We set H to 50ms based on cross-validating different values of H, which is found to not qualitatively impact the prediction accuracy. Note that when integrated with Firefly, the prediction is performed in an online manner: at runtime, Firefly continuously (1) trains a linear regression model based on the motion trajectory observed within a window (H), (2) uses this model to predict the viewport, and (3) discards this model immediately.

Figure 8 and 9 plot the prediction results for translational and rotational movement, respectively, across all users (H=50ms, P=150ms, the Office scene), with the SPs excluded. The accuracy metric is the mean absolute error (MAE, in distance or degree). The overall accuracy is high: the median MAE is around 1.4 cm for translational movement, and 1.6°/7.4° for vertical (pitch) / horizontal (yaw) rotational movement. The results for the Museum scene are similar. We discuss how Firefly further tolerates prediction errors in §3.3.

3.3 Client-side Tile Fetching Scheduling

The client needs to judiciously decide which (mega) tiles to fetch and in which order. Recall that the client continuously predicts the viewport trajectory within a prediction window (§3.2). The trajectory is a time series of 6-tuples $\{t, x, y, z, pitch, yaw\}$ where t is the (future) timestamp; x, y, and z are the grid position (translational movement); $pitch$, and yaw are the viewing direction (rotational movement). The timestamp difference between two consecutive tuples is $1/F$, where F is the frame rate. In other words, each tuple corresponds to the predicted viewport of a future frame. The client then translates yaw and $pitch$ of each tuple into a list of tiles according to the projection algorithm (*e.g.,* Equirectangular).

The client now has a preliminary list of tiles to be fetched. It next prunes the list using two rules. First, if a tile is already in a client-side cache (§3.5), it will be removed from the list. Second, if a tile appears multiple times in the list, only the earliest appearance (with the smallest t) will be kept. This pruned list where the tiles are ordered by their t values will then be sent to the server. To adapt to users' motion, the above scheduling process is performed continuously on a per-frame basis. The server therefore sees a stream of mega tile lists for each user. We describe how the server processes it in §3.4.

Tolerating Viewport Prediction Errors. Due to users' randomness, viewport prediction errors are inevitable. Firefly employs three mechanisms to tolerate them. First, it uses large tiles (90°×180°) that can absorb rotational prediction errors, as a tile needs to be fetched as long as the predicted viewport has any overlap with it. Second, to further tolerate rotational prediction errors, we virtually enlarge the field-of-view by $p\%$ in each direction when calculating the to-be-fetched tiles. p is configured to 10% given the rotational prediction MAE shown in Figure 9. Third, recall from §3.2 that sudden translational movement after a stationary period (SP) is difficult to predict. To address this issue, when the user is stationary, we add the tiles (corresponding to the current viewing direction) of all four neighboring grids to the predicted tile list. In this way, no matter which direction the user moves towards, the corresponding tiles are always in the to-be-fetched list.

3.4 Adaptive Quality Control (AQC)

AQC takes as input the lists of tiles requested by the users, and outputs each user's appropriate quality level. It runs on the server that has the global knowledge of all users. An ideal AQC algorithm has the following features. (1) For each user, AQC will maximize the quality level while minimizing the stall (rebuffering); meanwhile, the number of quality switches should be minimized to provide a smooth user experience. (2) The selected quality levels should be fair across all the users; in other words, the quality levels should be largely proportional to the users' wireless channel capacities. (3) AQC needs to execute in a fast-paced manner (ideally at the per-frame granularity for each user) to adapt to users' motion. (4) AQC should scale well for multiple users.

At a first glance, AQC is similar to a video bitrate adaptation algorithm where a plethora of studies have been conducted [40,41,51,66]. However, AQC in Firefly is much more challenging. In particular, requirements (2), (3), and (4) do not appear in typical bitrate adaptation algorithms running on a single client for regular video-on-demand services.

In our initial design, we attempt to establish a principled optimization framework that maximizes a QoE (Quality of Experience) utility function. However, we find that this approach is computationally infeasible on a per-tile basis, as the solution space expands exponentially as the number of users increases. To this end, we develop a lightweight, heuristic-based algorithm that produces empirically good quality selection decisions. Our design considers all four requirements mentioned above. It runs efficiently on commodity servers, achieving frame-level scheduling for 10+ users.

AQC Algorithm. We now walk through the detailed logic of the algorithm listed in Figure 10. It uses the available bandwidth obtained from the wireless AP and the recently received to-be-fetched tiles (§3.3) to adjust the quality level (`Q[i]`) for each user `i`. In each invocation, AQC gets the total available downlink bandwidth across all users (Line 01), as well as each individual user's available downlink bandwidth from the AP (Line 03). They represent the global and local network bandwidth constraints respectively (see §4 for their details). λ (empirically set to 90%) adds a safety margin for

```
    n: total number of users
    T: total available bandwidth across all users
    Q: users' current quality levels (input & output)
    Tiles: users' to-be-fetched tile lists (input)
    Q': local copy of Q
    B: individual user's available bandwidth
    λ: bandwidth usage safety margin
    RESERVE: reserved bandwidth for each user
    ---------------------------------------------------------------------
01  T = get_total_bw_from_AP() * λ
02  Q'[1..n] = Q[1..n]
03  B[1..n] = get_individual_bw_from_AP([1..n]) * λ
04  foreach user i:
05      while (bw_util(Tiles[i],Q'[i])≥B[i] and Q'[i] is not lowest):
06          Q'[i] = Q'[i] - 1
07      T = T - min(B[i], max(RESERVE, bw_util(Tiles[i], Q'[i])))
08  if (T < 0):
09      lru_decrease(Q'[1..n]) until (T≥0 or Q'[1..n] are lowest)
10  else:
11      lru_increase(Q'[1..n]) until (T≈0 or Q'[1..n] are highest)
12  Q[1..n] = Q'[1..n]
```

Figure 10: The multi-user AQC algorithm.

tolerating the bandwidth fluctuation. Lines 05–06 deal with the local bandwidth constraint. For a given user **i**'s tiles to be fetched (**Tiles[i]**), as long as their bandwidth utilization (calculated by **bw_util()**) exceeds the available bandwidth **B[i]**, the quality is lowered to avoid stalls. Line 07 then subtracts the user's used/reserved bandwidth from the global bandwidth budget **T**. An important design decision we make is to reserve a certain amount of bandwidth (**RESERVE**) for each user to handle the user's sudden movement (§3.2) that may incur unexpected bandwidth utilization. The reserved bandwidth for each user is set to $\eta T/n$ where T is the AP's total bandwidth, n is the number of users, and η is a tunable parameter. A large η reserves more bandwidth, which can help increase the resilience to users' bursty movement at the cost of a lower flexible (*i.e.,* non-reserved) bandwidth of other users. We empirically choose η=0.75 that yields a satisfactory tradeoff between the two above factors.

We next consider how to estimate the tiles' bandwidth requirement, *i.e.,* realizing **bw_util()** in Line 05. Recall from §3.3 that each tile has its display deadline. Let the total size (in bytes) of the tiles at quality level q with a deadline at or before t_i be $S_{i,q}$. Let t_0 be the current time, t_c be the estimated decoding time, and t_s be the server-side queuing delay. t_0 and t_c are reported by the user and t_s is estimated by the server. In order to not miss the deadline t_i, the required bandwidth should be at least $b(t_i) = S_{i,q}/\max\{0, (t_i - t_0 - t_c - t_s)\}$ (it can be ∞ when a stall occurs). Then the overall required bandwidth is conservatively estimated as $\max_{t_i}\{b(t_i)\}$.

Lines 08 to 11 deal with the global bandwidth constraint. If the global bandwidth budget **T** is depleted (Line 08), then we reduce the users' quality levels (Line 09); otherwise we try to increase them (Line 11). To facilitate fairness and make the quality switch smooth, the decrease/increase of the quality levels is performed in a "least recently used (LRU)" manner, one user at a time, *i.e.,* the user whose quality level was least recently changed is selected. The quality level increase is subject to the local bandwidth constraint.

Since users' requests arrive asynchronously, AQC needs to be invoked to update **Q[1..n]** whenever a new request arrives. Then the tile transmission thread will retrieve the tiles from the content database and put them into the tile transmission queues. If the requested tiles for a user change, or if AQC produces a different schedule in a future invocation for this user, the not-yet-transmitted tiles in the user's queue will be updated. Thanks to AQC's lightweight nature, users' motion and network bandwidth fluctuation will be immediately reflected in the tiles' quality levels, making Firefly robust.

3.5 Client-Side Hierarchical Cache

When a user receives mega tiles from the server, the tiles will be cached, decoded, and rendered. Since tile decoding takes non-negligible time, it needs to be performed in advance. Firefly, a *decoding scheduler* determines which tiles to decode. Its logic is similar to the tile fetching scheduler (§3.3), by using the viewport prediction results. Predicted tiles with a closer display deadline take a higher decoding priority.

To handle large VR scenes, Firefly needs to fetch and decode a large number of tiles. Firefly thus employs a 3-layer hierarchical tile cache. Borrowing the CPU cache terminologies, we name the three layers L1, L2, and L3. Residing in the GPU memory, The L1 cache stores *decoded* mega tiles that can be immediately rendered by the GPU. It is the fastest cache, but its capacity is the smallest (hundreds of tiles) due to the large size of decoded tiles and limited GPU memory. The L2 cache stores *encoded* tiles in the main memory with a capacity of thousands of tiles. The L3 cache dumps encoded tiles in the persistent storage; it has the largest size but is the slowest. When a tile arrives, it is first stored in L2 cache; if L2 is full, some old tiles in L2 may be swapped to L3 in an LRU manner. The L2-to-L3 swap involving writing to flash drive, and is thus performed in a batched manner for good write performance. Swapping back from L3 to L2 is triggered by the decoding schedulers' decisions. This typically occurs when a user visits a previously explored grid position.

3.6 Handling Dynamic Foreground Objects

A VR scene may consist of a background view as well as one or more foreground objects. The background view at a specific virtual location is static. Due to its large area and complexity, its rendering typically dominates the workload for preparing the scene. In contrast, foreground objects are more dynamic and less complex than a background scene. Their examples include moving objects (*e.g.,* other users' avatars) and interactive objects (*e.g.,* a virtual control panel). Despite being less complex than the background view, due to their dynamic and interactive nature, failure to render foreground objects in time may also cause considerable QoE degradation.

Firefly employs two mechanisms to handle foreground objects. First, objects' 3D models (polygons, textures, *etc.*) are distributed to the clients *offline*. This reduces the network bandwidth consumption and eliminates the server's rendering workload at runtime. In a typical VR scene, the objects' 3D

Quality	High	Medium	Low
# Polygons, Size (MB)	30016, 3.30	14566, 1.30	7283, 0.68

Table 1: Three quality levels of the avatar object.

Client Device	High	Medium	Low
Samsung Galaxy S8 (SGS8)	✗,✗,✗	✓,✓,✗	✓,✓,✓
Samsung Galaxy S10 (SGS10)	✓,✓,✓	✓,✓,✓	✓,✓,✓
Samsung Galaxy Note 8 (SGN8)	✓,✗,✗	✓,✓,✗	✓,✓,✓
Motorola Moto Z3 (Z3)	✓,✗,✗	✓,✓,✓	✓,✓,✓

Table 2: Rendering profiles for different phones: whether 60+ FPS can be achieved with 3,6,9 concurrent objects in different qualities.

models are not large (*e.g.,* tens of MBs in total) so they can be bundled with the app installation package or be fetched when the app launches for the first time.

Second, foreground objects are rendered locally by the client. This eliminates the uncertainty caused by the network as well as the potential resource competition from other users compared to a server-side approach. A challenge here is that the number of objects appearing in the viewport may change dynamically. If there are too many objects, the local rendering may still become the bottleneck. For example, in multi-user social VR, a user "sees" other users as 3D avatars; depending on the users' position, more than 10 avatars may appear in the viewport, incurring high rendering overhead. To address this challenge, Firefly supports trading off the rendering quality for a high frame rate. Specifically, the client creates low-quality versions for each object type by downsampling its polygon meshes. Table 1 shows an example of an avatar object originally with 30K polygons. Firefly downsamples them (using Blender [4]) to the medium and low quality with 14.6K and 7.3K polygons respectively. This downsampling process is an offline, one-time effort. Then at runtime, depending on the number of objects to be rendered, their qualities are dynamically determined to facilitate 60 FPS. Downsampling may also use more sophisticated polygon simplification techniques such as bounded-error polygon simplification [42], progressive encoding [45], or adaptive display elision based on the size of the object and its position in the scene [34].

To properly determine the objects' qualities, each client creates a *rendering profile* offline. Let us first assume that there is only one object type (*e.g.,* the avatar). As exemplified in Table 2, for each quality level, the profile maps the number of concurrent objects (3, 6, 9 are shown) to whether 60+ FPS can be achieved. Note that we assign the same quality to all objects to simplify the quality selection. The profile is created by the client through automated tests. During a test, the client is also performing tile decoding/rendering to mimic the workload of generating the background view. Then at runtime, the client can directly consult its profile to determine the objects' quality level. For example, when there are 6 objects, SGS8 should use the medium quality (Table 1) to achieve 60 FPS. When there are multiple types of objects, it may be infeasible to exhaustively enumerate their combinations. In this case, we can apply simple machine learning to predict the rendering performance, using features such as the number of objects, the total number of polygons, *etc.* We leave this as future work.

4 System Implementation

Client and Server. We have integrated the components in §3 into the holistic Firefly system that works on commodity Android/Linux OSes. The client is implemented using Android SDK with a total line of code (LoC) of 14,900. Tile decoding is realized using the low-level Android MediaCodec API [3]. We leverage multiple concurrent hardware decoders, whose optimal number depends on the device, to boost the decoding performance. We use OpenGL ES to perform tile projection/rendering, and use the OpenGL FBO (Framebuffer Object) to realize the L1 decoded cache (§3.5). We have successfully tested Firefly on four mobile devices: SGS8, SGS10, Moto Z3, and SGN 8 (full names in Table 2). These devices can be readily plugged into affordable VR headsets. The rotational and translational motion is provided by the on-device motion sensors and the VR headset controller, respectively. The server is implemented on Ubuntu 16.04 with about 1,000 LoC. The clients and the server communicate over TCP.

WiFi AP. The clients and server are wirelessly connected by a commodity WiFi AP. Since the server is only one wireless hop away from the users, AQC can directly obtain accurate global and per-user available bandwidth from the AP (Line 01 and 03 in Figure 10). This avoids the error-prone bandwidth estimation process widely used in Internet video streaming. To obtain the AP-wide overall bandwidth, we modify the AP's firmware to collect statistics on the maximum PHY rates of the clients, the wireless bandwidth used (20–160MHz in 5GHz Wi-Fi bands), and the busy channel time from hardware registers. To estimate each user's available bandwidth, we also collect statistics on the PHY rate and the frame error rate. The available bandwidth for a client i is estimated as $\Phi_i(1-\varepsilon_i)(1-U)O^{TCP}/N$, where Φ_i is its PHY rate, ε_i is the error rate, U is the channel busy airtime, N is the number of clients taking into account that the airtime will be shared fairly among clients, O^{TCP} is the TCP overhead estimated offline through bandwidth saturation experiments. Similar statistics are available on other APs via interfaces such as WebUI.

The Offline Rendering Engine (§3.1) consists of a rendering engine (developed in C# using Unity) and a mega tile encoder (developed in Python) with a total LoC of 1,500. We use H.264 encoding supported by all mainstream mobile devices.

5 Evaluation

5.1 Evaluation Setup

Content Preparation. We use two commercial VR scenes purchased from the Unity store: Office [16] (30m×26m) and Museum [13] (35m×30m, L-shape). The offline rendering engine (§3.1) discretizes both scenes into 5cm×5cm grids, which are fine-grained enough to provide a smooth translational movement experience. The offline engine renders each panoramic frame in 1440p (Quad HD, 2560×1440) resolu-

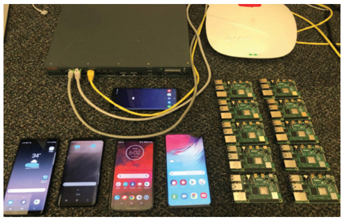

Figure 11: Our equipment: phones, Raspberry Pis, and WiFi AP.

tion, and encodes each mega tile into four quality levels, using the following CRF (Constant Rate Factor) values: 19, 23, 27, 31. A higher CRF corresponds to a lower quality and a lower encoded bitrate. The CRF values are selected by following prior recommendations [17, 20] where the encoded bitrate ratio between two neighboring quality levels is approximately 1:1.5. The content database size is 137 GB and 99 GB for Office and Museum, respectively. When exploring each scene, a user can see other users as avatars, which are rendered by the client as foreground objects. The statistics of the avatar's three quality levels are listed in Table 1.

Hardware and Software. As shown in Figure 11, we use 15 client devices. 5 of them are COTS smartphones with different computational capabilities: SGS8×2 (released in 2017), SGN8 (2017), Z3 (2018), and SGS10 (2019). They all run unmodified Android 9.0. For the remaining clients, we use 10 Raspberry Pi 4 (model B) to emulate them, each having a quad-core ARM Cortex-A72 CPU @ 1.5GHz and 2GB memory. The Pis run Raspbian OS (Debian v10 with Linux kernel 4.19). We run full-fledged Firefly on the 5 smartphones. For the Pis, we create an emulated version of Firefly by replacing the decoding and rendering components with their emulated counterparts. The decoding/rendering latency is properly emulated using the numbers profiled from the 5 smartphones. All other components such as AQC, viewport prediction, tile fetching scheduler, decoding scheduler, L2/L3 caching are identical to those running on a real Firefly client. The server is a desktop PC with an octa-core CPU @ 3.6GHz, 16 GB memory, 1TB disk, and Ubuntu 16.04. The server does not have a dedicated GPU. Clients and server are connected by an Aruba AP running 802.11ac on 80MHz bandwidth.

Physical Environment. The experiments are conducted in a typical office room (7.9m×7.3m) where all the devices, the server, and the AP are located. We distribute the devices at random locations. We find that their locations have a small impact on network performance. For a single device, placing it at the spot nearest to the AP and the spot furthest from the AP yields a throughput difference no more than 11%.

Experimental Approach. To ensure reproducibility, our high-level experimental approach is to replay real users' motion traces collected in §3.2. Recall that we have 25 user traces and 15 devices. In each run, we randomly pick 15 users and assign them in a random order to the devices. Each device then replays the corresponding user's motion trace by feeding the sensor stream to Firefly with precise timing. By default, each experiment consists of 5 back-to-back runs with different user-to-device assignments. We set the users' field-of-view (FoV) to a typical value of 100°×90° [53]. Unless otherwise mentioned, the presented results are based on the Office scene as the results for the Museum scene are qualitatively similar.

5.2 Overall Performance Comparison

We first evaluate the overall performance of Firefly, with the following metrics. (1) **Missed Frame Count (MFC).** In our client implementation, a high-precision rendering timer is triggered every 15ms (or 66.67 Hz). If a frame is not ready at the current timer event, it needs to wait for the next timer event, *i.e.,* after 15ms. In this case the client reports one MFC. MFC is highly correlated with the motion-to-photon delay [69], the time needed for a user's motion to be reflected on the display. When MFC=0 (the ideal case), the motion-to-photon delay is minimized to no longer than 15ms, *i.e.,* the motion is reflected in the immediate next frame. When MFC>0, a stall occurs. (2) **Average frame rate** is measured by sliding a 1-second window over a VR session and calculating the *average* FPS within each window. Our target FPS is 60. (3) **Stall duration** is the rebuffering time experienced by a user. We normalize it to seconds per minute for a VR session. This metric is correlated with the MFC. (4) **Content Quality.** Recall that a tile's quality is defined by the CRF value ∈{19,23,27,31} (§5.1). We then define the quality of a frame as the average quality of all tiles visible in the viewport. (5) **Inter-frame Quality Variation** is measured by sliding a 1-second window over a VR session and calculating the standard deviation of all frames' quality values (defined above) within each window. Since frequent quality switches degrade the QoE [66], a lower value of this metric is preferred. (6) **Intra-frame Quality Variation** of a frame is defined as the standard deviation of the quality values of all tiles appearing in a frame's viewport. Similar to the inter-frame quality variation, we prefer a lower intra-frame quality variation. Metrics (4), (5), and (6) are defined for the background view only. We evaluate the adaptation mechanism for foreground objects in §5.3.

Approaches to Compare. We compare three approaches: (1) full-fledged Firefly, (2) full Firefly with perfect prediction, and (3) the multi-user version of Furion [44]. Approach (2) represents an ideal scenario where users' viewport trajectories are known a priori. It helps us understand how much performance improvement we can further gain by having the perfect knowledge of users' motion. Regarding Approach (3), Furion is the state-of-the-art solution for single-user untethered VR. We create a multi-user version of Furion as follows. We use the full Firefly as the base (to handle multi-user), and then make (and only make) the following modifications according to Furion's design. First, we remove viewport prediction that Furion does not perform. Second, Furion does not use viewport-adaptation; the client instead always requests for all tiles belonging to all four neighboring grids; we thus modify

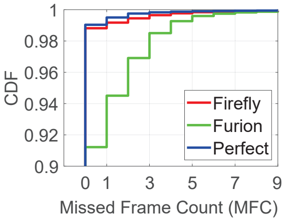

Figure 12: Missed frame count.

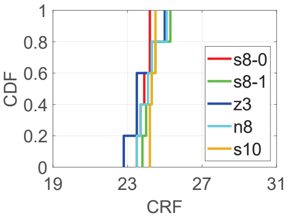

Figure 19: Quality fairness.

the tile scheduling module (§3.3) accordingly.

We next present the results for the Office scene. Figures 12, 13, 14, and 15 plot the distributions of the aforementioned four metrics: MFC (across all timer events), average FPS (across all 1-sec windows' measurements), stall (across all users' sessions), and average content quality (across all users' sessions). Thanks to its adaptiveness to available network/computation resources and its resilience to motion prediction inaccuracy, Firefly achieves overall good performance across all these metrics, which are the same or only slightly worse compared to Firefly with perfect prediction. Specifically, (1) 99% of the timer events (99% for perfect prediction) have MFC=0, *i.e.,* a motion-to-photon delay ≤15ms; (2) for 90%/99% of the 1-sec windows (95%/99% for perfect prediction), the average FPS is at least 60/50 FPS; (3) the median stall duration is only 1.2 sec/min (1.0 sec/min for perfect prediction); (4) the median content quality is around CRF 24.2 (CRF 22.2 for perfect prediction). In Figure 15, the slightly lower quality compared to that of perfect prediction is due to the additionally fetched tiles. The bandwidth consumed by these tiles is wasted because they are not viewed by the users due to viewport prediction errors.

The multi-user Furion exhibits much worse performance. This is because without prediction, it can only blindly fetch an excessive number of tiles without any prioritization. As a result, the bandwidth consumed of many tiles is wasted, leading to a much lower content quality; wasted tiles may also cause head-of-line blocking for useful tiles, causing stalls and a lower FPS. The results for the Museum scene are qualitatively similar, as exemplified in Figures 16 and 17, which plot the MFC and content quality results, respectively.

We also measure the inter/intra-frame quality variations, and find them to be low. For Firefly, the 25th, 50th, and 75th percentiles of the inter-frame quality variation (across all 1-sec windows' measurements) are 0, 0.2, and 0.3, respectively; the 90th percentile of the intra-frame quality variation is 0. Both metrics are very close to Firefly with perfect prediction. The low quality variations are attributed to AQC's quality selection mechanism. It (1) assigns the same quality to all the tiles in a viewport and (2) performs LRU-style quality changes that not only ensure fairness (to be shown next) across users but also facilitate smooth quality switches for a given user.

Fairness. Figures 18 and 19 plot the distributions of FPS and content quality respectively, for five smartphones. Note that although the instantaneous available bandwidth may differ across the devices, in the long run, each device largely gets an equal share of the bandwidth (as verified by us). Also, since each device replays multiple human users' motion traces, this should largely smooth out the impact of motion diversity among the human users. In addition, the devices' computational power heterogeneity is considered by the adaptive object quality selection mechanism (§3.6). Therefore, we expect the distributions to be similar among the devices. This is indeed shown in Figures 18 and 19, confirming that AQC can achieve a decent level of fairness among the devices.

Real Phones vs. Emulated Devices. We observe small performance differences between the two device groups: the 5 real smartphones and the 10 Raspberry Pis. Their average stall duration (across all users' sessions belonging to each group) differs by less than 2%; for both groups, 99% of the timer events have MFC=0; both groups also exhibit very similar FPS distributions; the median content quality is CRF 24.2 and 26.1 for the phone and the Pi group, respectively. This difference is likely attributed to the conservative emulation settings (*e.g.,* decoding latency) used in emulation. Overall, We believe that Firefly is accurately emulated on the Pis.

5.3 Micro Benchmarks

We now present several micro benchmarks to showcase the impact of key design decisions of Firefly.

Impact of AQC. Figure 20 plots the stall duration across all VR sessions with AQC enabled vs. disabled. When AQC is disabled, we consider two extreme cases: always fetching

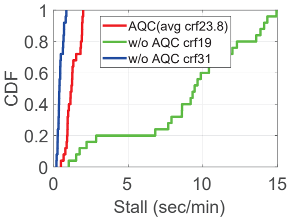

Figure 20: Impact of adaptive quality control (AQC).

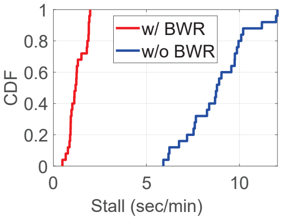

Figure 21: Impact of BW reservation in AQC.

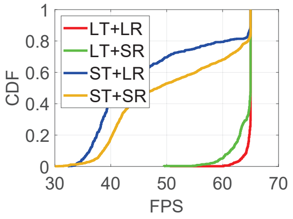

Figure 22: Impact of viewport prediction method.

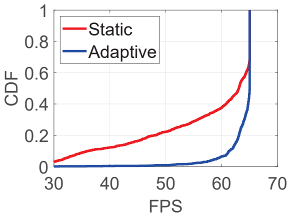

Figure 23: Impact of adaptive foreground object quality selection.

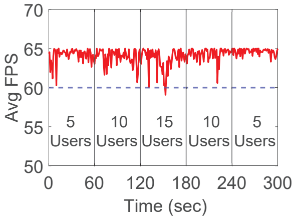

Figure 24: Impact of user dynamics on frame rate.

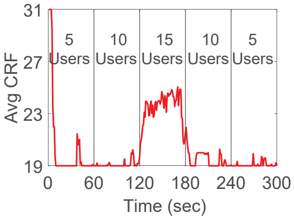

Figure 25: Impact of user dynamics on content quality.

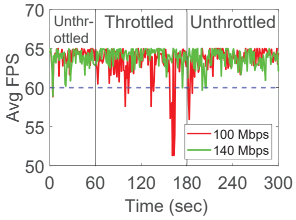

Figure 26: Impact of BW changes on frame rate.

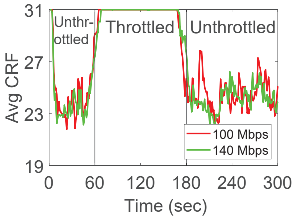

Figure 27: Impact of BW changes on content quality.

the highest quality (CRF=19) and always fetching the lowest quality (CRF=31). As shown, the former suffers from very long stalls (median: 9.6 sec/min); the issue with the latter is the low content quality (CRF 31). AQC instead strikes a much better tradeoff: the achieved average quality is CRF 23.8, while the stall duration is only slightly increased compared to statically using CRF=31 without AQC.

Impact of Bandwidth Reservation in AQC. Recall from §3.4 that we make an important design decision in AQC by reserving for each user a fixed amount of bandwidth to handle the user's sudden motion that may incur unexpected bandwidth utilization. Figure 21 indicates that this mechanism is highly beneficial. If bandwidth reservation (BWR) is disabled, the median stall duration increases drastically from 1.2 sec/min to 8.8 sec/min.

Impact of Viewport Prediction. To justify our viewport prediction design, we consider four variations shown in Figure 22. "LT+LR" is Firefly's approach where we use **L**inear regression (LR) for both the **T**ranslational movement and **R**otational movement prediction; "ST+SR" represents a naïve **S**tatic strategy: directly using the current viewport as the predicted viewport by assuming the user is stationary in both the translational and the rotational dimensions; "LT+SR" corresponds to using LR for translational prediction and Static for rotational prediction; "ST+LR" represents using Static and LR for translational and rotational prediction, respectively. Here, we consider all 25 users' motion traces by replaying them sequentially using one Samsung Galaxy Note 8 phone.

Figure 22 shows that Firefly's approach, LT+LR, achieves the overall highest FPS. Also, LT+SR significantly outperforms ST+LR and ST+SR. This suggests that translational prediction accuracy plays a more important role in determining the system performance compared to rotational prediction accuracy. The reason is that large tiles (90°×180°) can shield many rotational prediction errors (§3.3) but not any translational prediction error.

Impact of Adaptive Object Quality Selection. By analyzing the logs produced by the experiments in §5.2, we find that oftentimes many avatars indeed appear in the viewport: in more than 40% (10%) of the viewports, 4 (8) or more avatars need to be rendered, and this number can reach 10. Too many foreground objects incur high local rendering workload in particular for computationally weak devices. This overhead can be effectively mitigated by the object quality selection scheme (§3.6), which adaptively reduces the fidelity of foreground objects (in our experiments, the users' avatars) to maintain a high FPS. Figure 23 suggests that by disabling this feature (the "Static" curve, which always renders the objects at the highest quality), the FPS drops significantly: the fraction of 1-sec windows with <60 FPS increases from 8% to 37%.

5.4 Adaptiveness to Number of Users

We conduct an experiment to demonstrate that Firefly can properly handle users dynamically joining and leaving the system. We begin with 5 randomly chosen devices at t=0; at t=60s, 5 randomly chosen devices join the system; at t=120s, 5 more devices start their VR sessions; at t=180s, 5 devices leave the system; finally at t=240s, 5 more devices leave. Figures 24 and 25 plot the average FPS and average CRF across all users, respectively, over time. As shown, regardless of the user dynamics, the frame rate almost always stays above 60 FPS. Meanwhile, the content quality well adapts to the bandwidth available to each individual device. When there are no more than 10 devices, each device can enjoy the highest content quality at CRF 19. With 15 devices, AQC reduces the average quality level to ∼24 due to bandwidth scarcity while maintaining fairness across users (Figures 18 and 19). The fluctuations in Figures 24 and 25 (also in Figures 26 and 27 to be described in §5.5) are attributed to our averaging method (first over a 1-second window and then over all users) for calculating each FPS and content quality sample.

5.5 Adaptiveness to Available Bandwidth

We conduct two experiments to investigate how Firefly adapts to changing network bandwidth. In the first one, we begin with unthrottled bandwidth (around 200 Mbps as reported by the AP) at t=0; we then use the Linux `tc` tool [12] to throttle the AP-wide bandwidth to 140 Mbps at t=60s; the bandwidth throttling is removed at t=180s. The second experiment is the same except that the bandwidth throttling is set to 100 Mbps. For both experiments, we fix the number of devices to 15.

Figures 26 and 27 plot the average FPS and average content quality across all users, respectively, over time. When the total bandwidth reduces, the content quality immediately drops to the lowest in order to maintain a high frame rate. For 140Mbps bandwidth throttling, AQC manages to stabilize the frame rate at 60+ FPS. For 100Mbps throttling, each device gets only ~6.7Mbps bandwidth on average that can barely support even the lowest quality level at CRF=31. As a result, the frame rate occasionally drops below 60 FPS.

5.6 Comparison with MUVR

MUVR [47] is a recently proposed, state-of-the-art multi-user mobile VR framework. It is also (to our knowledge) the most relevant work to Firefly. In MUVR, a server maintains a centralized cache that stores the rendered and encoded VR content. Given a user's translational position, the server can directly transmit the view if it is cached; otherwise the server needs to render the view and properly cache it. In their evaluation, the authors emulated 4 concurrent users of MUVR.

We quantify the effectiveness of MUVR on our Office dataset using simulation. The setup is similar to §5.2 where we replay 15 randomly selected users' motion traces 5 times. Meanwhile, we simulate the centralized cache: for every frame, all devices simultaneously "send" their translational positions to the server; upon cache misses, the server will "render" the corresponding positions and add them to the cache. We assume the cache is initially empty and has unlimited capacity. We find that for 27% of the time, there are more than 5 concurrent cache misses, *i.e.,* the server needs to render for more than 5 devices. According to our pilot experiment in §2, this cannot be supported by even a high-end GPU, leading to poor scalability. Firefly eliminates this issue by performing *exhaustive* offline rendering (§3.1). It also introduces other important components that MUVR does not have such as AQC, viewport adaptation, and handling foreground objects.

5.7 Resource Usage and Thermal Overhead

CPU, GPU, and Memory. Firefly incurs acceptable runtime overhead and resource footprint on mobile devices. During a VR session, the CPU usage (reported by the Android Studio Profiler) is no higher than 30% across the five smartphones.[1] The overall memory usage (CPU+GPU) is no higher than 1.6 GB, which is mostly spent on L1 and L2 cache. Note that the cache capacities (L1, L2, and L3) are adjustable in Firefly.

Energy Usage and Thermal Characteristics. To profile the energy usage, we fully charge the five phones, and then repeat the experiment in §5.2 by running on each phone five back-to-back VR sessions. After that (25 minutes later), we record the remaining battery percentage, which ranges from 92% to 96% (average 93.8%) depending on the device's power consumption and battery capacity. We also monitor the CPU/GPU temperature. After continuously playing the VR content for 25 minutes, the highest temperature (either GPU or CPU) among the devices is 50°C, which only feels moderately warm. Overall we think the above energy and thermal characteristics are completely acceptable for mobile VR.

6 Related Work

360° Video Streaming. There exist a plethora of work on streaming 360° videos. Prior systems such as Flare [53], Rubiks [38], Freedom [60], and POI360 [62] also take a viewport-adaptive streaming approach. Some other studies focus on viewport prediction for 360° videos [24, 33, 39]. Compared to the work above, Firefly extends the viewport-adaptation idea to generic VR that involves both the rotational and translational viewport movement. In particular, we demonstrate how viewport adaptation can benefit multi-user VR systems.

Single-user Mobile VR has also been well investigated. Flashback [27] and Furion [44] demonstrate high-quality single-user VR on COTS smartphones. Flashback is a completely local system (on a single device, content stored in SD card). We leverage its core concept of offline rendering to support high-quality, networked multi-user VR. We extend Furion to a multi-user version and quantitatively compare it with Firefly in §5.2. MoVR [22, 23] employs 60 GHz mmWave wireless for mobile VR. Liu *et al.* [48] proposed system-level optimizations for the mobile VR rendering pipeline. Tan *et al.* explored supporting mobile VR over LTE [61]. None of the above work explicitly focuses on the multi-user scenario.

Multi-user VR/AR. Despite a plethora of work on single-user VR, much fewer studies have been conducted on its multi-user counterpart. The most relevant work to Firefly is MUVR [47] that is described in detail in §5.6. Bo *et al.* developed a multi-user 360° video streaming system based on multicast [25]. A recent positioning paper [49] discusses several practical issues of designing a multi-user VR system (without implementation). Some studies investigated multi-user or collaborative augmented reality (AR) [54, 55, 68]. Compared to the above work, Firefly is a generic multi-user VR system. It achieves much better scalability compared to MUVR.

[1] Android Studio Profiler does not report the GPU utilization.

7 Discussion

Efficient Offline Rendering. Future VR applications can involve large and complex scenes, drastically increasing the overheads of offline rendering. Firefly plans to explore well-known rendering optimization techniques [29, 50] which use different hierarchical structures for adapting to the surface tessellation and level of detail.

Handling Dynamic Background. While significantly boosting scalability, Firefly's offline rendering assumes the background content is static (but can be arbitrarily complex). Simple dynamic content involving short animation sequences can still be rendered offline. Complex dynamic content (involving lighting, reflection, *etc.*) has to be rendered at runtime.

Enhancing Firefly using Computer Graphics and Multimedia Techniques. While the contributions of Firefly are mostly on the system side, we are aware that Firefly can be enhanced by various techniques developed from the computer graphics and multimedia community. For example, the 3D models of foreground objects can be simplified using techniques proposed by [31, 32, 35, 56]; visibility or distance culling [34, 36, 52] can be applied to reduce the runtime rendering overhead while maintaining objects' visual qualities; more sophisticated partitioning [58, 59] can be employed to make caching more efficient for both static background and dynamic foreground; more efficient video codec such as H.265 [37] and the next-generation H.266 standard [1] can be leveraged to further reduce the bandwidth footprint for background content delivery; powered by recent advances in deep learning, deep neural networks (super-resolution) can be applied to enhance the image quality [30, 65]. The above approaches are orthogonal to Firefly's exhaustive rendering paradigm and are compatible with the AQC scheme.

Improving Motion Prediction. Firefly employs online linear regression for motion prediction. Despite being simple, it is experimentally demonstrated to be efficient and effective. The prediction accuracy could be further improved using more sophisticated prediction methods. For instance, over 3-DoF (degree-of-freedom) head movement data, deep learning approaches such as LSTM (Long Short-Term Memory) was found to outperform classic machine learning in particular when the prediction window is long [64]. Another promising direction is to enrich the feature set using, for example, velocity, acceleration, and even VR content features such as saliency [33]. We plan to explore the above directions in our future work.

7.1 Lessons Learned

We learned several important lessons from Firefly, which may guide the design of future multimedia systems.

First, Wirth's law [21] also applies to multimedia: the content resolution/quality increase may outpace the graphics technology evolution. While 3D computer games already use some pre-computation techniques such as projecting pre-rendered 2D panoramic background [2] and rendering faraway 3D objects as 2D sprites, we believe that more extensive offline computation and caching will remain a core technique that can scale up high-quality content rendering on commodity hardware, in particular in emerging multimedia services such as mixed reality and cloud gaming.

Second, scheduling content delivery in a multi-user system requires considering a wide range of factors: network bandwidth, device rendering capability, users' QoE, users' interaction, and cross-user fairness. Our experience of developing AQC indicates that while establishing a full-fledged optimization framework may be difficult, a robust heuristic-driven algorithm can work well in practice. In addition, to adapt to users' fast-paced, bursty interactions, the scheduling algorithm needs to run at a frequency that is much higher than traditional videos' bitrate adaptation algorithms [40, 41, 51, 66].

Third, from traditional videos (0 DoF) to 360° videos (3-DoF) and then to VR/volumetric (6-DoF), multimedia content tend to become more immersive and interactive. To embrace such trends, future multimedia systems need more intelligence, which is not limited to motion prediction as showcased in Firefly. Elements such as users' eye movement [43, 46], users' voice, salient visual content [33], and sound source, to name a few, can all be leveraged to infer viewers' intention and henceforth to facilitate system-level decision making such as content prefetching and scheduling.

Fourth, in addition to content, client devices, and server, the network (in particular, the wireless one) is also a key component whose interplay with the multimedia system needs to be carefully optimized. The lower-layer wireless channel information could be leveraged to guide network resource allocation. In Firefly, we demonstrate this over 802.11ac WiFi (§4). Similar cross-layer design could be conducted for other WiFi standards (802.11ax [26]) and cellular networks [62, 63].

8 Concluding Remarks

We have demonstrated with Firefly that it is feasible to support 15 VR users at 60 FPS using COTS smartphones and a single AP/server. Our design makes judicious decisions on (1) partitioning the workload (offline vs. runtime, client vs. server), (2) making the system adaptive to the available network/computation resources, both collectively and locally to each user, and (3) handling users' fast-paced, bursty motion. We believe that the core concepts of Firefly are applicable to other multi-user scenarios such as those of augmented reality and mixed reality.

ACKNOWLEDGEMENTS

We thank the voluntary users who participated in our study, the anonymous reviewers for their valuable comments, and Philip Levis for shepherding the paper. This work was supported in part by NSF Award #1903880 and #1915122.
